Foreword

HOWARD GARDNER

Harvard Project Zero, Cambridge, Massachusetts, U.S.A.

Next to its close relative *intelligence*, no topic in psychology or education has been as salient and controversial for so long a time as that of *giftedness*. Interest in human gifts—broadly defined—has been perennial in diverse societies, as those believed to have special powers have been variously honored or damned. This interest in human beings who display unusual capacities is hardly surprising, given the desirability of harnessing these gifts to the public good and the fear of what might happen if such extraordinary gifts were turned against those in power. Once systematic investigations of individual differences began, about a century ago, lay concerns about human talent were joined to scientific curiosity and to policy decisions, thus ensuring heated discussions which continue unabated to this day.

From early on, discussions about giftedness among both theorists and practitioners have been framed by competing positions. The most fundamental arena of dispute has concerned the origins of gifts. While the majority of researchers have assumed that gifts are largely inborn, a cohort has insisted on the contribution of family and other environmental factors to the development of talent. A topic arousing equal controversy has been the singularity of giftedness. Many of the pioneering researchers believed it was most parsimonious to assert the existence of general giftedness (sometimes parading under the name “g”), but a contrary position has posited the existence of a multiplicity of gifts.

On the more practical side, an analogous set of contrasts has arisen. When it comes to the identification of the gifted individuals in a society, many practitioners seek to rely on the simplest, least ambiguous form of evidence—usually the score on an objective instrument such as an intelligence test. Other practitioners, however, are reluctant to place faith in such measures, preferring to look directly at evidence of high-level performance in the scholastic or other areas. Once gifted individuals have been identified by whatever means, controversy surrounds the question of how best to nurture talent. A clear majority of workers in the gifted area favor forms of tracking, organized either around general giftedness or along the lines of specific talents. However, especially in recent years, the costs of tracking have frequently been noted—costs not only at the expense of competing values such as equity, but even in terms of the alleged costs of such isolation for the gifted individual herself.

In some areas of research, controversy proceeds but without notable progress. Indeed, after some brilliant initial flourishes in the early part of the century, investigations of giftedness languished until the 1970s. In the last two decades, however, the area of research on giftedness and related topics has come alive again. There is an ever-expanding set of journals, books, conferences, special interest groups, and encyclopedic handbooks. Issues of giftedness have become of interest not only to researchers with a long-time declared interest in the area but also to other accomplished scientists who find that their investigative curiosity draws them to individuals or groups of exceptional promise and/or exceptional achievement.

The handsome volume that you hold in your hands is eloquent testimony to the progress of the field in the last few decades. Following Abraham Tannenbaum’s magisterial review of the history of interest in the field of giftedness, one encounters important essays on many topics that could

hardly have been imagined earlier in the century. Of special note are new theories of giftedness, put forth by scholars like François Gagné, David Feldman, Franz Mönks, and Robert Sternberg; biologically-oriented accounts offered by Robert Plomin, Hans Eysenck and their colleagues; studies of giftedness in particular domains, ranging from music and art to leadership and mathematics; a plethora of essays on practices for the gifted across the age range and from a large number of countries; as well as treatments of a number of special topics, ranging from after-school programs to underachieving gifted students to gifted handicapped individuals. Nearly every major worker in the field is represented in this compendium; the selection is even-handed as well as comprehensive. Themes recur in various articles, often with a somewhat different slant, conferring a beguiling contrapuntal quality on the book. Anyone who takes the time to sample across the *Handbook* will be exceedingly well informed about the work of today and in a privileged position to speculate about, and perhaps contribute to, the prospects for tomorrow.

Given the relatively long history of the study of giftedness, one might ask what would most astonish such pioneers as Francis Galton and Alfred Binet, Lewis Terman and Walter Lippman, Leta Hollingsworth, and Catherine Cox, were they to display an unanticipated talent of returning to the earthly scene today. In my own view, they would be surprised to see the extent to which the evidence has accrued in support of both hereditarian *and* environmental accounts of giftedness. On the one hand, powerful neurophysiological evidence has accrued to demonstrate the “physical reality” of “g” and other symptoms of general intelligence. Yet, on the other hand, evidence from a variety of quarters points to the important, indeed indispensable role played by family support, cultural values, and vast amounts of practice in the realization of any and all gifts.

Along a parallel line, I think that these early students of giftedness would be surprised to find the continuing hegemony of the notion of a single intelligence, in the face of persistent attempts to develop a more capacious notion of intellectual competence. Joseph Renzulli’s three-ring approach to giftedness, Sidney Marland’s six forms of giftedness, Robert Sternberg’s triarchic conception of intellect, and my own theory of multiple intelligences represent but the tip of an ever-expanding iceberg of efforts to go beyond a singular view of giftedness. Our predecessors would note, properly, that those of a psychometric bend tend to favor a single view of intellectual power, while those who attend to cultural, social, and environmental factors are more comfortable with a more expansive (or looser) conception of giftedness.

Whatever their theoretical bent, these visitors from our history would be fascinated by a concern with many issues that had scarcely arisen in their day. A preoccupation with gifted young girls, with gifted minority youngsters, with gifted handicapped children, and with individuals gifted in a plethora of domains and crafts would seem astonishing to those raised at a time when a young white male scholar was the prototype of the gifted child. Even as they would be amazed by the attention now paid to the occasional young Hungarian chess player, Oxford schoolgirl, or Chinese painting prodigy, they would probably be intrigued by the ever stronger uneasiness found among educators and the general public concerning any effort to single out for special attention those individuals who appear to have special promise. And although they might take comfort in the fact that most gifted programs still admit youngsters on the basis of test scores, their attention would be caught by those innovative programs which allow self-nomination, parental nomination, or admission by a panel of peers and experts.

Some issues from days past continue to cry out for explanation. We still do not understand why some gifted youngsters go on to enormous adult accomplishment, while others essentially drop out; nor why otherwise unremarkable normal youngsters occasionally surpass the performances of even the most promising of their peers. We still are uncertain about the relative contributions of intellectual, social, affective, motivational, and sheer energetic and temperamental factors to unusual promise and startling achievement. Much work remains to be done before we can understand the relationship among intelligence, giftedness, creativity, precocity, prodigiousness, and ultimate achievement, however defined and however exhibited. Yet, if there is far to go, the distance traversed in the past quarter

century is impressive indeed. The progress has been brought into a state of high readiness by the hardworking and shrewd editors of this volume. Professors Heller, Mönks, and Passow deserve our congratulations—and our thanks.

Cambridge, Massachusetts
May, 1993

Preface

In his presentation at an international meeting on “Research Problems in Developing Giftedness” at the University of Munich in May 1988, A. Harry Passow, then President of the World Council on Gifted and Talented Children, Inc. (WCGTC), observed that the time had come for the development of a handbook on research on giftedness. Such a handbook, he argued, would provide researchers, theorists, practitioners and program planners with an understanding of what the knowledge base was and what lacunae existed regarding the identification and nurturing of the gifted and it would help in the framing of questions and the designing of studies which would enhance our understanding of the complex phenomenon of giftedness.

Serious research on the gifted began at the turn of the century and has intensified in the past two decades or so. As early as 1916 the German psychologist William Stern wrote already an article about the identification, the needed provisions for the gifted student and he described giftedness as a multifactorial concept. About 40 years later Terman came to the conclusion that Intelligence is a necessary but not sufficient condition for giftedness. Stern concluded almost the same in his 1916 article.

Hundreds of studies are done each year dealing with every conceivable aspect of giftedness. These studies range from sophisticated research to both well- and poorly-designed master theses and doctoral dissertations and include quantitative and qualitative designs, experiments, surveys, case studies, descriptions of school programs, and classroom practices, etc. Some are replications of previous studies, intended to extend and deepen insights. Many add to the knowledge base concerning the identification and development of potential or the achievements of the gifted.

Until relatively recently, publication of research findings and other material concerning the gifted was thought by many to be a “peculiarly American phenomenon”. While it is true that more publications emanate from the United States sources in the form of books, journals, reports, dissertations and other materials than from any other nation, the improvement in international communication has made it clear that the U.S.A. has no monopoly in this field.

The increase in international and regional meetings and the exchange of various kinds of publications has had two consequences: (a) it has enhanced the flow of information cross-nationally and (b) it has made clear the need for taking stock of the knowledge base if the field of the gifted is to move ahead.

The published proceedings of the biennial World Conferences on Gifted and Talented Children include contributors from many nations but, since these are conference presentations, they tend to be primarily nondata based reports and program or practice descriptions. Numerous books are published each year dealing with some aspect of giftedness, but these tend to be topic-specific. In the U.S.A., a monthly publication titled *Resources in Education* (issued by the ERIC system which includes one center responsible for materials on the gifted and talented) disseminates abstracts primarily of unpublished reports and papers. International exchanges are somewhat sparse—there are few international journals. Most publications cover only local, national or regional projects. The expanding cross-national communication between individuals and groups has done much to sensitize many persons in the field to the growing body of information about the gifted and talented.

Thus, it seemed to the editors that the field of gifted education could profit from a comprehensive handbook designed to provide a synthesis and critical review of the significant theory and research dealing with all aspects of giftedness, one which included contributors from the many nations where such research and program development was occurring. We viewed the undertaking with 80 contributors from 18 countries on six continents as a kind of international stock-taking. While the contributors provide a broad base for an international information exchange, they also provide insights into research deficits and research needs.

Since the majority of studies of giftedness over the last two decades and even earlier has been carried out in North America, there is a danger that one will take a noncritical perception of the material from the perspective of their origin—e.g., conceptions of giftedness and appropriate educational and nurturing strategies. However, we have long known from cross-cultural socialization research that the assumption of universal validity of many educational and psychological theories of human behavior—e.g., learning and thinking—has become obsolete. Moreover, many recent

studies, as well as programs and practices outside the English-speaking regions, particularly in Europe, Africa, Asia, and South America, are not known among specialists in the field. Progress in research and practice regarding the identification and nurturance of talent potential to talent performance is dependent on the broad cross-national exchange of information. A major purpose of this handbook is to document the state of the art of research and development on giftedness from an international perspective.

The process of turning an idea into a product is often a long and time-consuming process, as the editors rediscovered. However, the editors were provided with a great deal of stimulation and support from many colleagues around the world for which they are grateful.

Kurt A. Heller was awarded an Academy Scholarship from the Volkswagen Foundation (Grant No. II/64 911) for the academic year 1989-90, and grants from the German Research Society (DFG 477/24/90-20 and 477/832/92) and the UNESCO (ROK/87/009-No. 116.040.2), which enabled him to make extensive trips to Western and Eastern European countries, Israel, the Far East (China, Taiwan, Hong Kong, Korea, Japan and Thailand) as well as the U.S.A. and Canada, visiting more than 60 research institutions, universities, special schools, and extracurricular programs in those countries, and conducting many discussions with colleagues about the concept of the handbook. The other editors, Franz J. Mönks and A. Harry Passow, participated in numerous international and regional conferences and consulted in a variety of countries during the period that the handbook was being prepared. Several meetings of the three editors took place at international and regional conferences.

The proposal for the handbook, together with drafts of chapter contents, was reviewed by an international panel whose suggestions and comments were incorporated in revised outlines. Possible contributing authors with expertise in particular areas were identified, keeping in mind that representation from as many nations as possible was being sought. Over 90% of the individuals asked to contribute accepted our invitations. Some could not accept because of our deadlines. With very few exceptions, the manuscripts were submitted on time and we are grateful for both the quality and the promptness of the contributions. The timing was especially critical since the editors and the publisher aimed for publication by July 1993 so that it would be available at the Tenth World Conference on Gifted and Talented Children in Toronto.

Our instructions to the contributors emphasized that each article should reflect the state-of-the-art from an international perspective, should offer a comprehensive review and should include contents that comprised the forefront of knowledge and thought about the gifted. All contributors responded to that request—some more than others with the sparsity or unevenness of available knowledge often determining the author's response.

The contributors and the editors have tried to provide this comprehensive review of research and practice on giftedness and talent in a form which will be useful to a variety of readers—researchers, practitioners, program planners, and policy makers, among others. If the handbook reaches politicians concerned with education and advocates of gifted education—lay or professional—then an important goal will have been attained. University and college students and teachers will find this handbook useful as a comprehensive source of information regarding the gifted and the talented. Anyone concerned with identification and nurturing of the gifted and the talented will find the handbook a rich resource.

The 53 chapters are divided into seven sections as follows:

Part I: Historical perspective and perennial issues.

Part II: Conceptions and development of giftedness and talent.

Part III: Identification of giftedness and talent.

Part IV: Programs and practices for nurturing the gifted and the talented.

Part V: Other components of nurturing giftedness and talent.

Part VI: Examples of country efforts, policies, programs and issues.

Part VII: Present and future of education of the gifted and talented.

Finally, we want to thank the editors of Pergamon Press—Barbara Barrett, Michele Wheaton, and Lesley Williams and their colleagues in the production department—for their very professional handling of this publication. We would also like to thank Dr Michael Katzko who did indepth English editing of some of the contributions and Dr Rebecca Geiger for her assistance in editing the final chapter.

Kurt A. Heller
Franz J. Mönks
A. Harry Passow

PART I

**Historical Perspectives and Perennial Issues Related to
Giftedness and Talent**

History of Giftedness and “Gifted Education” in World Perspective*

ABRAHAM J. TANNENBAUM

Teachers College, Columbia University, New York, U.S.A.

Introduction

Does genius make history, or does history make the genius? A seemingly intriguing question for school children and scholars alike. But a deceptive one nonetheless, since the choice is not “either–or”. Actually, neither individual geniuses nor historical forces predominate, the real relationship being interactive and interdependent. Great ideas by highly creative individuals often carry enough power to influence the course of history; conversely, the *Zeitgeist* (spirit of the times) exercises an enormous influence on great minds and on the domains of excellence in which their precious ideas are generated.

Western Perspectives on Domains of Excellence

Although the precise manner in which geniuses and their eras inter-relate will always be a mystery, one impression seems clear: the work of seminal thinkers throughout the ages and societies is so important that unless we learn to appreciate it we cannot hope to learn how the human family *makes* history. Indeed, there are historians whose theories are bound up with the nature and impact of creative accomplishments in every historical period.

Spengler (1918), who compared the development of a society to that of a human organism, each with its own life cycle and distinctive personality, believed that every stage of growth is *defined* by the style and substance of great creative works produced at that time. Medieval Europe is characterized by the Gothic cathedral in architecture, the Gregorian Chant in music, and “Everyman” in drama, all treasures of creative thinking and fitted perfectly to Church–State political leadership. In the Romantic Period, sumptuous government buildings and

elegant homes for the bourgeoisie are the representative architecture of flourishing democracies; Beethoven’s music and Shelley’s poetry bespeak the idealization of the human collective spirit as it replaces the earlier authority of monarchy and aristocracy and the still earlier power of the Supernatural. It would therefore be anachronistic for a late twentieth-century composer to create music in the style of Mozart’s *Divertimenti* or for an artist to produce a Gainsborough-type “Blue Boy” in the 1990s. The voices of present-day genius are not only different from those of previous times—they also codify current history as both reflectors and shapers of the society in which *they* live, just as their predecessors did in their own idiomatic, but era-inspired, ways when Western society was younger.

In an essentially different approach to history, Toynbee (1967) emphasizes society’s need to respond successfully to periodic challenges as a condition of survival. Today, the most obvious obstacles facing the world include threats to the environment, huge regional pockets of overpopulation and hunger, the dread of nuclear warfare, urban decay and violence, inter-ethnic and inter-class tensions, and a host of diseases that resist cure thus far. Whatever progress is made in confronting these problems will be spear-headed by some of the most advanced thinkers of our times. Toynbee is explicit in estimating the importance of creativity in guaranteeing the survival of Western civilization when he writes:

To give a fair chance to potential creativity is a matter of life and death for any society. This is all-important, because the outstanding creative ability of a fairly small percentage of the population is mankind’s ultimate capital asset, the only one in which Man has been endowed (p. 24, italics in the original).

*Since the terms “giftedness”, “talent”, “creativity”, and “genius” appear in this chapter, a brief note is in order concerning their intended meanings. “Giftedness” and “talent” are used synonymously to encompass publicly valued abilities possessed by no more than one to two percent of people at each developmental stage. “Creativity” is regarded here as representing one of two aspects of “giftedness” (or

“talent”), namely, innovation or invention that deserves critical acclaim, in contrast to the other aspect of “giftedness” (or “talent”) which refers to highly developed proficiency in highly demanding tasks. “Genius” is the most advanced extension of “giftedness” (or “talent”) or “creativity”, denoting Olympian-level accomplishments by the rarest of adults.

In essence, then, there is not only a history of giftedness, but also history *and* giftedness. It makes little sense to recount the life of a people without taking special note of at least some of its best minds. These leading figures produce immortal artifacts that symbolize the distinctive nature of culture and civilization as they are preserved and changed in the course of time (according to Spengler). Viewed differently, the nature and degree of creative thinking are critical in determining whether a culture can survive and continue to grow or become truncated relics of an unrecoverable past (according to Toynbee).

Historical Drives

The human psyche seems to have a phenomenal potential for achievement. There are no known limits to the *kinds* of talents it can demonstrate and to the heights to which it can climb in any talent domain. But the mind is not motivated to achieve every possible form of excellence. The cultural milieu makes that decision in the broadest possible sense. Spengler suggested that the predominant characteristic of Western society is "Faustian", a term based on the medieval legendary character, Faust, who is depicted in masterpieces by Marlowe, Goethe, Gounod, Boito, and Thomas Mann. In its reified form, this governing power is said to produce an insatiable urge in individuals to explore the unknown and even the unknowable, to reach the unreachable, to grasp at the fringes of eternity, as it were, no matter what sacrifices are necessary to solve the mysteries of the universe and to serve the cause of aesthetics. Spengler offers no clue as to why the West adopted Faust as its inspiration to thrust ever upward with the Gothic arch in the Middle Ages and into outer space and the firmament in our own time. But according to him, the high-intensity drive has always been there; penetration of the heavens with cathedral architecture in one period of history and with jet propulsion in another era represent similar Faustian impulses emanating from different world views. Both also represent accomplishments of some of the best minds of their respective generations. Thus, the history of a people comes to life and takes on meaning through feats of supreme intellect and artistry in every generation.

In the course of Western history, considerable consensus has evolved concerning domains of excellence that have come to receive highest valuation and emphasis. Phenix (1964) describes these domains from the perspective of a philosopher-educator, as follows:

(1) *Symbolics*, including basic forms of communication through ordinary language, mathematics, and such nondiscursive symbolic forms as gestures, rituals, and rhythmic patterns. These systems are structured according to socially accepted rules of formation and transformation and, as carriers of messages between human beings, they are the most basic of all realms of

meaning since they have to be used to express ideas in each of the other realms.

(2) *Empirics*, comprising the sciences of the physical and living world. Their content includes factual descriptions, generalizations, and theoretical formulations based on objective evidence in a world of matter, life, mind, and society. Hypotheses introduced into these realms are tested according to specified rules of evidence and verification before acceptable truths can emerge.

(3) *Aesthetics*, including the various arts, such as music, painting, sculpting, theater, and literary creation. "Meanings in this realm are concerned with the contemplative perception of particular significant things as unique objectifications of ideated subjectivities" (pp. 6,7).

(4) *Synnoetics*, derived from the Greek word *Synnoesis*, meaning "meditative thought", or more specifically, a combination of *syn*, meaning "with" or "together", and *noesis*, meaning "cognition". Synnoetics therefore signifies insightful relationships between people or psychological understandings about people. It applies to other persons or to oneself in the sphere of *knowing*, just as sympathy relates to individuals in the sphere of *feeling*.

(5) *Ethics*, which emphasizes moral meanings that are concerned with *obligation* instead of fact, what ought to be rather than what was, is, or will be. "In contrast to the sciences, which are concerned with abstract cognitive understanding, to the arts, which express idealized aesthetic perceptions, and to personal knowledge which reflects intersubjective understanding, morality has to do with personal conduct that is based on free, responsible, deliberate decision" (p. 7).

(6) *Synoptics*, which embraces meanings that integrate history, religion, and philosophy comprehensively. The tools for building such meanings are empirical, aesthetic, and synnoetic, and the outcomes are new insights that amount to more than the sum of the parts from which they are derived.

Psychologists observing the trained and habituated skills in modern Western society classify human aptitude structures in fairly much the same way as Phenix does, albeit from a different vantage point. For example, DeHaan and Havighurst (1957) list the following domains of excellence:

(1) *Intellectual ability*, which is related most directly to success in school subjects, encompasses the verbal, number, spatial, memory, and reasoning factors of the primary mental abilities. Combinations of these aptitudes are regarded as basic to other talents, such as fine arts, social leadership, science, and mechanics.

(2) *Creative thinking*, which is revealed through some complex mental powers, such as the ability to recognize problems, to be flexible in thinking, to originate ideas or products, or to find new uses for old objects and materials.

(3) *Scientific ability*, including skills in the use of numbers and algebraic symbols, arithmetic reasoning, curiosity about the natural world, and facility with the scientific method.

(4) *Social leadership*, specifically the ability to help a group reach its goals and to improve human relationships within a group. Such skills are necessary for those who will eventually assume leadership positions in business and industry, labor unions, professional organizations, community groups, government, and international agencies.

(5) *Mechanical skills*, otherwise known as "craft skills" and closely related to talents in the fine arts and in science and engineering. Success in this category depends on manipulative facility, spatial ability, and perception of visual patterns, details, similarities, and differences.

(6) *Talents in the fine arts*, which are required of artists, writers, musicians, actors, and dancers.

In a similar vein, Gardner (1983) lists seven human intelligences: (1) linguistic, (2) musical, (3) mathematical, (4) visual-spatial, (5) bodily kinesthetic, (6) social-interpersonal, and (7) intrapersonal. What is noteworthy about Gardner's theory is that it derives partly from his observations of individuals who had sustained injuries in different parts of the brain. This source of data is a far cry from the primarily cultural and historic corpus of material from which Phenix (1964) drew his observations. Yet, the overlap in their domain listings is extensive enough to give a clear picture of what is generally recognized as the major types of excellence treasured in modern Western civilization, in contrast to earlier times in the West and to present-day life in some Western subcultures and in parts of the world that remain relatively untouched by Western influence.

Among the talent domains that define the West's particular brands of Faustian strivings, there seems to be something of a prestige hierarchy which has remained fairly stable over the years. Highest in valuation are the *scarcity talents*, so called because they are always in short supply. Medieval society could never get its fill of leadership and inspiration from the clergy who created an orderly, protective environment and provided its constituents with keys to personal redemption from sin and from the threat of divine retribution. In our modern world there is also an insatiable need for people inventive enough to make life easier, safer, healthier, and more intelligible. But hopes for survival are no longer vested primarily in special talents possessed by leaders of the clergy. Instead, the creative scientist and social leader are seen as most indispensable, and therefore the demand for them cannot be satiated as long as life itself is vulnerable to extinction or dysfunction.

Although it takes only a single Jonas Salk to achieve the breakthrough in conquering polio, there can never be enough talent like his for the great leaps forward that still need to be made in medical science. The same can be said for an Abraham Lincoln in political leadership, a Martin Luther King Jr. in race relations, a Winston Churchill in defense of human freedom, and a Sigmund Freud in mental health. Society will always venerate such talents as they appear, while thirsting for more and more since the shortage can never be filled, principally

because the public's motives are more self-preserving than self-serving. It makes sense, therefore, to consider these special abilities as symbols of excellence in greatest demand.

Ranking second are the *surplus talents*, so named because their cumulative accomplishments over the years are so abundant, rich, and varied that they exceed the capacity of individuals to sample and derive benefit from all of them. For example, it is said that multitudes acknowledge the greatness of Dante for his *Inferno*, but hardly anyone ever reads it even once in a lifetime. For the non readers, such a masterpiece is considered "surplus" in the sense that it is underutilized as literary fare, although it could never be considered "superfluous" inasmuch as some people, albeit a handful, do read and adore it.

Those who possess surplus talents have the rare ability to elevate people's sensibilities and sensitivities to new heights through the production of great art, literature, music, and philosophy. Few individuals can excel in this category, and some who do achieve celebrity status, which means that they are the most widely recognizable people in the eyes of the general public. But despite the fame and fortune of a Picasso and a Beethoven, they are treated as "divine luxuries" capable of beautifying the world without guaranteeing its continued existence. Of course, a Michelangelo and a Bach are always welcome as cultural assets; still, the need for such talents represents a *craving* for ways in which to enhance the quality of life rather than a *demand* for finding means of preserving life itself. People are more likely to suppress their cravings than their demands, as evidenced by the vast treasures of art, literature, and music that are widely unappreciated.

The terms *scarcity talents* and *surplus talents* are not intended to express value judgements, as if one were superior to the other. They are simply different in the *kinds* of admiration they elicit from society and in the popular hierarchy of importance if a choice between them had to be made. Scarcity talents are treated as if they were vital human resources that will always be in short supply as long as utopia is yet to be attained. Their primary preoccupation is with fathoming the unknown and even the unknowable, and modern Western society has committed itself to investing all it can to further such an enterprise. The physical survival of individuals depends on the existence of scarcity talents, whereas the cultural survival of the civilization depends on surplus-type talents. Therefore, it is no surprise that many schools and their supporting communities are more eager to cultivate scarcity talents in order to keep body and soul together rather than to nurture surplus talents for the sake of keeping the human spirit alive.

Third in rank are the *quota talents*, which include specialized, high-level skills needed to provide goods and services for which the market is limited. The job to be done is fairly clear; there are no creative breakthroughs expected and no way of knowing precisely how long the opportunities for such work will

last. Job openings for the relatively few who qualify depend on supply and demand, which can be irregular and geographically bound. Thus, a person with aptitudes for local political leadership has a chance of becoming elected only on special days designated for voting in a democracy, provided that an appropriate vacancy in public office exists at that time. Physicians, teachers, engineers, lawyers, commercial artists, and business executives are but a few of the kinds of highly skilled people whose work is valuable. But they are sought after only in response to market demand and opportunity. Sometimes there are low supplies of such talents, as in the case of physicians needed in poverty-stricken areas of the world; occasionally there are surpluses, such as liberal arts PhDs who are working at unskilled jobs because they cannot find professional employment for which they are trained, even though some positions are filled by less capable people hired ahead of them and protected by tenure policies.

Like scarcity and surplus talents, quota talents emerge in response to popular demand, but only up to the point where the public feels that its needs for such productivity are being met. For example, major symphony orchestras are kept alive by appreciative audiences that support first-rate performances by first-rate musicians. Sometimes there are vacancies to be filled in orchestral sections, and the search is on for candidates who qualify. But the number of such positions is necessarily limited by the number of orchestras the public is willing to sponsor. Hence, there is a quota system against which to measure shortage and surplus.

Schools have historically been most responsive to the public's needs for quota talents. These types of advanced skills are appreciated for the specialized services and goods they supply and for their market value. Schools can therefore be alerted to areas of expertise where there are many openings and the pay is good for those who are bright and trained enough to qualify. In many schools, the advanced training programs designed to fill quotas in various professions have traditionally constituted the total effort at differentiating education for the gifted.

Ranking last in the hierarchy are *anomalous talents*, including those which are either unappreciated or disdained. Yet, they reflect how far the powers of the human mind and body can be stretched and still not be recognized for excellence. Included among them are many prodigious feats, some having practical meaning, others being appreciated for the amusement they provide, and still others that strike fear and awe in people. Speed reading, mastery of mountains of trivia, gourmet cooking, trapeze artistry, performance of complex mathematical calculations faster than a computer, and even the numbers of sexual seductions boasted by a Don Juan are just a few examples of such talents. In this category there are also "extinct" abilities such as oratory and various types of manual craftsmanship that belonged among the scarcity, surplus, or quota talents in another era, but can now be considered anomalous because they have become anachronisms.

The condemned talents include the demagoguery and craftiness of a Hitler or a Stalin, which may require as much ingenuity as do extraordinary leadership skills for constructive purposes, except that they are threats rather than boons to humanity.

Schools have habitually emphasized the development of harmless anomalous talents, especially those that attract crowds and build morale, such as sports, glee clubs, and marching bands. The popularity of such activities among students and alumni, especially in the United States, is communicated to faculties who respond by mounting elaborate talent hunts and devoting considerable effort to sharpening these talents.

Thus we see that scarcity, surplus, quota, and anomalous types of giftedness have always been valued differently by patrons of excellence. The four categories may encompass all forms of giftedness, but the differential categorization helps describe, if not fully explain, their differential acceptance.

Historical Constraints

In his psychoeconomic approach to the study of creativity, Rubenson (1992) weighs the intrinsic and extrinsic costs as well as benefits of innovation in different historical periods. The intrinsic costs refer to the pressures on creative minds who, by virtue of their inventions and discoveries, render obsolete at least some cherished wisdom that had also been innovative at one time and had also upset established dogma before gaining acceptance. Indeed, iconoclasm and revisionist thinking is likely to meet resistance which can exercise restraint on the impulse to create, or even demoralize it. But the countervailing, if not overpowering, drive is toward newness, which is seen as progress in some domains of excellence and venturesomeness in others. Among the sciences, changes in theory often meet the stiffest objections from those who have mastered and adopted older concepts, but eventually the change is accepted as progressive. For example, Galileo's proposition that the sun is immovable in the center of the universe and that the earth has a diurnal motion of rotation has long been seen as a major breakthrough in astronomy. Yet, Galileo languished in what amounted to house arrest for the last eight years of his life because his theories were considered heretical.

It is awesome to contemplate how much richer and more abundant the West's cultural treasures would be if countless potential geniuses had not elected to suppress or abort their creative impulses because they feared ostracism or even reprisal if they would dare revolutionize style and substance in the world of ideas.

Unlike intrinsic costs, which relate to the creative person's courage (or lack of it) to render received wisdom obsolete, extrinsic costs focus on societal influences that stimulate (or inhibit) creative activity. Obviously, freedom of expression encourages daring, avant-garde thought and productivity. Coupled with liberty is the

impact of opportunity and access to audiences, clients, and customers. Rubenson (1992) cites evidence to show a relationship between the number of journals in an academic domain and research output by discoverers in that discipline. He also refers to patent data to measure how changes in demand can affect the frequency of invention. It is not just demand that makes a difference; patronage and sponsorship do also. And the effect is not only on quantity, but also on fashion and content of creative products. Simonton (1990a, b), for example, lists many instances where ingredients of musical and literary products relate directly to variations in external demand. How else to explain the special Russian thematic material—and indeed the very existence—of Beethoven's Rasumovsky Quartets without reference to their being subsidized by the person to whom these works are dedicated, and to his native origin?

The combination of personal freedom and encouragement would seem to create historical imperatives for the production of excellence. That is, times and places which provided these conditions should have been rewarded with a flowering of genius, whereas under oppressive and restrictive conditions the landscape of creativity would be expected to remain barren. However, here is an instance where logic and reality are not always compatible. Somehow, the human spirit that is strong enough to overcome internal restraints is sometimes able to survive and even create under brutal political regimes.

True, a Werner Von Braun could develop his considerable talents even in a police state under Hitler because his own Nazi convictions may have given him access to opportunities for cultivating and dedicating desperately needed talents in rocketry to help the German war effort. The same may apply to the multi-talented Albert Speer, whose superior abilities together with his deep loyalty to Hitler enabled him to design an enormously productive slave labor operation, as well as a vision of a Third Reich capable of maintaining its hegemony for a thousand years. But how to explain the genius of an Osip Mandelstam, who wrote great poetry while declaring his enmity toward Stalin, which eventually led to his death by order of that tyrant? How did he, and his wife Nadezhda too, manage to achieve immortality for their literary works while suffering so much oppression and humiliation in their native country? Perhaps Amabile (1983) and Hennessey and Amabile (1988) are on target when they reveal the enormous power of intrinsic motivation in creative work. Indeed, it may even be strong enough in some cases to overcome the pain of extreme adversity.

The emphasis has to be on "some cases", to point up the fact that wide generalizations cannot be drawn from them in any view of history. More typical are the consequences of changes in political leadership in late fourteenth- and early fifteenth-century China. As Mokyr (1990) points out, before the fourteenth century, Chinese technology was clearly superior to that of the West in textile production, ship building, the measurement

of time, movable type printing, the invention of the wheelbarrow, and the development of chemicals for explosives, pharmaceuticals, and insecticides. In fact, it would take the West several centuries to catch up with some of these technological feats. Artistic technique and imagination were similarly encouraged to flourish as China was approaching the fourteenth century. Grousset (1959) attributes this outpouring of creative productivity to the climate of cultural freedom, and probably public appreciation as well.

But as the Ming Dynasty came into power in the late fourteenth century, support by the ruling elite shifted away from technological and artistic creation to more immediate economic needs. Instead of emphasizing innovation, the regime urged imitation of the past. It also blocked the development of letter alphabets, preferring instead to stay with the old ideograms, which fostered artistic activity through calligraphy but stifled literary excellence for many years. Thus it appears that a relaxation of political policing of cultural life, together with a powerful popular thirst for excellence, helps account for periodic outbursts of greatness in different localities. These conditions were surely prominent in the early sixteenth-century Florence of Leonardo Da Vinci and Michelangelo, the late sixteenth and early seventeenth-century London of Shakespeare, Milton, Bacon, Jonson and Donne, the nineteenth-century Vienna of Beethoven, Schubert, and Mahler, the late nineteenth- and early twentieth-century Paris of Cezanne, Matisse, Monet, and Picasso, and the nineteen-twenties' Weimar Republic of Wedekind, Reinhardt, Thomas Mann, and the Bauhaus.

In a grotesque expression of political and public frenzy to generate progress, especially in science, nations at war can be "credited" with "inspiring" breakthroughs meant for human destruction but turned into major blessings for people at peace. Examples abound in the wake of World War II, but two obvious ones come to mind immediately. The first, of course, is the Manhattan Project, which brought together some of the world's greatest scientific minds to create an atomic bomb, and that in turn ushered in forever the real and potential peaceful benefits of nuclear energy. The other is experimentation with jet propulsion of bombs over Britain by Germany's scientists at Peenemünde, which paved the way to today's jet travel and space exploration. And who can gainsay the countless benefits to modern medicine of treatment drugs, devices, and methods developed originally for use on the wounded in battle? On the other hand, wars have destroyed, crippled, exiled, demoralized, and misdirected so many creative spirits that the discoveries and innovations gained in wartime, dramatic as they may be, cannot possibly make up for the real and potential talent lost in the upheavals of conflict.

Disastrous living conditions around the world have also brought scientific breakthroughs in recent decades. Witness, for example, the so-called "green revolution", with its outcropping of agricultural abundance, thanks

to new methods of selecting, planting, and fertilizing crops to produce enough surplus edibles to feed famine stricken areas of the world. But unfortunately, the magnitude and effects of famine clearly overwhelm the benefits of a green revolution in making enough of a difference worldwide. There are now some three billion people who have no easy access to fresh water, and millions of them live in arid climates, mostly in the southern hemisphere where the once fertile land is already, or is becoming, desert-like in its failure to yield any crops to sustain human life. Aside from the unspeakable misery that exists in that part of the world, there is the added tragedy of a scarcity of talent, brought on by the need to alleviate suffering which saps all energies, physical and mental.

Until the late eighteenth-century, starvation also threatened the lives of many settlers in the North American continent, and artistic life had to be compromised accordingly. But the settlers had brought with them from Europe a social legacy which eventually evolved to what Laski (1948) calls "the quintessence of a secularized puritanism" (p. 42). Its origins are in the familiar Protestant ethic (Weber, 1948), but is applied singularly to the North American condition. It extols effort and the belief that success is its inevitable consequence. In a pioneering society, it is praiseworthy to take risks, show courage, innovate and adapt, and even engage in "rugged individualism" to build and maintain a modern society. It takes so much ingenuity and hard work to get the job done that there is hardly much time to cultivate the arts. Indeed, artistic life is a luxury that few can afford when so many shoulders have to be put to the wheel.

Only later, when the pioneering days in America were over and political, social, and economic institutions were established, could increasing numbers of people allow themselves to turn to the life of the mind. Great political theory and science flourished earliest in the post-pioneer years because they were rooted in the necessities of the pioneer period; great drama and music began to appear much later, also as symbols of hard work and self-perfection in conformance with the Protestant ethic. However, in too many parts of the southern hemisphere, where survival is constantly under threat, and living conditions are indescribably brutal, any confidence people may have had in their ability to overcome adversity has been buried beneath layers upon layers of tragedy accumulated over generations. If they ever inherited a belief in achieving excellence through hard work, their histories of abject misery *despite* hard work could only have had a demoralizing effect on them. And yet, faith in oneself and in the perfectibility of the world are prerequisite to creative activity that is of great value. Sadly, there are too many people today, especially in the southern hemisphere, whose life circumstances deprive them of such basics and deny them access to membership in a global circle of immortals.

Ancient Origins of Interest in the Gifted

Western society has generally looked to Ancient Greek (i.e., Athenian) and Judaeo-Christian traditions for sources of its own cultural identity. In following this practice, a reviewer of history of/and the gifted must beware not to view these forebears as child-like in their mental powers compared to the mature moderns simply because the age of the human species is older now and therefore presumably wiser. True, today's storehouse of music, art, literature, and scientific knowledge is much greater than ever before, a fact that makes contemporary Western society culturally richer than that of Ancient Athens, Judea, or Babylon. But for sheer intellectual power, and the ability to achieve immortality in creative production, the ancients could easily match the moderns in domains of excellence that were characteristic of their societies.

The Legacy of Athens

In the case of Athenian culture, the talent domains were fairly much the same as those which would eventually be valued in the West. They include intellectual ability, often expressed in philosophic speculation, moral excellence, political insight, literary, musical, oratorical, and artistic talents, as well as physical strength for beauty's sake. Hellenism also spread its influence to Ancient Rome and, indeed, to much of the Middle East long before it took hold in Western countries.

There was no state-sponsored education at any level in Athens, even though Plato advocated its establishment. Instead, private citizens opened schools for boys, ages 6 to 14, or to later ages for those who could afford it. (Girls studied at home where their mothers or nurses taught them how to weave, spin, embroider, sing, dance, and play an instrument.) The boys' course of study was divided into three parts: writing (including arithmetic and reading), music, and gymnastics. In Aristotle's time, drawing and painting were added. Everyone learned to play the lyre, and much of the instruction emphasized creating music and poetry. Although no time was spent on acquiring foreign languages, great care was taken in learning the correct usage of the mother tongue. Gymnastics were major features of the curriculum, especially wrestling, swimming, and the use of bow and sling. By age 16, the boys were well trained to run, leap, wrestle, hunt, drive chariots, and hurl the javelin, skills needed for military service. When they became soldier youths at age 18 they learned and practiced the skills of democratic governance and engaged in intensive studies of literature, music, geometry, and rhetoric before being sent off as 19-year-olds for a two-year assignment to a frontier garrison to protect the city.

For advanced study, Aristotle, who was recognized in his time as a philosopher, scientist, and statesman, established the Lyceum, a major learning center rivaling the Academy and the School of Isocrates. All three

became severe competitors until they began to emphasize different courses of study. The School of Isocrates concentrated on rhetoric, the Lyceum on natural science, and the Academy on mathematics, metaphysics, and politics. At the Lyceum, Aristotle assigned his students to gather and coordinate knowledge in many fields: the customs of barbarians, the constitutions of the Greek cities, the chronology of victories in the Pithian Games and in the Athenian Dionysia, the organs and habits of animals, the character and distribution of plants, and the history of science and philosophy.

Athenian citizens, mainly the well-to-do aristocrats, could thus provide their sons with an education that came reasonably close to Plato's version of special enriched schooling for so-called Guardians, or men of silver, whose performance in advanced studies would determine who qualifies as a man of gold, or philosopher king. Plato believed that citizens in his republic should be trained to maximize their potentialities. He insisted that young men who possessed unusual mental ability, based on evidence derived from various tests, be separated from those of average intelligence and given a specialized type of education. The program would require mastery of science, philosophy, and metaphysics. Those who excelled in the program would form a pool out of which future leaders of the state could be drawn. Plato was convinced that Athenian democracy could sustain its greatness only as long as it provided the best educational opportunities for selected young people who would then become its future leaders.

The Classical idea of a ruling elite based on wealth and merit is anathema to modern Western democracies and has been effectively satirized by Young (1959) as a portent of social upheaval and possible disaster. However, Athenian tradition highlights the need to nurture human excellence for its own sake and for the betterment of life in society, an ideal which should be made attainable without sacrifice of egalitarian principles. Classical society also calls attention to domains of excellence which came alive during the Renaissance period in Europe and which are so very much alive today in the entire Western world.

Judaic Influences

The Jewish people have often been called "children of the book", with a tradition of studying, creating, interpreting, teaching, and disseminating ideas wherever they have lived in Western countries. This intense devotion to learning, which has spread its influence to the larger Western community, can be found in several biblical sources, of which the medieval Jewish philosopher, Maimonides, in Chapter 2 of *Laws of the Study of Torah (Mishna Torah)* singles out one: "The Torah which Moses commanded us is a legacy for the congregation of Jacob (i.e., the Jewish people)!" (Deuteronomy, 33:4). *Torah* encompasses a vast literature, including the Old Testament, Mishna and Talmud

(i.e., codifications of centuries of Rabbinic exegeses of scriptural law, lore, and philosophy), along with the wisdom and scholarship of *Gaonim*, *Rishonim*, and *Acharonim*, leading exegetists of post-Talmudic times to the present day.

Maimonides' extolling the centrality of *Torah* learning in traditional Jewish life deserves some explication because it reflects the pronouncements of generations of scholars before him, and his influence has remained powerful, even in large segments of today's Jewish world. Here are just a few examples of his thoughts on *Torah* studies:

(1) There is no biblical positive commandment that outweighs the study of *Torah*.

(2) *Torah* should be studied for its own sake (i.e., self-betterment and enlightenment), not for the sake of material reward.

(3) Even if economic circumstances reduce persons to sustain themselves on bread and salt and on severely limited measures of water, and they are forced to sleep on the ground, they may not renounce immersion in *Torah*.

Religious Jews throughout their history have devotedly adhered to the sentiments expressed by Maimonides. To achieve the status of a *Talmid Chacham* (literally a student-scholar)—everybody a student, including the scholar—was an incomparable accomplishment in early Jewish history and remains so to this day. Not even material wealth could gain so much public veneration for its possessor. Indeed, the rich have often sought the brightest, most scholarly young bachelors for possible marriage to their daughters, and the promise of a substantial dowry could enable the groom to spend a lifetime in *Torah* study free from want, even while building a family. There is never any thought of using the money to enter the business or professional world, or even to support a luxurious lifestyle. Young women had no such educational opportunities until the early twentieth-century when seminaries were opened for them in various Western countries and have multiplied ever since, rapidly in recent years.

Usually, the male's advanced academic work is conducted at a *Yeshiva* (*Torah* Academy) where partners or small groups of three or four adolescents or adults study together for up to ten hours a day and attend regular lectures by leading student-scholars. Since there is no end to the breadth or depth of study, there is no completion of coursework and therefore no diplomas or any other material awards granted, or even sought, except for the few—not necessarily the brightest—who are ordained as Rabbis after some years of prescribed study, and they serve in pulpits, or in Jewish education, or in community leadership positions. This kind of intensive learning that begins soon after the cradle and extends to the grave has permeated large pockets of *Torah*-loyal Jewish life in every Western country where Jews have settled, since the destruction of the Temple in Jerusalem in A.D. 70.

When the male child enters the *Cheder* (i.e., a Jewish school containing one or more classrooms),

with much joy and celebration, often as early as age 3, he quickly develops literacy in the Hebrew language and then spends most of the time, until the pre-adolescent years, mastering the scriptures and the accompanying commentaries. Thereafter, for the rest of his student years at Yeshiva, including the many informal learning periods outside of school hours and beyond the school years, most of the concentration, by far, is on the Talmud and its vast collection of related literature. His deep penetration into Judaic jurisprudence and codes of behavior requires a most sophisticated level of logical insight simply to understand the text, let alone to draw brilliant inferences from it. The highest honor bestowed by learned peers and even by the uneducated public is upon the rare student who can gain intimate familiarity with Talmudic thought in all its depth and breadth and can also create original interpretations that illuminate it as perhaps never before. This gifted individual thus qualifies as a student-scholar, the person for whom the Yeshiva is primarily meant to exist. In short, it is an educational system that fosters a kind of intellectual elitism in which the Talmudist *par excellence* reigns supreme.

Since Jews lived for many centuries as second class citizens in Western society, their Gentile neighbors were rarely inspired by the Jewish love for learning. In fact, some of the richest, most intensive scholarly activity took place in ghetto-like settings, small town (*Shtetl*) communities where religious oppression and separatism was greatest, and there was little desire or even opportunity for Gentile to emulate the often-hated Jew. It was not until the emancipation proclamations all across Europe and in the United States, mostly in the late eighteenth and early nineteenth centuries, that ghetto life began to crumble as Jews were given freedom to prosper in financial centers and to participate in Western cultural life. From that time on, a huge majority of "children of the book" (i.e., *Torah*) became children of *all* books. The devotion with which Talmudic study was pursued shifted, for a vast majority of Jews, to secular learning, with far-reaching consequences for the Jewish *Shtetl* and for Western society in general.

The *Shtetl* lamented the hemorrhaging of religious commitment and Torah learning among its youth, while Western society gained a talent pool that enriched cultural life immeasurably and permanently in virtually every domain of advanced-level activity. Unreconstructed anti-semites have derided highly motivated, high achieving Jewish students as grindingly overambitious as they scramble and compete to get ahead. So conspicuous have these students been in their self-sacrifice for mastery, that the American novelist, Thomas Wolfe, whose university classes contained large Jewish enrollments, once described them as "burning in the night" with a seemingly endless fire of enthusiasm for matters cerebral and secular.

For sheer volume of great Western achievements in the arts and sciences over the past two centuries, Jews have contributed far out of proportion to their

numbers within the general population. Such immortals as Freud, Einstein, Kafka and von Neumann, among others, even succeeded in revolutionizing whole domains of productive activity far beyond their lifetimes, possibly for all time. Others, though lesser lights, have enriched cultural life in the West not only as creative contributors but also as patrons, mentors, and role models by enabling others to achieve renown while remaining virtually unknown themselves. The magnitude of Jewish constructive involvement in Western arts and sciences can only be a matter of conjecture, the few hints coming out of facts concerning pre- and post-Holocaust Europe. Engelmann's (1984) powerful treatise on Germany without Jews reports on their critical role in German medicine, politics, higher education, artistic, literary, theatrical, and musical life, and even in that country's record in winning Nobel prizes. The precipitous drop in quality and abundance of German talent since the liquidation of almost all Jewry in that country illustrates how a life of the mind among ancient Jews, passed on from generation to generation, plays a vital role in the recent history of giftedness in Western society.

Christian Influences

To the extent that Christianity is rooted in Judaic sources, it has also extolled studiousness and achievement, concentrating in its early history on the scriptures, including the New Testament. When it was at its peak of power during the Middle Ages, it created an everlasting learning tradition without causing Europe to be "blissfully ignorant of the 'spell of the classics' and interested only in theological speculation" (Lamonte, 1949, p. 553). Great ideas in science, law, literature, philosophy, and art were, in fact, studied and propounded vigorously at that time. Yet, to the modern Westerner, Medieval Europe appears as a tradition-oriented society in which high-level talent was devoted primarily to the preservation, understanding, and enhancement of Church ideals.

Among the most significant developments in creative thinking by the end of the fifteenth-century, besides ideological treatises, were those associated with early technology and the renaissance. Advances in the chemistry of ink, skills in paper making, and metallurgy enabled Gutenberg to invent movable type sometime around the mid-fifteenth-century, and this new device almost immediately facilitated the wide dissemination of ideas, some of them highly critical of the Church. Among the most powerful polemics were Martin Luther's ninety-five theses which he nailed on the door of the Castle Church at Wittenberg, Germany, in 1517, a document that received wide circulation with the help of movable type. The theses bitterly attacked the Pope's practice of selling indulgences, whereby sinners were promised forgiveness if they sent substantial sums of money to the papal treasury. Luther was branded a heretic, but the authority of the Vatican was shaken, not only in his

native Germany, but also in France and Switzerland, where John Calvin led the struggle for Church liberalization soon afterwards. These three countries were already leaning toward reformation, so they provided fertile ground for the sowing of new ideas by Luther and Calvin.

With the advent of the Protestant Reformation came the movement toward widespread growth of literacy. Protestants suggested that the masses can serve their religion directly without relying heavily on Church intermediaries. But in order to do so, everybody had to be able to read and understand the scriptures. True, it requires hard work, but the rewards are substantial, since human beings are considered perfectible through their own efforts, according to Protestant tradition.

The growth of the Protestant spirit and ethic over the past five centuries, and the conversion of the Western world from an agrarian to a highly commercial and industrial society have exerted deep influences upon present-day concerns about the development of talent. In the Protestant urban centers the individual quickly learned that the highest rewards in life could be attained through self-enlightenment and self-betterment in some culturally approved area of activity. This orientation to life's opportunities brought with it the seeds of universal education, scientific and technological development, and an intense intellectual restlessness that conforms with the Faustian nature of Western society.

Reinforcing the spirit of reformation and humanism was the contemporaneous renaissance movement which vitalized creative behavior through new freedom of style and substance. Although the Church and its sages retained their prominence in the art of Titian, Tintoretto, Michelangelo, and El Greco, among many others, these masterpieces reflected an inspiration to idealize the human form and to place the human being at center stage as divinely conceived and precious beyond measure. The powers of reason and the senses gained new respect as they brought back to life the Greek and Roman Classics. The scope of the new enthusiasm for learning widened rapidly, incorporating in it a need to advance the sciences for a better understanding of the laws of nature, of the structure of the planet, and the place of the planet in the wider universe. It was a break from the past in which intellectually gifted behavior was dominated by logicians trained in scholastic disputation and in speculating mostly about the human soul that was often shrouded in mysticism. The Renaissance replaced mysticism with humanism and its belief in the goodness and dignity of the human species, as well as its great powers of thought and imagination, as evidenced by the wealth of ideas inherited from the ancient Greeks and Romans.

The Modern Scene

The Reformation and the Renaissance eventually led to the industrial revolution which further reinforced belief

in human potential for fashioning a new world with better-than-ever standards of living and qualities of life. Understandably, the public bestowed renown—sometimes fortune, too—upon those who excelled as conquerors of nature through science, producers of masterpieces, and masterful performance on the stage and in various professions. The names associated with these great achievements took on an importance of their own, sometimes exaggeratedly so, when the so-called “Matthew Effect” drew critical accolades for inferior work simply because the high reputation of its creator had been earned through earlier success. Fame, or at least recognition among peers, became a powerful spur to self-fulfillment and self-advancement and remains to this day a prime incentive for potentially gifted people to fulfill their promise.

As popular belief in the powers of the individual and in opportunities for individualism grew over the past two centuries in Western countries, so did democracy as a preferred social system and form of government. Egalitarianism and excellence emerged as ideals to be preserved, even though they have always been counterpoised and resistant to reconciliation. Among the democracies there are constant changes and variations in emphases on people's rights to social, political, economic, and educational entitlements, especially those individuals who are poor in status and in finances. A democracy that leans far in the direction of egalitarianism seems to weaken its commitment to excellence and is therefore in danger of losing honor in the family of nations—a threat from without. On the other hand, a strong commitment to excellence can compromise equality of status and opportunity within a democracy and arouse serious civil unrest—a threat from within.

Examples of both kinds of threat seem to surface from time to time in modern Western history. Conscious efforts to foster excellence could be seen under the benevolent monarchy of late nineteenth-century Austria, which was determined to maintain its status as one of Europe's premier cultural centers. At that time, secondary education was of a kind that some of today's educators would consider elitist. The famous literary figure, Stefan Zweig, was then a student at a Viennese *Gymnasium*, along with others from bourgeois families, who could afford the tuition and who were bright enough to qualify for pre-university studies. In his autobiography (1943), Zweig described his *Gymnasium* as an eight-year program, following five years of elementary school, and requiring French, English, and Italian (the “living” languages) along with Greek and Latin (“dead” languages) plus geometry and physics, among other subjects. In more egalitarian democracies, the Viennese program would perhaps qualify as differentiated education for the gifted, since the mainstream curriculum is geared to accommodate students who are closer to average in ability, many of whom have no plans to enter college.

In a fairly unusual situation where commitment to excellence is a national priority, one may consider the

relatively short history of education for the gifted in Singapore. A city-state established in 1965 as an independent, Western-oriented democracy, it has adopted English as its official language and geared its educational system as a means of finding a place in the economic and cultural atmosphere of the much larger, more established Western nations. Law and order are strictly enforced, efficiency and proficiency are emphasized, and there are relatively few special educational provisions for handicapped learners. However, the academically gifted are placed in special programs which provide advanced-level studies in English language and literature, the maths and sciences, foreign languages, history, geography, social studies, moral education, and computer appreciation. Australia's commitment to the gifted, on the other hand, varies according to the social ideologies of its states. In Victoria, where there is a relatively strong emphasis on egalitarianism, political office holders tend to resist singling out the gifted for special enrichment experiences. They would rather "cut down tall poppies" to equalize educational opportunity than adjust curricula to accommodate individual differences at the upper ability levels. As a result, proponents of special enrichment for the gifted have had to struggle hard, with only occasional success, in influencing public policy. Not so in New South Wales, where egalitarianism seems to be a less sensitive issue and where there is more eagerness to single out the gifted for special studies.

It should be emphasized that modern Western democracies have always paid attention to the needs of the gifted, albeit with various degrees of intensity. From 1917 until Hitler came to power, Germany made some efforts on behalf of precocious children. Special schools and classes with enriched curricula were formed on the basis of psychological tests. France, Great Britain, Belgium, and Switzerland also have a modern tradition of identifying and training gifted children, or at least providing support for their continued advancement up the educational ladder. However, none of the democracies invested as heavily as did the dictatorships, which considered the gifted as vital human resources for furthering the power of the state. In its early period, the Soviet Union's overall curriculum emphasized heavy indoctrination in communism but only incidental coverage of the physical sciences, mathematics, and languages. In later years, government leaders recognized that physics, chemistry, and mathematics are essential to national aspirations, culturally and militarily. Schools intensified requirements to the point where relatively few could manage to graduate from high school since requirements included five years of physics, biology, and foreign language, four years of chemistry, one year of astronomy, and as many as ten years of mathematics (*Soviet Commitment to Education*, 1959).

The United States has lived with the conflict between egalitarianism and excellence throughout its history, but it took on new meaning in 1918, when the Commission on Reorganization of Secondary Education issued its *Cardinal Principles of Secondary Education* (1918) which

took careful note of human differences and characterized the function of the high school program as open to all young people but differentiated according to their abilities and aspirations. For some students, high school education remained preparatory to college studies, but for others it served as terminal schooling. Inasmuch as democracy is sweeping through the Western world and beyond, the American post-war history of balancing egalitarianism and excellence, and its effect on the gifted, is instructive to more and more societies in present times.

The American Experience: Pre-Sputnik

Since World War II, the greatest swings between devotion to excellence and to egalitarianism have occurred between the late nineteen-fifties and the early nineteen-seventies. Because of these changes, the five years following the launching of *Sputnik* in 1957 and the last half-decade of the 1970s may be viewed as twin peak periods of interest in gifted children. Separating the peaks was a deep valley of neglect in which the public fixed its attention more eagerly on the low functioning, poorly motivated, and socially handicapped at school. In the late 1960s, there was a revival of earlier sensitivities to the needs of the gifted. These fluctuations in national temperament seem to indicate that the country had not succeeded in paying equal attention *simultaneously* to its most and its least successful achievers at school.

Unlocking the secrets of the atom during World War II to produce the bomb represented a scientific as well as a military breakthrough that increased the dependency of armed power on the innovativeness of the scientist. Since the bomb was produced on American soil, its citizens had grown confident that America's leadership in science and technology was unchallengeable. The nation expected itself always to be the first in creating new gadgetry to make life and death easier, be it through sophisticated home appliances, computer systems, communications equipment, or explosives with the power of megatons of TNT. It is easy to imagine, therefore, the shock when this illusion was shattered with the orbiting of *Sputnik* by none other than America's arch enemy in the midst of a Cold War that at any moment could turn hotter than any conflict in history. *Sputnik* was not just a demoralizing technological feat; it had potential military applications, too. Suddenly, the prestige and survival of a nation were jeopardized because some of the enemy's greatest minds of the day had taken the lead in achievement, and the Soviets capitalized on this coup by broadcasting to every nation on earth its success in reducing America to a second-class power at long last.

As might be expected, the targets of criticism for the national humiliation were elementary and secondary schools. But it was by no means the first time that American education had been put on the defensive in those years. Four years before *Sputnik*, a sensational indictment of public education had been published

(Bestor, 1953), which accused the schools of practicing what the author considered their special brand of fraudulence on America's children. The main charge was that schools were not governed by learned educators but rather by know-nothing "educationists", a term the author used in referring to teachers, administrators, and those responsible for training them on college campuses. To his way of thinking, it was tragically ironic that "educationists" should exert nearly total influence on the content of curricula while caring so little about the world of ideas. How could anyone presume to dictate what should be taught at school if he/she is not immersed personally in any scholarly discipline or artistic pursuit? Because of what he regarded as a misplacement of power in the hands of "educationists", Bestor was convinced that schools provided meager intellectual nourishment or inspiration, especially for the gifted, who often marked time in their studies until graduation released them from boredom.

An even more prominent critic was Admiral Hyman Rickover, famous as the "father" of the atomic submarine and long an advocate of programs that would identify and educate an intellectual elite for leadership in the United States. Rickover saw a deadly link between scientific advancement and military strength and warned that the Soviets were moving ahead menacingly on both fronts. Ennobling excellence was no longer just a means of improving the quality of life in a free society; it had also become a key to the survival of the free world.

Beyond the military advantages of producing knowledge and technology, there was also the matter of national prestige that Rickover saw clearly. He warned that the Soviets were in a do-or-die race with the democratic West to produce excellence in every arena that the world respected. Even the number of gold medals it accumulated at the quadrennial Olympics was counted as a badge of honor. Rickover warned that, in order to compete on an equal footing, America had to overcome its traditional guilt about singling out the gifted for special opportunities at school. Even after *Sputnik* was launched, he observed that "anti-intellectualism has long been our besetting sin. With us, hostility to superior intelligence masquerades as belief in the equality of man and puts forth the false claim that it is undemocratic to recognize and nurture superior intelligence" (Rickover, 1960, p. 30). In other words, America could not afford to indulge in a complacent sense of egalitarianism which granted compensatory education for those who needed it while denying enriched education for others who deserved it.

Since Rickover was not an educationist, his "outsider" status prevented him from influencing school policy. However, the pre-*Sputnik* evidence that America was neglecting its gifted could hardly be ignored much longer. In a lengthy report prepared by the director of the Commission on Human Resources and Advanced Training (Wolfe, 1954), it was asserted that the United States failed to prepare enough men and women in the natural sciences, health fields, teaching,

and engineering. Only six of ten in the top five percent and only half of the top twenty-five percent of high school graduates went on to earn college diplomas. At the more advanced levels, a mere three percent of those capable of earning doctorates actually did so.

What made matters worse were expectations that the shortages would soon become even more acute in the late nineteen-fifties unless the schools succeeded in encouraging gifted students to continue on to advanced studies. These concerns were later echoed by the chairman of the U.S. Atomic Energy Commission when he warned the nation that its public schools were not maintaining educational standards, especially for gifted students, thereby causing dangerous shortages of scientists and engineers and other technically trained individuals (*New York Times*, November 27, 1955). An earlier *New York Times* report (May 1, 1955) estimated that, in 1954, American industry needed thirty thousand engineers but that colleges and universities had graduated only eighteen thousand. A mere two hundred physicists earned diplomas that year, and half chose not to enter the field of physics. Serious shortages existed also in industry, medicine, nursing, pharmacology, clinical psychology, and social work, among other important fields. The alarm spread to the National Education Association's Ninety-third Annual Convention in 1955. A committee report pointed out that each year two hundred thousand outstanding high school graduates did not enroll in a college and that an equal number dropped out of college before graduation. The report went on to warn that an annual loss of 400,000 highly trained men and women could force the United States to lose its superiority to the Soviet Union in the realm of technology.

And yet, pre-*Sputnik* America of the 1950s was not entirely unmindful of the nature and nurture of its gifted. In addition to conducting basic research that generated new hypotheses about intellectual functioning and preserving long-standing special school programs in a few scattered cities, behavioral scientists and educators were already demonstrating how university resources could reach out to schools and to school systems in order to further the cause of special education for the ablest. Pioneering such efforts on a nationwide scale was the Talented Youth Project under the direction of A. Harry Passow, at Teachers College, Columbia University. Initiated in 1954, three years before *Sputnik*, the project assisted school administrators and their staffs in different parts of the country to develop, implement, and evaluate their own programs for the gifted. This outreach service was in the tradition of the 1930s activities of Leta Stetter Hollingworth and her staff, also of Teachers College, who experimented with curriculum enrichment and conducted research on behalf of gifted children, albeit only in New York City's public schools rather than nationwide.

The Talented Youth Project existed for twelve years, during which time it provided technical assistance to

many practitioners at their own sites and at various professional conferences concerned with the needs of the gifted. The Project staff also conducted some large-scale studies on ability grouping (Goldberg et al., 1966), underachievement (Raph et al., 1966), the comparative effectiveness of several special programs for the mathematically gifted (Goldberg et al., 1966), and the attitudes of high school students toward academic brilliance (Tannenbaum, 1962). At the outset of its service and research activities, Passow and his associates wrote a problems-and-issues monograph (Passow et al., 1955) that turned out to be not only timely for its day but surprisingly timeless, or at least as applicable nearly forty years after its publication as it was then.

The American Experience: Post-Sputnik

When the American educational community finally took action on behalf of the gifted, it did so with alacrity. Enormous public and private funds became available to assist in the pursuit of excellence, primarily in the fields of science and technology. Academic course work was telescoped and stiffened to test the brainpower of the gifted. Courses that had been offered only at the college level began to find their way into special enrichment programs in high school and eventually in elementary school.

Rickover's alarms concerning Soviet advancement in technology were finally taken seriously, especially since they were expressed by a man whose own career symbolized the marriage between science and the military. His criticisms of public schools were basically motivated by concerns about national security. This coupling of education and defense became public policy through a significantly titled piece of legislation, the National Defense Education Act of 1958, which revealed a new and far more critical role for the schools than they had ever played before. While remaining obliged to produce an enlightened people capable of living together happily, responsibly, and productively in a democratic system of government, schools are also in the business of protecting its citizens from being buried ideologically, and perhaps militarily too, by a fearsome foreign power. The Act provided funds to strengthen six components of American education, one of which was the identification of gifted children. In addition, it set aside money to help schools mount programs in science, mathematics, and foreign languages, which showed where the emphasis in high-level education was to be placed.

Another influential figure in promoting excellence in American schools was James B. Conant, a renowned chemist and public servant and a president of Harvard University. In his report, titled *The American High School Today* (1959), he addressed the concerns of the post-Sputnik 1950s by offering a broad twenty-one step plan for changing secondary education with special emphasis on core courses that were challenging in content and required of all students regardless of their

career plans. His proposal also took special note of the academically gifted (defined as the upper fifteen percent) and the highly gifted (defined as the upper three percent), and schools took serious note of his recommendations. Perhaps the combination of the report's timeliness and Conant's personal credibility in the public schools enabled his message to get through and retain its influence for a long time, while the earlier critics' ideas, which were fairly similar to his, were taken less seriously.

In addition to the outpouring of special enrichment activities initiated in the schools during the late nineteen-fifties and early nineteen-sixties, there was a good deal of research activity dealing with the characteristics and education of gifted children. Lewis M. Terman's studies of high-IQ children, which began in the early nineteen-twenties, had produced several landmark results that cleared the way for efforts on behalf of the gifted. One important outcome of his research was that precocious children are not mutants who possess some kinds of freakish powers bestowed upon them by biological accident. Instead, they differ from lesser abled peers in degree rather than in kind. Those who find themselves in the upper extreme of the ability continuum merely have more powerful versions of the same attributes possessed by those who are closer to average in ability.

A second enduring outcome of Terman's work was his finding that potential giftedness reveals itself even in childhood. "Early ripe, early rot" is a once-popular platitude that he helped turn into a canard by his studies of high-IQ children growing up. Despite the many cases of aborted genius, his data provided some assurance that children with high potentialities and reasonably stable personalities stood a better-than-average chance to excel eventually in their careers, provided they were given the right opportunities at home and at school. Because of his finding that greatness does not materialize suddenly and unaccountably in adulthood, but instead has its roots in the early years of growth, professional education was convinced of its key position in helping bright children fulfill their promise. In other words, Terman confirmed the need for special educational programs for the gifted, an idea that would be irrelevant if there were no developmental connection between early promise and later fulfillment.

In claiming to reach beyond the IQ, Guilford's Presidential address at the American Psychological Association in 1950 introduced creativity as an unsung dimension of precocious development. The need to measure creativity encouraged psychometrists to abandon the assumption that tests of general intelligence, such as those developed in the early part of the century by Terman and his associates, could be used to locate the entire pool of children out of which virtually all the gifted would probably emerge. This led to a highly influential paper by Getzels and Jackson (1958) which reported a comparison of "high-creative, low-IQ" and "high-IQ, low-creative" students at the University of

Chicago Campus High School. This study had a stunning influence on educational researchers because it announced a breakthrough in the use of so-called "creativity" measures to identify a talent resource that was allegedly overlooked by IQ tests.

Other investigations in vogue in the immediate post-*Sputnik* period focused on the relative effectiveness of different administrative designs, such as ability grouping, enrichment in regular classes, and acceleration; the social status of the gifted at school and its effect on their motivation to learn; the causes and treatment of scholastic underachievement among children with high potential; achievement motivation and other non-intellective factors in high-level learning; and the psychosocial correlates of divergent thinking processes. Professional journals in America were deluged with research reports and with exhortations to do something special for the gifted. So rapid was the build-up of literature in the field that one writer (French, 1959) claimed there were more articles published in the three-year period from 1956 to 1959 than in the previous thirty years.

Perhaps the most vivid recollection of the post-*Sputnik* years is that of the Great Talent Hunt. It was a time when every possible effort was exerted at federal, state, and local levels to identify gifted children and to educate them to the limits of their potential. So intense was the search for young brains, their nurture, and utilization that a parallel can be drawn between the way in which America dealt with high-level *human* resources in the 1950s and its approach to precious *natural* resources during the energy shortages of the late nineteen-seventies. Just as the nation grasped at new energy sources out of fear that it could not continue to function without them, so did the post-*Sputnik* leadership cast about frantically for signs of giftedness in the schools. And just as natural resources were dealt with in an objective, efficient manner, so did the talent hunt show signs of detachment and impersonality, as if gifted people's usefulness to society mattered more than their individualities and sensibilities as human beings.

High scholastic standards and standing, academic advancement, studiousness, and career mindedness were conspicuous themes in America's schools when the bandwagon for the gifted was rolling in reaction to the Soviet *Sputnik* threat. It became virtually unthinkable for a gifted child to bypass the more difficult courses in favor of the less demanding ones. It certainly was no time for young people to be free spirited or to enjoy the privilege of doing nothing. Instead they were brought up in a period of total talent mobilization, requiring the most able-minded to fulfill their potentials and to submit their developed abilities for service to the nation.

The American Experience: The 1960s Decade of Turmoil

The 1960s opened with John F. Kennedy's election to the Presidency amid promises and dreams of a modern

utopia. There was excitement in the air as the nation prepared itself to sweep away the stodginess of the 1950s and to create a new age of excellence. Kennedy was particularly attractive to young people who saw in him (and his family) a refreshing blend of youthfulness, vitality, intelligence, idealism, and beauty. His earliest messages as President of the United States made it clear that brains and loyalty to the flag were among the nation's most precious assets. He announced boldly his intention to put a man on the moon by 1970, a clear sign that he was accepting the Soviet challenge for supremacy in space exploration and that the most brilliant scientists would be called upon to make such a feat feasible. This meant encouraging the largest possible number of able students to enroll in science programs that offered them the best possible specialized education. For who else but the gifted could yield forth from their ranks a team of scientists qualified to honor the President's commitment?

There were other hints of meritocracy in the air. Kennedy gathered around him some of the most precocious men (though few women) of his generation to advise him on governmental matters. Known then as the "Whiz Kids", some had earned their reputations as scholars at leading universities and others as promising ideas men in industry. All of them projected an image of braininess with a zest for unraveling the Chief Executive's knottiest problems. They were gifted children grown up and enjoying the glamor of fame and power rather than living in relative obscurity as so many other gifted people have to do even in their most productive years. At last, able children had their own celebrity role models to emulate, much as budding athletes and entertainers have theirs. The nation's leaders were demonstrating by their own example that it pays to be smart at school if you want to get ahead in life. It certainly made good economic sense because the best paying jobs were going to the best educated.

It would, of course, be naïve to suggest that America had reached a time in history when brilliant students were taking their place alongside the sports stars as heroes on campus. Far from it. Research by Coleman (1962) and Tannenbaum (1962) demonstrated that acclaim among peers was achieved far more easily on the athletic field than on the honor roll. Still, the Kennedy years were making good on promises of social and economic rewards for those willing to cultivate their superior scholastic abilities despite the lack of enthusiastic cheering from schoolmates.

The bids were high for brains in the early 1960s, but there was a string attached. President Kennedy expressed it best in his immortal admonition to his countrymen: "Ask not what your country can do for you—ask what you can do for your country." It was a call for unselfish accomplishment, to dedicate the work of America's citizens to the greater glory of the nation. Those with higher abilities had more to contribute and were therefore under pressure not to bury their talents or even to indulge in creative productivity that was

impractical. The feeling during the Cold War was that the scientist could better serve the nation than could the poet. Judging from the career plans of gifted children in the late nineteen-fifties and early nineteen-sixties, they evidently believed that the nation was worth serving. By far the largest number of students with high tested intelligence majored in the sciences, and many of them aspired to enter fields of technology that could somehow help the defense effort. Employment opportunities in these industries and professions were reinforced by the glamorization of science as humanity's most exciting modern frontier.

Yet the flurry of activity on behalf of the gifted left some unfinished business to haunt America ever since. Even the threat of *Sputnik* and the indulgence of excellence during the Kennedy era were not enough to guarantee that the needs of the gifted would be cared for perpetually at school. Instead, enrichment was considered a curricular ornament to be detached and discarded when the cost of upkeep became prohibitive. This is as true in the 1990s as it was in the 1960s, as evidenced by reports of cutting back on programs for the gifted as a result of budgetary crises and tax revolts in many school districts, where only programs for the handicapped learners are mandated by law to receive their usual share of special support (*New York Times*, November 29, 1992). Moreover, the fervor with which guidance counselors ushered gifted youths into sciences programs backfired to some degree as large numbers of these students changed their academic majors by the time they reached their sophomore years in college (Watley, 1968) and many who did stay on to pursue careers mapped out for them became victims of the shaky fortunes of the aerospace industry.

When the *Sputnik* scare began to wane, some special programs and curricula were retained, partly through the efforts of the newly formed advocacy groups on behalf of the gifted. But for the most part, the vast majority of educational innovations triggered by *Sputnik* and sustained in the Kennedy era proved trendy rather than long-lived despite their early promise. Perhaps the decline of interest in the gifted would have been inevitable, considering how conflicted the American public often feels about such children. Intimations of meritocracy can never fit easily into a democratic frame of reference. There will always be egalitarian-minded people who consider it necessary to withhold special opportunities that might aid the ablest to get far ahead of the pack. These critics often argue that bright children are advantaged and can fend for themselves, so why invest in them? This sentiment has circulated widely for a long time and is compatible with the popular notion of idealizing the norm, encouraging the deficient to reach as close to it as possible, and either ignoring or frowning on the efforts of the highly proficient to move far beyond it.

Nevertheless, it would be a mistake to assume that America merely grew tired of the gifted in the mid-1960s because its interest in them had been less than

wholehearted all along. While attention might have declined, the fact is that there were pressures forcing the nation's preoccupation away from the gifted toward realities that seemed to be far more relevant to the events of those days. Among the most prominent were the Civil Rights Movement, school integration, and compensatory education; Vietnam and the disenchantment of youth; and growing distrust of scientific discovery.

Focus on Underprivileged Minorities

The 1954 Supreme Court decision to desegregate public schools set off an inexorable movement toward updating the Constitution and the Bill of Rights. Once again, education became the linchpin of a national priority, this time for social justice, as it had formerly been for the Great Talent Hunt. Separatism and equality were declared an impossible combination and therefore unconstitutional. In 1955, Martin Luther King Jr began his leadership in the struggle for racial integration in all community institutions, including employment, housing, and transportation, as well as the schools, when he led his historic boycott of buses in Montgomery, Alabama, to protest at the treatment of black passengers, an event that led to similar action throughout the country. His efforts placed the classroom in perspective as one of many battlegrounds in America's all-out campaign to raise the status of its underclasses. Educators learned quickly that pressures were mounting everywhere—not just in the schools—to take decisive action to eliminate even the subtle forms of discrimination that had hardly been noticeable over the years. It was the wave of those times and it could not be ignored.

At the top of the educational agenda, far ahead of the needs of the gifted, was the cause of low-achieving disadvantaged children. There was a new sense of urgency to avert internal unrest by using every possible means to close the gap between the "haves" and the "have-nots", and it was generally acknowledged that schools would figure prominently in the process. Attention was thus shifted away from the need of the nation's talent reservoir to be kept well filled for the sake of defense and world prestige. The feeling was that somehow these problems could take care of themselves while only lightly attended to, whereas failure at school among the disadvantaged could not. In short, America was more concerned about bolstering freedom and equality within its borders than in playing the lead on the world stage, despite the unabated pressures of cold warfare that brought confrontations between East and West in Europe, Southeast Asia, and the Middle East.

In addition to diverting interest away from the gifted, the advocacy movement for the socially disadvantaged actually contested at least two features of special programs for able children: (1) the use of IQ tests and other conventional measures of mental functioning as a

means of determining who deserves to be called gifted, and (2) grouping children in special classes for the gifted on the basis of their performance on these kinds of assessments.

Since racial minorities, such as Hispanics, Blacks, Chicanos, and Native Americans, traditionally performed less well at school than did white majorities, it was logical to suspect ability grouping for the gifted as *de facto* racial segregation. Critics argued that schools were practicing blatant favoritism by creating special classes for children who were rated superior on conventional measures of intellect and also by offering the chosen few a kind of enrichment in their curriculum that was denied everyone else. Objections were not necessarily against special ability grouping *per se* for the gifted, or even the enriched educational experience reserved for them because of their ability. What created the furor was the practice of denying enough children from disadvantaged subpopulations their rightful access to these classes. There was an overwhelming sentiment favoring the idea that high potential is distributed equitably among all races, privileged or underprivileged, but that life's circumstances in some groups are oppressive enough to cast a shadow over their innate competencies. And since nobody had ever devised a way in which to locate and nurture giftedness that was thus hidden from view, it was impossible to integrate special classes for the gifted with balanced racial quotas.

American education could not reconcile its interest in the gifted with its concern for the disadvantaged, nor could it design a satisfactory methodology for locating and cultivating giftedness among minority groups. The dilemma was easy to resolve inasmuch as it reduced itself to a choice between battling for social justice to achieve egalitarianism as against pursuing excellence, and there was no doubt as to which of the two would better fit the mood of the post-Kennedy 1960s.

Vietnam and Dissenting Youth

Although Vietnam was by no means the first confrontation between West and East, it turned out to be disastrously different, despite the fact that Kennedy's successor, Lyndon B. Johnson, justified America's entanglement on the same grounds that his predecessor defended his risks of war in Berlin and Cuba. What started out as a limited police action that was supposed to last only a short time before the expected victory would be won and American soldiers returned home, it degenerated into a nightmarish entanglement with staggering sacrifices of life and no end in sight. The leadership in Washington kept the public's hopes for a quick end to the war alive by issuing deceptive reports about success on the battlefield. Eventually, the nation grew tired of war, suspicious of politicians' promises of a quick victory, and increasingly convinced that America was meddling in affairs of other nations rather than serving as a judge and enforcer of what was morally right in the world.

Among the many casualties of the Vietnam conflict was America's perception of giftedness and political leadership. The Whiz Kids of the Kennedy years, many of whom had stayed on in the Johnson era to help formulate strategy for the war effort, eventually turned out to be *The Best and the Brightest* (Halberstam, 1972). While they were quick-minded, articulate, hard-working, and self-confident, Halberstam argued that they lacked wisdom and sensitivity to the feelings of the masses. Their cerebral artistry proved to be flashy rather than profound. They were rapidly losing their image as people who could become heroes in public life by virtue of their brainpower alone. In fact, their sad history seemed to prove that being super-smart scholastically was not a guarantee of super understanding of humanity's most serious problems and how to solve them. Gifted youths on campuses throughout the country learned to despise them for their role in the Vietnam debacle rather than revere them as graduated honors students distinguishing themselves as national leaders.

A serious by-product of Vietnam was growing unrest among students in the colleges. Many of them saw the war as an unprincipled adventure of the establishment in Washington and perhaps even of the senior generation (ages 30 and above) who either did not care or did not understand how their actions were affecting the conscience of idealistic young people.

Kenneth Keniston, who studied campus protestors in great detail, made it quite clear that a complex mix of personal attributes, familial influences, peer associations, and school environments set them apart from their more conforming agemates (Keniston, 1971). However, it is noteworthy that a disproportionate number of disaffected youth on campus distinguished themselves in their studies at school and were frequently enrolled in some of the more enriched and prestigious programs. Their immediate targets were the colleges they were attending, which represented to them an establishment with archaic standards for success and unreasonable controls over their lives. Yet these same gadflies in centers of learning were themselves described in one study as possessing high degrees of intellectualism, defined as "concern with ideas—desire to realize intellectual activities—high valuation of intellectual creativities—appreciation of theory and knowledge—participation in intellectual activity (e.g., reading, studying, teaching, writing)—broad intellectual concerns" (Flacks, 1967, p. 70).

The unrest on campus underwent some dramatic changes over a relatively short time. As one observer remarked, "the key difference between the Berkeley [University] riots of 1964 and the Columbia [University] crisis of May 1968 is that in the pre-Columbian sense the major impetus for unrest stemmed from the perceived abuse or misuse of authority, whereas the later protest denied the legitimacy of authority . . ." (Bennis, 1970, p. 599). One might add that, when attention was called to the *misuse* of authority, it was an expression of protest, but when it evolved into doubts about the *legitimacy* of authority, it became a sign of insurrection.

The revolt was not only against institutions (educational or otherwise) and their leaders; it was also against a tradition of rationalism that sanctified ivory-tower scholarship. When Columbia University rioters willfully destroyed a professor's research files, the act may have carried a message that went beyond ordinary malicious mischief and vandalism. It seemed to imply that all the work invested in accumulating those files was a waste of the professor's talent, which ought to have been dedicated to building a better society rather than to dabbling in esoterica. And to make matters worse, the educational establishment expected its brightest students to follow in the footsteps of professors like him.

Many questions were raised among gifted college students as to whether they ought to funnel their psychic energies into a life of the mind. Many were attracted to the sensitivity-training movements, which told them that "talking is usually good for intellectual understanding of personal experience, but it is often not effective for helping a person to *experience*—to feel" (Shutz, 1967, p. 11). Accordingly, the human being was increasingly seen not as a thought machine but rather as a complex biological, psychological, and social organism that can fulfill itself through all these dimensions of being. Every part of the body had to be exercised to its fullest potential, which meant building up the strength and stamina of its muscles, its sensory awareness and aesthetic appreciation, its motor control, and the gamut of its emotional and social feelings. Inhibiting other aspects of self for the sake of the intellect was regarded as amounting to robbing life of its multi-dimensionality, so the task of individuals was to make something of *all* their capacities, even if in so doing they could not make the most of *any* of them.

Significantly, a new utopia emerged in the form of Consciousness III depicted by Charles A. Reich in his then best-seller, *The Greening of America* (1971). One of the postulates of this new world was described by Reich as follows:

Consciousness III rejects the whole concept of excellence and comparative merit . . . [it] refuses to evaluate people by general standards, it refuses to classify people, or analyze them. Each person has his own individuality, not to be compared to that of anyone else. Someone may be a brilliant thinker, but he is not "better" at thinking than anyone else; he simply possesses his own excellence. A person who thinks very poorly is still excellent in his own way. Therefore people are in no hurry to find out another person's background, schools, achievements, as a means of knowing him; they regard all of that as secondary, preferring to know him unadorned. Because there are no governing standards, no one is rejected. Everyone is entitled to pride in himself, and no one should act in a way that is servile, or feel inferior, or allow himself to be treated as if he were inferior (p. 243).

Thus we see how life for campus dissidents became strangely paradoxical. Many of them espoused the

habits of intellectualism generally associated with gifted students. At the same time they rejected excellence and its trappings as violations of democracy and too stultifying to the attainment of total joy and liberation. Even those consenting to live the life of the mind learned an unforgettable lesson from the events in Vietnam. No longer could they be adjured to cultivate their talents for the sake of their country's prestige and need for survival. The war in Southeast Asia tarnished the nation's image enough to discourage such commitments among a large number of students who could potentially be counted among America's high-level human resources. Besides, some may have felt it faintly dehumanizing to be treated like natural resources; it simply did not fit well with the new spirit of selfhood and individuality.

The Devaluation of Science

Gifted youth in the age of *Sputnik* had been bombarded with the message that a lifetime devotion to achievement in science in particular was not only in the interests of the state but of humankind in general. Such pursuits had their own built-in ethic, that any efforts at pushing back the frontiers of theory and research deserve the highest commendation because they attest to humanity's divine-like power of mastering its environment and creating its own brand of miracles. Suddenly the nation was told that science is as fallible as the one who advances it. Among the most vocal critics were the environment-minded scientists who warned that, in America's enthusiasm for conquering nature, it may be destroying its people in the process unless it imposes restraints on such activity (Bereano, 1969).

Perhaps the best known writer of the 1960s to forecast doom if science were to continue on its conventional course was the biologist, Barry Commoner, whose book, *Science and Survival* (1966), enjoyed wide circulation and influence. Commoner took the ecological point of view that the elements of nature are integrated, but human knowledge of these elements is so limited that it is not yet possible to see their connectedness. Expressing deep concern about science's preoccupation with the elegance of its methods rather than the danger of its products, he directed much of his fire at the polluting effects of such symbols of technological giantism as nuclear testing and industrial waste. He acknowledged the need for brainpower to enrich scientific thinking, but he also warned that "no scientific principle can tell us how to make the choice, which may sometimes be forced upon us by the insecticide problem, between the shade of the elm tree and the song of the robin" (p. 104). With such caveats, it became more difficult to convince gifted children that a life dedicated to science was the kind of high calling it had once been unless closer links were made between the intellect and the conscience.

Besides being tarnished because little account was taken of their human consequences, careers in science lost more of their glitter when the job market in various

related fields began to tighten. The manpower crisis dramatized by *Sputnik* gradually calmed down when America began to overtake the Soviets in the technology race and achieved a victory of sorts by transporting the first man to the moon in 1969. Previous personnel shortages in the various fields of science were no longer critical, partly because the flood of graduates in the early 1960s had filled available jobs and also because the Cold War was not considered serious enough to create new jobs through lucrative defense contracts. In fact, by the late 1960s, many Americans were suspicious of the so-called "military-industrial complex" for carving too much out of the tax dollar to support projects that they considered wasteful in times of peace. The primary need, as seen then, was to solve the problem of social unrest rather than to prop up defense technology. Many would-be scientists and engineers began to realize that these professions attracted neither the prestige nor the occupational rewards that would have been guaranteed only a few years earlier. However, the supply of scientific talent did not slow down in accordance with the reduced demand, and as a result of the imbalance, many highly trained personnel found themselves either unemployed or working at jobs outside their fields.

The American Experience: Renewed Interest in the Gifted in the 1970s

The decline of attention to the gifted in the 1960s is evident in the contrasting volume of professional publications on that subject at the beginning and end of the decade. The number of entries under "Gifted children" in the 1970 volume of *The Education Index* was less than half the number in the 1960 volume. Nevertheless, by the outset of the 1970s, there were unmistakable signs of a revival of interest.

Probably the biggest boost came from a 1970 Congressional mandate that added "Provisions Related to Gifted and Talented Children" to the Elementary and Secondary Educational Amendments of 1969. This document expressed a legislative decision to include gifted students among those receiving help from the Elementary and Secondary Education Act and the Teacher Fellowship Provisions of the Higher Education Act of 1956. It also directed the Commissioner to: (1) determine the extent to which special education assistance programs are necessary or useful to meet the needs of gifted children; (2) show which federal assistance programs are being used to meet the needs of gifted children; (3) evaluate how existing federal educational assistance programs could be used more effectively to meet these needs; and (4) recommend new programs, if any, required to meet these needs. The target population was defined as the upper three to five percent of school-age children with outstanding promise in six categories of giftedness: general intellectual ability, specific academic aptitude, creative or productive thinking, leadership ability, visual and performing arts, and psychomotor ability.

In response to the mandate, the then-commissioner Sidney P. Marland, Jr issued a report of his findings and recommendations that set the stage for doing something significant about the deteriorated condition of programs for the gifted (Marland, 1971). He estimated that only a small percentage of the 1.5 to 2.5 million gifted school children were benefitting from special educational services and that such services had a low priority at virtually all levels of school administration. Furthermore, even in those localities where there were legal or administrative directives to provide special offerings, little was accomplished due to other funding priorities, more threatening crises, and the absence of adequately trained personnel. Clearly, Marland saw the gifted as a deprived group whose talents were in danger of serious impairment unless appropriate intervention strategies were planned. He therefore declared his intention to initiate a series of major activities at the federal level with the hope of inspiring and pressing for more commitment on behalf of the gifted throughout the nation's schools.

As a result of federal encouragement and some public and private initiatives, the gifted were exposed to an increasing number of special educational experiences in the 1970s. While as late as 1973 fewer than four percent of the nation's gifted were receiving satisfactory attention at school, and most of the fortunate ones were concentrated in ten states, the nationwide picture improved considerably within the decade. Zettel (1979) reports the following outcomes of a survey conducted in 1977:

- (1) nearly 75% of the states already had statutory definitions of gifted children;
- (2) thirty-three (or 66%) of the states reported an aggregate increase of nearly 25% over the previous year in the number of gifted children served;
- (3) thirty-one (or 62%) of the states increased their appropriations for the gifted by 50%;
- (4) forty-two states reported sponsoring some kind of in-service training for persons interested in serving the gifted, a 110% increase over the previous year.

There was talk about possible legislation that would change the Federal Bureau of the Handicapped to the Bureau of Exceptional Persons, thus including gifted individuals as eligible for sustained support of their education, along with the handicapped. If this kind of move had been made, it would have gone a long way toward erasing the image of gifted education as being only a periodic fad in the schools. It was admittedly a way of forcing attention on the ablest by tying their fortunes to those of the handicapped, for whom funding has rarely abated appreciably. The change in name never came to pass, possibly because the American public could never feel equally sympathetic to the needs of children at both ends of the ability continuum.

Despite the fact that the definition of giftedness had been broadened by the Marland report, little more than lip service was given to children who showed precocity in domains other than academics. Even less fortunate

were the gifted among the underprivileged minority populations who remained largely neglected, except in the arts and sports, but not deliberately so. There is no doubt that many educators would gladly have initiated enrichment experiences for these children and that support was obtainable for such plans if they had stood a chance of success. However, the profession was stymied in its efforts to find a clear way of discerning high-level academic potential that was buried under a thick overlay of social and economic handicaps. In fact, it is hardly less difficult today than it was then to inspire the fulfillment of scholarly talent in the nation's underclasses.

In its desire to sustain interest in the gifted, the federal government funded projects designed to strengthen leadership in the field and to spread advocacy at the grass-roots level. The National/State Leadership Training Institute received federal funds to help state education departments develop viable plans for educating the gifted. In addition, Teachers College, Columbia University, was provided with support to coordinate efforts by seven universities in recruiting and training graduate students to become seminal figures in the field. It was seen as a long-range investment in the careers of men and women who had shown promise for making significant contributions in the 1980s and beyond. Besides these nationwide projects, the federal government, along with state, city, and private agencies, sponsored many regional and local programs for the gifted. The emphasis was mainly on enrichment practices, whereas research and experimentation received relatively little encouragement.

A review of the state of research for the years 1969 to 1974 reveals a fairly bleak picture (Spaulding, undated). These efforts continued to be limited throughout the 1970s, but there are several major exceptions worth noting. They include the 1971 initiation of Julian Stanley's (1976) continual studies of mathematical precocity, Halbert Robinson's (1979) investigations of the cognitive development of young able children, and Pauline Snedden Sears' (1979) and Robert Sears' (1977) assessment of the Terman population in their senior period of life.

What prompted the resurgence of activity in the education for gifted children after nearly a decade of quiescence? A full answer will probably never be known, but the explanation that seems most obvious is American's backlash against what it saw as a youth turned excessively self-indulgent, indifferent to scholastic achievement, and hostile towards some sacred, scholarly traditions. Wagner (1976) published a scathing indictment of universities for compromising academic standards, inflating grades, and diluting degree requirements to fend off unrest among students. His sentiments, shared by many other educators at the time, were signs that the pendulum had swung away from extreme egalitarianism in the direction of excellence. It is hard to imagine the youth of the late 1970s accepting the Consciousness III notion that brilliant minds are not better at thinking than anyone else. However,

the revival of interest was no more a sign of pure historical inevitability than was its decline a decade earlier. What accounted for the revival, at least in part, was evidence of initiatives taken by people who believed in differentiated education at every ability level and who participated in vigorous campaigns to save the schools.

Prescriptive Teaching for All Children

When Riessman published his highly influential book on the culturally deprived child in 1962, he reiterated a number of criticisms of the schools made some fifteen years earlier by Davis and Havighurst (1947). The charges were that the curriculum was excessively loaded with verbal content and therefore placed underprivileged children at a disadvantage; that the subject matter was irrelevant to the vital concerns of these children; that teachers espoused values and behavior codes that were oriented too narrowly toward middle-class living; and that schools were so preoccupied with teaching the disadvantaged how to become socially mobile that they were in effect trying to create a melting pot rather than striving to strengthen cultural pluralism. However, researchers did not take their lead from such charges. Instead of tampering with the old curriculum, they tried to create a learning environment that would enable the disadvantaged to meet the more conventional demands at school.

Among the most notable experiments that sustained their influence at the time were those conducted a decade earlier by Martin Deutsch (1964) and his associates. They attempted to forestall educational retardation by intervening early in children's lives and equipping them with the readiness skills that they could not derive from their social milieu. This required developing elaborate ways in which to diagnose individual learning profiles and to match instructional treatments to them. It paralleled developments in special education for the handicapped, which emphasized prescriptive teaching based on increasingly sophisticated methods of diagnosing intellectual processes. This orientation led to nationally mandated requirements that every handicapped child have an individual diagnosis, prescription, and evaluation.

Attention to specific competencies among the handicapped dramatized the need for individualized education, with *all* children receiving a fair share of what is uniquely appropriate for them, regardless of how deficient or proficient they are in mastering curriculum content. Advocates for the gifted argued that these children should also receive special attention to accommodate their unique learning strengths and thereby demonstrate the educator's attention to human differences. These protagonists pointed out that the more sophisticated educators become in discerning human individuality, and the more inventive they are in providing for individual needs of the ablest, the more likely that America could achieve equality at school.

The Role of the Gifted in "Rescuing" Public Education

It is no secret that educators in the 1970s searched desperately for ways in which to maintain order in thousands of classrooms. This was especially true in big-city schools where ten percent of the nation's pupil population was enrolled. The dismal picture was a familiar one: scholastic achievement levels were three, four, and even five years below norms; drugs, violence, vandalism, and truancy reached epidemic proportions; and costs climbed to such a height that there was always the danger of insufficient funds to pay the bills while maintaining an adequately staffed program. Many middle-class families fled the inner city in the 1970s or sought help from private schools in order to provide a meaningful educational experience for their children. This further aggravated the situation in urban centers.

School administrators became aware that one way in which to bring back the middle classes to inter-city schools was to initiate special programs for the gifted. They therefore opened so-called "magnet schools" that offered enrichment activities in particular subject matter areas to attract sizable numbers of children who would otherwise have been studying elsewhere. The presence of the ablest began to make a difference in the total school atmosphere, which demonstrated that these children were capable of enhancing all education if their learning capacities were properly respected. Again, special education for the gifted was initiated for the sake of solving social problems rather than solely for the sake of those who need, or could benefit from, it.

The American Experience: Peaks and Valleys in the 1980s

At the conclusion of his personal retrospective on three decades of education for the gifted in the United States, Passow (1980) wrote: "I was once again struck by the cyclical nature of our interest in and efforts on behalf of the gifted and talented" (p. xvi). Perhaps the most positive statement that can be made about the gifted in the 1980s is that they prevented George Orwell's "Big Brother" era from arriving in 1984 as he had predicted. In fact, if Orwellian forecasts ever come true, it will be tragic proof of how ineffectual educators have been in nurturing talent for the strengthening of selfhood in the human family. But even the failure of "Big Brother" to materialize is no guarantee that America will succeed in finally breaking its vacillation between public enthusiasm and apathy toward gifted children in the foreseeable future. All that can be said about the 1980s is that there were both positive and negative developments in the school and society, and that it is too early to tell what the eventual effects of these developments will be.

New Sources of Talent

It was already apparent that women and low-status minorities were moving toward parity with middle-class white males in the extent and variety of their advanced education. Trends have indicated a sharply rising representation of women in every creative field over the ten-year span from 1975 to 1985, when there was only a 6% increase in first professional degrees for men, as compared to a huge 122% increase for women. During the same period, the number of earned doctorates among men inched up from slightly under 27,000 to about 28,000, or 4%, whereas for women the jump was from some 8000 to about 14,000, or about 75%.

Considering the changing status of women in society, it is difficult to imagine that talent among them will continue to be suppressed as in former generations. Parents of school-age girls do not tolerate such biases as readily as the girls' grandparents might have, especially if the mothers of these children are themselves members of the new generation of women with advanced training and are in mid-career. Furthermore, opportunities for employment at higher skill levels have increased dramatically for women in recent years, and will continue to do so in the foreseeable future. According to the U.S. Bureau of Labor Statistics, the number of men added to the labor force from 1979 to 1985 was 8.1 million, not even half the 16.5 million figure for women. By 1995, more than 60 of every 100 women of working age will be employed, an increase from 43 per 100 in 1970. They will then constitute over 45% of the prime-age work force. Some of the professional occupations filled mostly by males possessing marketable talents that require advanced training are now absorbing unprecedented numbers of women. These professions include engineering, law, medicine, dentistry, and the life sciences.

The educational and occupational opportunities for bright African-Americans has also improved over the past half century. In 1940, total black enrollment in post-secondary education was less than 50,000, and over 95% of that group was enrolled in traditionally Negro Colleges (Pifer, 1978). By 1976, the number of blacks in colleges and universities had risen dramatically to 1,062,000, and for the 1975-1976 academic year alone, more than 83,000 blacks earned baccalaureate, masters, medical, law, and PhD or EdD degrees (Pifer, 1978; National Center for Education Statistics, 1978).

There is reason to expect the upward trend to continue as more and more people from minority groups are accepted into the managerial, professional, and technical segments of the labor force. What women, blacks, and other minorities have found in the high-skill labor market in the late 1980s is an increase of about 29% over the mid-1970s in the number of professional, technical, and kindred occupations. What they also discovered, unfortunately, is that the total number of adults with advanced education increased more sharply, thus dimming the employment outlook for them. The

openings for PhDs over the 1972–1985 period for growth and replacement was about 187,000, whereas the actual supply of new PhDs numbered as many as 580,000 in the second half of the 1980s. It stands to reason, therefore, that doctoral recipients from all subpopulations have found it difficult to locate work commensurate with their training. But the women and other minorities are most vulnerable on account of age-old prejudices that bar them from many positions of prestige.

New Trends in Diagnosing and Nurturing Excellence

Traditional tactics for identifying gifted who might qualify for the talent pool are under pressure to undergo change, some of it radical. There is no end in sight to the debate over the meaning of IQ, its measurement, and the nature–nurture issues that revolve about it, all of which arouse powerful emotions as well as scientific interest. In the 1970s, some behavioral scientists (Estes, 1976; Voss, 1976) foresaw a decline in the concept of intelligence as a useful description of higher-level cognitive powers. They expected it to be replaced by more diagnostic analyses of the patterns and processes of human functioning. This kind of orientation to the measurement of intellect conforms to the pioneering approach taken by Piaget (1952) in monitoring clinical development of children’s problem-solving behavior.

Despite the criticisms of IQ for identifying gifted children, there has never been a complete let-up in such practice. In a recent review of all empirical studies published in the *Gifted Child Quarterly* over two years (1990 and 1991), Tannenbaum (1992) discovered that in the 22 published reports of research on the gifted, all of them listed IQ, or alternative tests that correlate highly with IQ, as the measure of choice for identifying experimental samples. This is not surprising in light of previous findings by Snyderman and Rothman (1988) which show that psychologists and educators knowledgeable in areas related to intelligence testing generally agreed that IQ instruments are valid and useful in measuring some of the most vital aspects of intelligence. Obviously, test users have been paying little attention to the advice and efforts of academic psychologists to promote new ways of assessing high potential in children.

Among the changes strongly advised by theoreticians has been to examine specialized talents that demonstrate extraordinary rates of mastery and of creativity. Gardner’s (1983) list of such aptitudes has been widely circulated, and includes linguistic, logical-mathematical, spatial, bodily-kinesthetic, musical, interpersonal, and intrapersonal intelligences.

Another major trend in describing high potential in children is through the study of mental processes, exemplified by Sternberg’s (1986) “Triarchic Theory”, so named because it contains three sub-theories. One of them is “componential”, and it consists of three kinds of components involved in the performance of

separate mental operations: (1) metacomponents, or the executive processes needed for planning, monitoring, and decision-making in a problem-solving situation; (2) performance components, which include processes needed for executing a task; (3) knowledge acquisition components used in the selective encoding, selective combination, and selective comparison operations. Another sub-theory is called “experiential”, which incorporates the ability to deal with novelty and the ability to automatize or habituate information processing. The third sub-theory is called “contextual”, which refers to the organism’s selecting, shaping, and adapting to its real-world environment.

Ramos-Ford and Gardner (1991) have experimented with ways of departing from the usual pencil-and-paper tests of ability to monitoring children carefully and systematically for their performance in learning environments that bear some resemblance to real working conditions. It remains to be seen whether such an approach can improve upon conventional testing methods, which critics consider antiquated and inefficient.

A sharply different testing method has been developed by Feuerstein (1979), who also opts for measuring the dynamics of human potential. This means determining the extent to which children’s functioning levels can be modified through what he calls mediation, or the examiner’s use of appropriate helping tactics and practice materials. The idea of mediating the child’s entering behavior in a test situation is novel in that it revises the role of the examiner from that of an objective observer to a participant observer who orients the child to the underlying cognitive principles involved in the test experience. Feuerstein asserts that the organism is so modifiable that mediated learning affects not only the cognitive functioning of the individual but the structure of intellect as well. Such is the power of regulated encounters between the individual and environment.

Programs and Provisions

In 1954, Tannenbaum conducted an informal survey of American schools singled out in a 1941 published report as offering exemplary enrichment programs for gifted children. The purpose of the communication was to find out what had happened to those programs over the intervening 13 years and how schools in 1954 could benefit from the experiences, including the successes and failures, of the 1941 programs. Of the 100 schools contacted, nearly all replied, and in every case the original programs were no longer in operation. In fact, they were never meant to last a long time. What they had amounted to were imaginative projects initiated by talented teachers and supported by administrators who shared their concern about the plight of the gifted.

The survey revealed a fundamental difference between *programs* and *provisions* for the gifted. A program can be defined as a comprehensive offering, sequenced over a long period of time, usually designed as a

requirement, and very much a major part of the total school curriculum. Thus, the school offers programs in mathematics, literature, art, social studies, and the like. A provision, on the other hand, is more fragmentary, an *ad hoc* offering, relatively brief in duration, often designed by an individual teacher with special abilities rather than by a curriculum committee, and supplemental to the major offerings, not integral with them. What the 1954 survey revealed is that the 1941 schools had offered provisions rather than programs. Indeed, wherever enrichment of any kind has been initiated into the school curriculum, in most cases it has amounted to add-on provisions that sooner or later disappeared because of lack of strong enough commitment or sufficient funds to retain what was generally seen as a curriculum luxury rather than necessity. In fact, the lesson learned in the 1954 study was confirmed more than 30 years later. The Richardson sponsored investigation (Cox et al., 1985) reports a survey of some 16,000 schools (of which only about 10% responded, an ominous sign in itself) that found once again only fragmentary enrichment provisions, not programs, in most schools that claimed to be servicing the needs of the gifted.

Despite schools' reluctance to invest in long-range programmatic development for the gifted, there were some encouraging signs in the 1980s that conceptual frameworks for curriculum development could at least be available to those interested in them. School officials were offered program paradigms that they could adapt or adopt for actual implementation. In Renzulli's (1986) *Systems and Models for Developing Programs for the Gifted and Talented* no fewer than fifteen such designs are described in detail by their creators. They are by no means the only ones available for implementation. Not included, for example, is the work of Stanley and the Johns Hopkins Study of Mathematically Precocious Youth (SMPY). Initiated in 1971, SMPY has spread to nearly every corner of the United States, with more and more school systems subscribing to Stanley's ideas about fast-paced instruction for junior high school-age children who are advanced in mathematics. By now, large numbers of young adolescents throughout America, and recently in Germany as well, are being tested in hopes of being placed in any of a number of enrichment settings, such as afternoon and summer classes as well as college courses that offer advanced study. If SMPY and other enrichment paradigms are adopted increasingly in the United States and in other Western countries, it will signal a movement away from *ad hoc* provisions to much longer range programs for the gifted.

Unquestionably, the largest-scale effort on behalf of the gifted in the last decade of the twentieth-century and possibly of all time, is the federally funded project conducted by the National Research Center on the Gifted and Talented. Initiated by Renzulli at the University of Connecticut, it involves three additional universities in joint leadership for the development of theory, research, and programs across the United States. More than 200 elementary and secondary schools throughout the

country collaborate as experimental sites, and as many as eleven major so-called "stakeholders" are targeted for dissemination and impact. "Stakeholders" include lay and professional organizations, business, industry and labor, legislative bodies, and the media, among others.

In its own summary of objectives (Renzulli, Reid, and Gubbins, undated), the Center is committed to designing and carrying out "theory-driven quantitative and qualitative research that is problem-based, practice-relevant, and consumer-oriented" (p. 3). It has thus dedicated itself to providing intellectual leadership that will hopefully ensure continued public attention to the needs of the gifted for years to come into the twenty-first-century.

It is much too early to assess the Center's realization of its lofty hopes. But it bears monitoring closely as a model that may deserve preservation and replication in Western countries because of its sheer scope, size, ambition, and organization, should it prove successful in the long run.

Final Thoughts About Present and Future Trends

Current prospects for recognizing the special needs of gifted children worldwide are still subject to the excellence-egalitarianism dilemma which Fetterman (1988) regards as universal. At the conclusion of his international survey of enrichment offerings for the gifted, Brickman (1979) observes: "the dogma that democracy is at the opposite pole from meritocracy based on individual talent, skill, aptitude, ambition, and ability is at least open to serious difference of opinion . . . A democratic society can pursue an egalitarian policy if it provides the fullest possible education for each person without regard to background and status, social, economic, political, religious, racial, sexual, physical, and mental. Under such a policy, all individuals will receive their democratic due, including those who are gifted and talented" (p. 329).

Indeed, there are some signs that Brickman's optimism may be justified. The membership in the World Council on Gifted Children consists mainly of professionals and lay advocates from democratic nations, and its biennial meetings have drawn large numbers of participants from these and other countries. Similar lively participation is shown at conferences sponsored by national and local associations on behalf of the gifted in the United States. Educationally, European democracies have tended to maintain their traditional school structures which differentiates education for university-bound students. These countries have also exposed at least some of their precocious children to various kinds of enrichment experiences in and out of school. Some of this activity is especially noteworthy, as more and more Western and Western oriented democracies are making highly promising contributions to the field. For example, Heller's six-year longitudinal study of the gifted in Germany is designed to clarify

identification criteria that may be used in all special programs; Israel's Ministry of Education is sponsoring many adventurous enrichment experiences for the gifted at the elementary and secondary levels, and the newly established Israel Academy for the Sciences and Arts has initiated an extraordinarily imaginative program for the gifted that is attracting worldwide interest; the SMPY program for the mathematically gifted is spreading throughout the United States and beyond; and the enrichment curricula designed by a permanent committee of expert educators in Singapore has been operating with notable success in recent years. (The emergence of national policies in a number of nations is discussed in Chapter 2.)

Yet, ambivalent feelings toward the gifted persist even to this day. Aside from fears of elitism in a democracy, there are suspicions that only a thin line separates genius, or even giftedness, from insanity. Some argue that in the interest of cosmic fair play, nature somehow balances off mental superiority with emotional or physical handicap. Others are suspicious of the creative as potential iconoclasts who make life uncomfortable; they find it easier to live with the familiar than to be prodded into the unknown by unconventional ideas, be they political, social, artistic, literary, or scientific. Still another, more recent, tradition is the belief that super-rational powers, which are so popularly associated with so many kinds of giftedness, are not all that critical in affecting the human condition, either because irrational impulses also figure greatly in individual accomplishment (according to Freud), or because no amount of effort by any one person, however brilliant he/she may be, can cause more than a ripple in the inexorable tides of history (according to Marx).

Opponents of differentiated education for the gifted surface time and again in professional journals and forums. They believe that talent is irrepressible in some children and impossible to nurture in others. Why, then, invest in special programs for the gifted? Sometimes the question is raised cynically by those opposed to any kinds of special programs, except for the handicapped. Many more objectors are skeptical rather than cynical about the need for providing "extras" to children who can allegedly excel without them. In the past, these periodic criticisms have placed advocacy for the gifted on the defensive despite anything anybody could say on its behalf.

The Changing Status of Gifted Achievement

Usually, an account of history of/and giftedness in Western society deals with outstanding individuals and their nurturance. There is rarely any doubt that gifted performance or production matters in the sense that it attracts critical admiration, even acclaim, temporarily or for all time. This seems to be changing. It is now necessary to take into account the prospects of noteworthy achievement *per se* by asking whether indeed it has a future.

Examples that come to mind include the classical

symphony orchestra and its repertoire as well as the literary novel that is written by an author and bound in the usual print form. Of the symphony orchestra, the Arts and Leisure section of the *New York Times* (January 31, 1988) offers the following speculation:

The date is January 31, 2038. At eight o'clock tonight, Carnegie Hall will be the scene of a special concert of rediscovered music—music that has not been played for three decades. There will, however, be no orchestra—not enough people play the violin, or the cello, or the oboe, anymore. All of the instruments will be played on a new computer, programmed for the occasion: the Bach 9000, which sounds more like an old-fashioned symphony orchestra than the real thing. For the last thirty years, Carnegie has specialized in Pop, Rock and Rage, the new fusion of New Age and Rock, but not tonight. The rediscovered works: Symphony #9 by Ludwig van Beethoven, Eine Kleine Nachtmusik by Wolfgang Amadeus Mozart, and Brandenburg Concerto #2 by Johann Sebastian Bach.

Such a scenario depicts a total break with the past rather than a creative accretion to it. Vivaldi and Schnittke do not survive in the company of their successors. Instead, the masterpieces of previous generations are banished to the archives, to be revived only on rare nostalgic occasions. Never before have artists and their art been declared obsolete, irrelevant, and unwelcome with such finality, as projected so seriously in the *New York Times* feature essay.

Should these speculations come true, they will constitute a major threat to the very concept of excellence as it is now known and accepted. No matter what differences exist in the way people define and evaluate giftedness, creativity, and genius, all agree that a high quality of human productivity or performance is a *sine qua non*. Some individuals who are celebrated for their work, even for many years, may eventually fall into disrepute. But at least the legacies of some *do* survive to maintain society's cultural treasures. By nullifying *all* of them at once, or even in time, raises doubts as to whether quality *per se* can survive as an essential ingredient of excellence. Surely *some* artists and their artistry contain enough brilliance to ensure their immortality. If they don't endure, then the criterion of quality has been replaced by something else. By what? Is it possible that mediocrity will some day be extolled for no other reason than its being new and different? How will music be critiqued, if not by its aesthetic value, however that is judged? Could Western society be entering an era when the beauty of musical statements counts for nothing, and all that matters is the arousal of people's deep impulses by *any* pounding, persistent beat with accompanying sound, however pedestrian it may be, even if it is programmed for "performance" electronically rather than *interpreted* by an instrumental artist? If so, giftedness in music will take on a radically new meaning, if indeed it retains any real meaning at all.

With respect to the future of literature, the novelist, Robert Coover (*New York Times*, June 21, 1992) states:

In the real world nowadays, that is to say, in the world of video transmissions, cellular phones, fax machines, computer networks, and in particular, out in the humming digitalized precinct of avant-garde computer hackers, cyber punks and hyperspace freaks, you will often hear it said that the print medium is a doomed and outdated technology, a mere curiosity of bygone days destined soon to be consigned forever to those dusty unattended museums we now call libraries. Indeed, the very proliferation of books and other print-based media, so prevalent in this forest-harvesting, paper-wasting age, is held to be a sign of its feverish moribundity, the last futile gasp of a once vital form before it finally passes away forever, dead as God.

Coover observes that the novel "is perceived by its would-be executioners as the virulent carrier of the patriarchal, colonial, canonical, proprietary, hierarchical and authoritarian values of a past that is no longer with us". In the novel, as it is traditionally constructed, the author is alleged to wield dictatorial power, not only over plot and character, but also over the format through which they are presented: on lines to be read from left to right (right to left in some languages), in sentences, paragraphs, pages, and chapters. Freedom from this kind of literary tyranny is supposed to come from the so-called "hypertext", in which the linear-sequential structure is eliminated with the help of computer programming. Unlike print text, hypertext liberates readers from control by the novelist and, instead, allows them to become partners in the creative enterprise by involving them in the process of mapping and remapping textual content, "not all of which is provided by what used to be called the author" (in Coover's words).

As the novelist is relieved of the burden of unilateral creation, he/she is no longer the shaper of a complete narration, but instead becomes a collaborative arranger of text, together with erstwhile consumers of text. This is done by providing readers only with sketches of fictional events in no particular sequence and allowing them to fill in details independently in any way they choose to form webs of connection among the sketches. In other words, talent in writing novels becomes democratized, as everybody enjoys the right to participate in the process of producing plot and character on an equal footing with the gifted novelist. By thus being stripped of the task of composing stories in full detail from beginning to end *alone*, creatives in this domain lose their distinction and even their visibility as potential contributors to quality literature.

The mere speculation about such changes raises questions concerning gifted children with promising careers on the concert stage and superb young writers of narrative who may have the next great novel stored in their imaginations.

In another vein, consider Flynn's (1987) large-scale

study of intergenerational gains in IQ in countries where such data were available. He found that present-generation 20-year-olds in Holland score about twenty points higher in IQ than did their counterparts some 30 years earlier. Both groups were compared on the same test using the same norms. An increase of such dramatic magnitude means that, in his sample at least, the number of persons with IQs of 150 and above has increased proportionately by a factor of almost 60 from the previous to the following generation. Yet, the number of patents granted has actually diminished, with the 1980s showing only sixty to sixty-five percent of the yearly rate for the 1960s. This may mean that IQ is no longer as relevant to the world of invention as it once was, or more probably, as scientific knowledge accumulates and inventions become more and more sophisticated, the threshold IQ has to rise in order to qualify a child as a potential producer of scientific ideas.

The Flynn (1987) results may be symptomatic of a trend toward fewer and fewer people capable of mastering more and more sophisticated knowledge, much of it sheltered from more popular consumption by convoluted neologisms. University professors in the 1960s were attacked by student activists who felt their would-be mentors were, in-effect, "fiddling while Rome burned". The students felt that the professors were elitist snobs, so tunnel-visioned that their own theories allowed no room for alternatives. Such criticisms may have led to the Consciousness III declarations of exasperation and Reich's (1971) rejecting the concept of excellence and comparative merit.

The Reich suggestion that everybody is brilliant implies that brilliance has no distinctive meaning. It democratizes abilities and thus leads to the conviction that all products of the mind are created equal, free of criticism or comparative evaluation. This stance is entirely compatible with that of Paul de Man, the Belgian scholar who was instrumental in spreading the theory of deconstructionism in the liberal and fine arts. Supporters of the theory regard it as a reexamination of the humanist legacy, but opponents see it as an attack against the traditional canon.

According to deconstructionism, language in literature, art, and music, never means what it appears to mean. It discards the evaluational aspects of these creative products by declaring them neither good nor bad. Also discarded are attempts to analyze the ideas of writers, artists, and composers. What counts instead is the emotion that literature, art, and music generates in the reader, viewer, and listener, regardless of whether these feelings are embedded in the creative products *per se* or in any way intended by the creators of these products.

The reactions to masterpieces are so personal and so differentiated according to who is reacting that the objects of these responses need not be masterpieces at all; anybody's work can qualify as a stimulator, which makes anybody as important a creator as everybody else. Sometimes the responses embody deeply felt political or

social convictions, or even sexual meanings (McClary, 1987).

Aside from the philosophical consideration of deconstructionism, if the excellence of a creative product counts for nothing because there is no concern for standards or criticism or appreciation, what is the meaning of precocity and its cultivation? How can educators differentiate curriculums for the gifted when there are no human differences acknowledged in a society where *all* children are considered gifted, or not gifted? Can there be patronage of the arts which have no intrinsic value except as objects of highly personal projections? In other words, is the world of ideas witnessing the end of history of the gifted?

Similar questions may be raised in relation to a growing distortion of multicultural education. Traditionally, multiculturalism has advocated the incorporation of great ideas of all cultures and subcultures in the curriculum. It has also fostered the appreciation of the different histories, languages, life-styles, and values of foreigners as a means of combatting xenophobia and racism. However, these highly constructive and much needed additions to school curricula are occasionally ignored in favor of a radically different version of multiculturalism, exemplified in the Stanford University students' chant, "hey, hey, hey—ho, ho, ho, Western Civilization's got to go". "Western Civilization", in this case, refers to the required course of reading great Western literature written by authors caricatured as dead white European males (DWEMs). Some of these great works, which have been treasured for centuries in Western society, had to be discarded from the requirements list and replaced by works selected primarily on the basis of their representing minority subcultures and achieving more of a balance of representativeness among the races and sexes.

Again, excellence is democratized by removing quality as the sole criterion for judging it and substituting in its stead an adherence to subcultural representation for its own sake. The gifted can continue making history and being part of history only if their products and performances are judged strictly by their worthiness, not as commonplace instruments for flushing out other people's emotions or *only* because they emanate from a minority group that seeks and deserves its place in the sun. It remains to be seen how long the element of quality in giftedness, talent, precocity, and genius will remain under attack in the years to come. The stakes are higher than ever in the world of the gifted, and indeed in the world at large.

National/State Policies Regarding Education of the Gifted

A. HARRY PASSOW

Teachers College, Columbia University, New York, U.S.A.

Introduction

The history of education of the gifted and talented has been a cyclical one with periods during which interest and programs have waxed and waned. Gifted education advocates have long asserted that one factor affecting program development has been the presence or absence of a policy, whether such policy be clearly stated or only implied.

A policy is a plan which provides guidelines for action. A national or state policy, for example, can mandate that giftedness be recognized, fostered and nurtured or it can actually limit or even prevent the development of programs for the gifted. A fundamental canon of a policy in support of gifted education is that there are children who, because they have manifested potential for outstanding achievement in a socially valuable area, require differentiated educational experiences adequate and appropriate to their special needs. What actually is considered "adequate and appropriate" may well differ from nation to nation or state to state, depending on the society and the educational system.

Because policy in the United States is expressed and imbedded in various federal and state legislation, regulations or rules, the U.S.A. provides good examples of the nature and impact of policy on the education of the gifted. Developments in the U.S.A. are first examined in detail as a case study of policy formation, followed by the experiences in a number of other nations.

The Nature and Impact of Federal and State Policy in the U.S.A.

The U.S. federal (national) government's educational role is limited by a constitution which leaves education as a function to be performed by the individual states. Each of the 50 states organizes, operates and supports its own schools, setting policy which is then implemented at the local level. It is state-level policy which drives and guides local education policy and program. Although local control of education has been the bedrock on which the common school and universal education have rested, the federal government exerts influence on both state and local policies, much of it indirectly since its

financial support is quite limited. While its share of funding ranges only between 5–7 percent of the nation's total educational expenditures, the actual federal impact and direction are much greater.

The federal government's significant involvement in educational policy direction and leadership began with the Soviet Union's launching of Sputnik in 1957. The perceived threat to America's national security triggered, among other activities, a resurgence of interest in gifted education. A year later, the National Defense Education Act of 1958 (NDEA) was passed, aimed at upgrading science, mathematics and foreign languages through curriculum revision and staff development. NDEA proved to be watershed legislation in that, for the first time, federal policy asserted a commitment to funding needed to enrich curricula and support staff development for teachers who would deliver the new curricula. While not specifically aimed at the gifted, many NDEA projects gave special attention to the needs of the "academically talented students" and gifted students profited from this federal policy which aimed at improving the quality of instruction and teacher education in order "to meet the challenge of the Soviet Union". Together with related agency efforts, such as those of the National Science Foundation, federal programs stimulated support and activity from states as well as philanthropic foundations. These efforts gradually dwindled as national priorities shifted and attention was diverted to other educational and political crises and issues. It was not until the 1970s that attention focused once again on the gifted.

While programs for the gifted were established long before the NDEA federally-supported activities—some programs trace their beginnings to the turn of the century—it has been federal policy and legislation which has stimulated most of recent and current state and local endeavors. Since the majority of state legislation and guidelines were developed after the publication of the *Marland Report* in 1971 and the enactment of the Education for All Handicapped Children Act of 1975 (Public Law 94-142), it is arguable that those two events were significant for subsequent developments in gifted education.

Although P.L. 94-142 was aimed at providing appropriate special education to "handicapped children", nine

states include the gifted as “another exceptionality”. The State of Alaska, for example, requires each local district to establish and implement written procedures for identifying all children ages 3–21 who require special education and related services, including those who are gifted. Pennsylvania’s standards for Special Education Services and Programs include the “mentally gifted”. P.L. 94-142 requires the preparation of an Individualized Education Plan (IEP) for each identified child. Thus, a federal law setting policy regarding handicapped children has resulted in a number of states complying with the legislation by including the gifted as one area of exceptionality.

Federal/National Policy Influence

The so-called *Marland Report* had considerable significance for gifted education. One of the Education Amendments of 1969 directed the U.S. Commissioner of Education, then Sidney P. Marland Jr, to undertake a study with four basic policy objectives:

- (1) Determine the extent to which special educational assistance programs are necessary or useful to meet the needs of gifted and talented children.
- (2) Show which federal education assistance programs are being used to meet the needs of gifted and talented children.
- (3) Evaluate how existing Federal educational assistance programs can be more effectively used to meet these needs.
- (4) Recommend new programs, if any, needed to meet these needs (Marland, 1971, p. viii).

The findings of the study, Marland reported, provided ample evidence of the need for action by the U.S. Office of Education to eliminate the widespread neglect of gifted and talented children. Federal leadership in this effort is required to confirm and maintain provisions for the gifted and talented as a national priority, and to encourage the States to include this priority in their own planning (p. xii).

Marland declared a need for federal efforts on behalf of the gifted, urged that immediate steps be taken and offered eleven recommendations, ten of which were to be taken under existing federal legislation.

The law required the Commissioner to define gifted and talented for the purposes of federal education programs and the *Marland Report* definition soon was labeled the “U.S. Office of Education definition” and became the guide for many state and local education agencies. It was as follows:

Gifted and talented children are those identified by professionally qualified persons who by virtue of outstanding abilities, are capable of high performance. These are children who require differentiated educational programs and/or services beyond those normally provided by the regular school program

in order to realize their contribution to self and society.

Children capable of high performance include those with demonstrated achievement and/or potential ability in any of the following areas, singly or in combination:

- (1) general intellectual ability
- (2) specific academic aptitude
- (3) creative or productive thinking
- (4) leadership ability
- (5) visual and performing arts
- (6) psychomotor ability.

It can be assumed that utilization of these criteria for identification of the gifted and talented will encompass a minimum of 3 to 5 percent of the school population (Marland, p. ix).

Beyond the broadened definition, use of the phrase “gifted and talented” and the assertion that these children and youth had special needs which required differentiated educational experiences, the *Marland Report* began the formulation of a national strategy for identifying and educating this special population. An Office of the Gifted and Talented (OGT) in the U.S. Office of Education was established which, although it lacked any programmatic influence, could stimulate activity through what could be called “persuasive advocacy”. The OGT undertook a needs assessment and a survey of what was happening around the country. It began a state level leadership training in order to:

(a) shore up already existing support among those in the field who had long been committed to gifted child education, (b) reach key educators, opinion shapers, and legislators, and to begin to develop the potential parent constituency, and (c) provide concrete skills in planning and program building at the state level.

In August 1972, some five months after the *Marland Report* was issued, the National/State Leadership Training Institute for the Gifted and Talented (LTI) was formed, funded primarily with a grant from the Education Professions Development Act. The LTI directed its efforts to translating the ideas of the *Marland Report* and the Office of the Gifted and Talented into planning and program development at the state and local district levels. The LTI focus was on effecting policy changes at state and local levels using three strategies: “(a) developing awareness of the educational needs of gifted and talented children; (b) training educational leaders in appropriate pedagogical strategies for these children; and, most importantly, (c) planning for the educational needs of gifted and talented children at state and local levels” (Jackson, 1979, p. 55). Between 1973 and 1975, three national and nine regional conferences with a total of 48 state teams received training in the development of long-range state plans for educating the gifted and talented. The LTI also developed a national network of individuals and agencies concerned with educating

the gifted and a publications program designed to assist advocates of gifted education with policy-making and instructional planning.

In 1975, for the first time ever, categorical funding for the gifted and talented was made available under the provisions of a section of Public Law 93-380. While the \$2.56 million which was appropriated was not very much, it was perceived at the time as "a beginning". Having an approved state plan in place was one of the requirements for grant applicants. More than half of the funds (\$1.5 million) were allocated to 26 state agencies for professional staff development. Another \$0.52 million went to local projects and model programs in selected categories and \$190,000 for graduate training for leadership personnel. To the regret of many educators, nothing was appropriated for research, research training or dissemination of findings from studies. In sum, the scarce funds were used for essentially "priming the pump", i.e., to both stimulate interest and activity on the part of the state and local education agency and to respond to their growing concern for the gifted and talented.

Through much of the 1980s, the federal role in gifted education declined significantly until the passage of the Javits Gifted and Talented Students Education Act of 1989. Once again the U.S. Department of Education had funding available to support programs for the gifted and talented and subsequently made more than 50 grants. By focusing the requests for proposals on projects aimed at identifying and nurturing the gifted among traditionally underrepresented groups (i.e., racial and ethnic minorities and poor children), the federal government influenced policy at the state and local levels. In addition, the Department of Education provided funds for a National Research Center on Gifted and Talented.

State Policies

Prior to the publication of the *Marland Report* in 1971, only two states had mandated programs for the gifted and three states had enacted discretionary or permissive programs. By 1990, all 50 states had policies on educating the gifted and talented in place. With the exception of the State of New Hampshire, all had state legislation (laws or regulations) which mandated services or which supported discretionary/permissive programs for the gifted and talented (Lukenbill, 1991).

While New Hampshire was alone in having neither mandatory nor discretionary legislation, it did have an Office of Gifted Education in the state education department, the creation of which was itself an expression of a positive policy regarding the gifted. New Hampshire's Office of Gifted's 128-page planning guide was meant to be a practical resource to aid schools in planning and implementing programming for the gifted and not "a mandate or a prescriptive set of policy requirements". New Hampshire's policy does not "mandate specific

actions, decisions, or models; impose on any school a specific set of methods or materials; require the use of specific identification instruments or procedures; limit or constrain the services which can be offered or the students for whom such services are provided by individual schools" (New Hampshire State Department of Education, 1989, p. 1). However, a clear message is sent encouraging "schools to conceptualize and define programming constructively" and the major areas in which decisions must be made are identified.

By enacting legislation, promulgating regulations, formulating rules or simply providing guidelines, however, every state has made a positive statement regarding education of gifted and talented students. In different ways and to different degrees of specificity and conviction, every state now acknowledges that there are gifted and talented pupils, though there is no single definition nor description of such students. In different ways, every state recognizes that nurturing talent potential is essential for self-fulfillment as well as societal benefit. Every state acknowledges that gifted pupils can and should be identified and that they require differentiated educational experiences and opportunities. Every state seems to grant, though not all provide for them, that extra or additional resources are needed in order to provide programs for the gifted. The policies of many states include attention to program options, teachers and program evaluation. There is no single model shaping the policies, regulations, rules and guidelines for gifted and talented education in the 50 states.

There are considerable variations in the extent and ways in which local school districts—the units which actually deliver educational services—implement state policies and translate them into instructional programs. Even within a state, there is often considerable diversity in the actual implementation of a state's rules and regulations, depending on the nature and extent of state control. A significant determinant of the implementation of a state policy which either mandates a gifted program or supports a discretionary one is the nature of the relationships between the state education agency (SEA) and the local education agency (LEA)—i.e., the kind of accountability, curricular and instruction direction, supervision or monitoring, funding, etc. that the state requires from or provides for its local districts in general. Because of these different relationships between SEAs and LEAs, it is not possible to state which policy—one that mandates or only permits programs for the gifted, one that is more or less specific, one that has clearer or less clear standards or one that provides more or less detailed directives, rules or requirements—actually results in gifted programs which are "better", more stable and have greater continuity.

A key element of policy is whether programs or provisions for the gifted are mandated or discretionary. Mandated services are required services, carry with them some variation of a *must* directive for local districts and usually include some provisions for accountability. However, the nature of the mandates vary

widely from simple, direct statements to quite detailed ones.

The State of Wisconsin, for example, requires each local school district to "provide access to an appropriate program for pupils identified as gifted and talented". The Georgia State Board of Education directs "the development and operation of programs of gifted education for pupils who have high intellectual abilities and the potential for exceptional academic achievement in grades K-12 in the public schools of this state".

In 1963, the first state to mandate that local districts provide for the gifted was Pennsylvania. Its 1986 guidelines set forth program requirements as follows:

All gifted school-age exceptional persons in Pennsylvania must be provided with a free public education that is appropriate and individualized. The individualized instruction may be provided as a special education approved program or as an approved differentiated basic education program. A combination of both options provides the greatest opportunity for flexible programming to meet the needs of the gifted.

Regardless of program option all programs for the gifted must provide for procedural safeguards including but not limited to: Screening and assessment, MDT, IEP, NORA, Biennial evaluation, Annual IEP review, Parent participation, Continuous access to due process, Confidentiality of records.

The student must be provided instruction at an appropriate level of challenge and with adjustments that accommodate individual needs in both program options.

The program must be described in the special education plan of the school district and intermediate unit and approved by their respective boards even if only differentiated basic education alternatives are used to meet the needs of school-age gifted persons. This plan must be reviewed and revised at least once each year. Programs shall be developed in accordance with planned courses (curricula) to provide a continuum of programs and services appropriate for the student's age and development (Pennsylvania Department of Education, 1986, p.12).

The policies of a number of states include either a recommendation or a requirement that local districts prepare a written plan for identifying and educating gifted and talented children with some specifying the specific components of such a plan. The State of California's policy regarding a written plan is as follows:

The district shall develop a written plan for the district program which shall be available for public inspection. The written plan shall describe the appropriately differentiated curricula for identified gifted and talented pupils as well as specify the methods used to examine the appropriateness of the identified pupil's total education experience including articulation with other specially funded programs

which serve gifted and talented pupils. The plan shall include:

(1) The purposes of the program, including the general goals and specific objectives which pupils are expected to achieve;

(2) The rationale for the district's method of identification of gifted and talented pupils;

(3) Where appropriate, procedure for the consideration of the identification and placement of a pupil who was identified as gifted or talented in the district from which the pupil transferred;

(4) The services to be rendered and the activities to be included for pupils participating in special day classes, receiving special services, or participating in special activities for an amount of time specified in Education Code Section 52206.

(5) Plan for evaluating the various components of the program. Evaluation shall include an annual review of pupil progress and of the administration of the program;

(6) Procedures for modifying the district gifted and talented program on the basis of the annual review;

(7) A staff development plan based upon a needs assessment which includes specification of requisite competencies of teachers and supervisory personnel;

(8) Procedures for ensuring continuous parent participation in recommending policy for planning, evaluating, and implementing the district program;

(9) A procedure to inform parents of a pupil's participation or nonparticipation in the gifted and talented program;

(10) An objective related budget (California State Board of Education, 1989, pp. 13-14).

The legislation or regulations of a number of states include statements which express a philosophy about the nature of gifted children and their education and provide a rationale for the policy for such programs. For example, the State of Kentucky voices its "Philosophy of Gifted Education" as follows:

All students shall be provided with an educational program which allows them to develop to their maximum potential. Gifted students possess superior abilities and/or capabilities and, therefore, are a unique segment of Kentucky's school population. In order to realize their potential, they need educational opportunities that differ from those available through the regular school program.

Gifted students exist at all levels of society regardless of sex, race, socio-economic, or ethnic origin. They must be identified through their outstanding intellectual capabilities, academic aptitudes, and/or creative abilities. An articulated K-12 program shall be provided with educational experience commensurate with their abilities. Such a program shall be conducted in an environment which will make it possible for these students to interact with others of high ability. The program shall afford students the opportunities to reach the highest level of learning

and accomplishment of which they are capable at each stage of their development (Kentucky Department of Education, 1988, p. 1).

The State of Wyoming's philosophy is phrased as follows:

All children and youth in Wyoming need opportunities to develop their individual talents, and the gifted and talented are no exception. The complex nature of giftedness may manifest itself through the interplay of many different intellectual abilities as well as through a variety of creative expression and non-academic talents. Giftedness implies that each child is distinctly different from children in general and from other gifted children, yet their unique abilities and interests are found in every culture, ethnic and socioeconomic group (Wyoming State Board of Education, 1981, p. xi).

The *Marland Report* definition of giftedness (see "Office of Education" definition above) used in federal policy and legislation influenced those adopted by states as well. The Lukenbill (1991) survey found that:

General intellectual ability was reported by 46 states to be the **most common area of giftedness identified** by their state's definition. Forty-four states report *specific academic aptitude*, followed by *creative thinking ability* (37 states), *advanced ability in the fine/creative arts* (32 states) and *leadership ability* (26 states). *Psychomotor ability*, *psychosocial* and *vocational aptitude* were included in the definitions of 5 or fewer states.

The State of Virginia was unique in including *practical arts ability*: "students who excel consistently in the development of a product or performance in any area of vocational education to the extent that they need and can benefit from specifically planned educational services differentiated from those generally provided by the general program experience" (Virginia Department of Education, 1984, p. 3).

In their policy statements, a number of states either used the Office of Education definition directly, paraphrased it or modified it to include only some of the original six areas. (*Psychomotor ability* was subsequently eliminated in federal legislation and usage.) Nevertheless, while the traditional areas of general intellectual ability and specific academic ability dominate state definitions, other elements of the *Marland* definition—creativity, fine and creative arts, and leadership ability—are included in more than half the policy statements.

Many policy statements are quite specific in detailing the procedures and, in some cases, the instruments which local districts may use in identifying gifted and talented students as defined by state legislation or regulation. The State of Arkansas's standards, for instance, require the "use of at least two objective and two subjective measures (one of which must assess creativity), chosen from" the list provided (Arkansas Department of Education, 1986, p. 13).

A number of state policies stress or specify procedures and instruments for identifying gifted youngsters who are "economically, culturally and/or environmentally" disadvantaged. More than half the states recommend or require the use of multiple criteria in identifying gifted students. Most include individual or group intelligence tests and achievement tests. Several states require or suggest that the identification process be conducted in two or three stages, such as screening, identification and placement.

Some states have established standards regarding the identification process to which local districts must adhere. The State of Colorado, for example, recommends that LEAs incorporate the following very comprehensive standards into their program plan, relating the identification to the instructional programming:

Referral and Assessment: It is recommended that students be referred for assessment by a variety of methods, such as parent nominations, teacher nominations, self nominations, peer nominations, scores on group tests of intelligence, product evaluations. Comprehensive and multiple criteria including tests of intellectual ability, achievement tests, teacher checklists, parent checklists, creative performance, grade, and product evaluations should be used for identification purposes. It is recommended that no student be denied the opportunity for needed programming on the basis of any one assessment criterion. It is recommended that specific plans be developed to ensure the identification of subpopulations of gifted and talented: minorities, girls, underachievers, highly gifted, and learning disabled and/or handicapped. Logical connections must be demonstrated between any diagnostic test administered, the areas of perceived educational need and programming delivered. Student learning plans based on assessed needs may be developed (Colorado Department of Education, 1989, p. 4).

"Program for the Gifted" has many different meanings in state policies. In some instances, "program" encompasses everything that has to do with the gifted including identification, instruction, organization, funding, etc. In others, the term is limited to the instructional aspects, the arrangement of teaching and learning conditions.

States vary with respect to the program elements required or suggested, although there is consensus that programs should be developed locally according to the needs of the population of a particular school community. The states differ in the components they choose to deal with—some stressing program parts such as rationale, goals, objectives, teaching methods and evaluation plans while others choose to highlight such aspects as grouping structure or early admission provisions. The various state policies include a variety of program recommendations such as part- or full-time classes, magnet schools, cluster grouping, resource rooms, special classes, Advanced Placement Program,

International Baccalaureate, independent study, summer and out-of-school classes, counseling or guidance programs.

The State of Oklahoma, for example, requires that: "School districts shall provide differentiated education for all identified gifted students. This differentiated education will include multiple program operation which shall be carefully matched with students' needs and interests" (Oklahoma State Board of Education, 1990, p. 1). Some states provide detailed criteria which must be applied by the local districts to their programs for the gifted while the policies of other states include sets of general standards that apply to all types of gifted and talented programs. Georgia urges schools to use a combination of the three delivery models—Self-contained Classroom, Resource and Facilitator—presented in its state regulations.

In those states where provisions for the gifted are tied to Public Law 94-142, Individual Education Plans (IEPs) are required. Some state departments require that detailed program plans be approved while others have few requirements.

Although most state policies refer to, advocate or even mandate "differentiated curriculum" or "appropriate curriculum", there is generally little specificity as to what is intended or required. Many states do not even mention the term "curriculum". Some policy statements specifically relate curriculum for the gifted to the regular curriculum. The State of Georgia specifies student competencies in its requirements:

Gifted curricula shall incorporate the 76 student competencies and State Board of Education approved curriculum, resource guides and courses. The Skills Areas Basic to Gifted Education shall be incorporated at each grade grouping in one or more of the following content areas: language arts, mathematics, foreign language, social studies and science. These skills shall not be presented as independent curricula.

The Skills Areas Basic to Gifted Education include—Area I: Cognitive Skills; Area II: Learning Skills; Area III: Research and Reference Skills; and Area IV: Communication Skills (Georgia Department of Education, 1988, p. 2).

The State of Arizona requires local school districts to develop a modified curriculum scope and sequence that will ensure that gifted students engage in learning experiences commensurate with their special abilities and potential. Each LEA is required to report annually on how special education for the gifted differs from regular education in areas such as: "(a) Content, including broad based interdisciplinary curriculum; (b) Process, including higher level thinking skills; (c) Product, including variety and complexity; and (d) Learning environment, including flexibility" (Arizona Department of Education, 1991, p. 2).

Some states encourage or even require accelerated instructional programs, while others simply permit acceleration.

The State of Kansas, for example, permits students "to test out of, or work at an individual rate, and receive credit for required or prerequisite courses, or both, at all grade levels if so specified in that child's individualized education program" (Kansas State Board of Education, 1990, p. 4). Kansas students may also receive credit for college-level study whether done at a college or high school—providing the student is responsible for college tuition costs.

Particularly in states in which the gifted are considered part of special education (P.L. 94-142), it is generally recognized that such students require guidance, psychological and other support services. For example, Wisconsin's statutes state that: "Many gifted children are at risk and need attention, counsel and support to help them realize their potential" (Wisconsin Department of Public Instruction, 1990, p. t-2). However, in a few states, the gifted and talented are specifically omitted from psychological and other support services mandated for special education students.

A number of states require involvement of such specialists in the identification process only, calling for the professional judgment of teacher specialists, counselors, psychologists or other "qualified professionals". A few states suggest that support services be given to particular populations such as underachieving gifted students. Others indicate that gifted and talented students have special needs, particularly in the affective areas of social and emotional development, requiring special counseling or psychological services. The State of Utah requires that districts "provide guidance to assist [gifted] students in addressing personal and interpersonal needs, in program selection, and in career and college choices" (Utah State Office of Education, 1988, p. 2).

Most state policies regarding the gifted require, recommend or suggest that parents be involved in their gifted child's education. Arkansas's standards require that parents grant permission for individual testing, be informed of program placement criteria, give written permission for their child's participation in the program and appeal a placement with which they disagree.

Colorado's standards for program development call for parental involvement in a variety of aspects:

It is recommended that parents be encouraged to take an active role in the education of their gifted and talented children, and that efforts be made to provide educational programs for these parents to orient them to the district's program and to help them address the needs of their own children. It is recommended that involvement of parents be documented at the local and state levels, and that parents be encouraged to participate on advisory and steering committees at the state, district and local school levels. It is also recommended that they be encouraged to join local and/or district parent groups supporting gifted education (Colorado Department of Education, 1989, p. 6).

Although state legislation and regulation have a good deal to say about the role and importance of

teachers in the identification and education of gifted students, relatively few have special certification or endorsement requirements. Many refer to the need for staff development and urge that it be provided but are often vague about the nature of such inservice education. Lukenbill (1991) reported that 14 states had special teacher certification requirements which "is accomplished primarily with graduate hours, in-service hours or levels of competency" (p. 33). In fact, program funding for the gifted/talented programs is linked to special teacher certification in 17 states (p. 33).

A few states list what are perceived as desirable competencies and characteristics of teachers for the gifted for LEAs to consider in selecting staff for such programs. Most state policies require that teachers have, at a minimum, valid teaching certificates for the grade levels or subject areas included in the gifted program.

Utah's mission statement sets forth both preservice and inservice goals in the form of nine standards and requires LEAs to promote statewide networking of approved endorsement programs through institutions of higher education. Several states spell out in considerable detail the requirements for certification as a teacher of the gifted, usually in terms of a minimum number of semester hours of study at a college or university.

While not requiring that teachers be certified in gifted education, LEAs in Texas must provide a prescribed number of days of staff development for teachers who have not previously received training in the area of gifted education and, beginning in 1991, teachers must have been trained prior to their assignment to the program for the gifted (Texas Education Agency, 1990, p. 26).

Evaluation plays an important part in many state policy statements—sometimes required, more often only recommended or suggested. In a number of states, no mention at all is made of evaluation. Where written district plans are recommended or required, program evaluation is usually a component of such plans. Program evaluation is often a part of the SEA's monitoring process, especially when the gifted program is linked to other special education programs. Evaluation requirements or recommendations may focus on either individual student assessment or program appraisal and states may provide specifics regarding the process, detailing what is assessed and how the assessment should be done.

Several states discuss evaluation as an integral part of an LEA's decision-making process, examining the appropriate use of both formative (continuing) and summative (final) evaluation. New Hampshire's guidelines discuss the reasons why evaluation of gifted programs is an important but difficult process—e.g., the complexity of outcomes, the delayed impact or benefits of gifted programming, the intricacies of isolating the impact of gifted program components from the rest of the school program and the diverse criteria needed to assess the effectiveness of a variety of program services.

The State of Kansas requires that every three years students in approved gifted programs undergo a comprehensive reevaluation by a multidisciplinary

team of professionals using multiple sources of data in order to decide whether to continue or discontinue services. Detailed suggestions are provided regarding sources of data, techniques and procedures for product evaluation, use of test data and "additional testing information indicated by specific needs including self-image, learning styles, career/vocational aspirations, creativity, cognitive or academic achievement, and other [specific needs] as identified by the reevaluation team".

The State of Florida provides a planning guide specifically aimed at helping extend educational opportunities to culturally diverse learners and minorities in gifted programs. The guide calls for an evaluation design which addresses specific questions regarding increased participation by students from these groups:

Possible activities include evaluating how effective the implementation of each component—screening and referral; criteria for eligibility student evaluation; instructional program philosophy; curriculum modifications or adaptations, and support services; and evaluation design—was in achieving the goal of increased participation of under-represented groups and ensuring their success and continued participation in the existing instructional programs (Florida Department of Education, 1992, p. 15).

Approximately 40 states distribute funds to local school districts or intermediate agencies employing a variety of funding formulae. In Fiscal Year 1990, total state funding for gifted programs ranged from as little as \$100,000 in Montana to \$87,989,649 in Florida, the latter serving 61,458 gifted/talented students (Lukenbill, 1991, pp. 24–25). States used a variety of bases for determining distribution of funds, including foundation units, weighted per pupil units, and fixed per pupil amounts. Depending on the state, local districts might be reimbursed for costs involved in identification, staff salaries and benefits, instructional materials, transportation and evaluation. Some states require approved written plans before considering funding. A few states link evaluation to funding.

Funding in the federal government and many state governments is a two-stage process: the legislative body first agrees to an amount of money and then actually allots or provides the funds. It is possible to take the first action but not the second—i.e., not to provide any money or a lesser amount. Thus legislation for the gifted does not guarantee appropriation of funds. The financing of programs for the gifted has been and remains precarious.

The Impact of Policies in the USA

What is different about education of the gifted during the past two decades since the publication of the *Marland*

Report is that states have enacted legislation, formulated rules and promulgated regulations which express policies favorable to providing for the gifted and talented. In a sense, gifted education has finally been legitimized and institutionalized.

All 50 states now have policies on educating the gifted and talented in place. These policies are quite diverse—some stronger, more comprehensive, more supportive, more directive than others. Even those policies which provide the strongest mandates provide leeway for local school districts in the design and implementation of programs.

The fact that all of the states have legitimized gifted education, sometimes through mandate and sometimes through discretionary support; that most states have established offices or bureaus for gifted education in their state departments, sometimes with full-time and sometimes with part-time directors or coordinators; that many states provide funding at various levels for various elements of gifted education; that many state departments produce or disseminate curriculum and other instructional materials for the gifted; that many states now require evaluation of programs for the gifted, sometimes as a requisite for funding—are all indications that education of the gifted and talented is, in some ways, on a firmer footing than it has ever been. The enactment and implementation in 1988 of the Javits Grant Program for the Gifted and Talented symbolized a new leadership from the federal government in educating gifted and talented. The focusing of most of the grants on the traditionally underrepresented minorities and poor demonstrates how federal policy influences state and local practice.

However, despite these positive consequences of policy on behalf of the gifted, such education does not take place in a vacuum or in isolation from other policies. A decade of intense activities aimed at school reform and restructuring, continuing controversy concerning issues of excellence and equity in an increasingly diverse society, greater understanding of individual differences and diversity, intensification of efforts to create national goals and standards and a variety of other problems and programs have resulted in policies or issues which have a direct affect on policies dealing specifically with the gifted and talented. When in 1991, federal, state and local districts throughout the nation experienced severe financial crises, funding for the gifted suffered once again. A number of states legislated funding or continued existing funding legislation but either failed to appropriate the monies or allocated a much smaller amount than was called for. Funding for state coordinators and offices for the gifted was reduced and even eliminated. In many districts, local funding for programs for the gifted was also reduced or eliminated.

In a sense, through various policy formulations, gifted education in the United States has won numerous battles but still has yet to win the war.

The Nature and Impact of Policy in Some Other Nations

It is not possible to survey policies in the many other countries which provide for the gifted in some way. Instead, a small sampling of how national, state or provincial policies have impacted on gifted education in a few other nations follows. Because each national education system has its own structure, sets of relationships and own contexts, the discussion which follows is necessarily somewhat limited.

Policies on education of the gifted in other nations are often not expressed in the same way as in the United States. Federal and state policies in the United States are communicated in the legislation, regulations, rules and guidelines of governmental agencies. Policies of the local school districts (LEAs) are usually expressed in the programs that are developed and implemented. This is, in part, a function of governmental structure. Different governmental structures—such as a centralized versus decentralized national educational systems—affect the ways policies are formulated and implemented. Different relationships between the national or state and local schools with respect to control, funding, accountability, etc. affect the nature of policies. Different social, cultural, political and economic contexts affect policy statements.

Thus, stated or implied policies of nations may range from outright hostility to an ignoring of the issue (“benign neglect”) to permissive or discretionary backing to strong positive support, including financial.

Cohen (1990) has observed that: “Public policy decisions and issues concerning services to the gifted rest on the values and attitudes of certain groups of people in particular time periods. Some ongoing issues include equity or excellence, perception of the gifted by others, cost effectiveness, funding, where gifted is housed, and accessibility” (p. 254). Similarly, Cropley (1989) notes:

Some political groupings, especially in Western European/North American societies, stigmatize special educational provisions as a device for maintaining the privileged position of certain groups, or for justifying and even increasing educational inequality, since the unusually able are assumed to be preprogrammed for success; in Europe this view is common in the Federal Republic of Germany, France and Italy, where there is nonetheless a certain degree of provision for the gifted, and in the Scandinavian countries, where there is little (p. 377).

Sweden and other Scandinavian countries provide a good example of how the socio-political context affects gifted education. Cohen (1990) attributes the few provisions for the gifted in Scandinavia to the fact that “the egalitarian ethic is dominant and special provisions for the gifted are viewed as a means of maintaining the privileged positions of certain groups” (p. 254). Edfelt (1992) traces the absence of any special educational programs for the gifted in Sweden to the work of

a 1968 governmental committee chaired by a leading theorist of the Swedish social democratic party, Dr Alva Myrdal. He points out that in "Sweden it is considered undemocratic not only to be mentally gifted, but also to be gifted and demand special treatment because of this fact" (p. 47). Whether or not Edfelt's characterization is totally accurate, clearly programs for the gifted are limited in Sweden and its Scandinavian neighbors.

In a number of European countries, particular secondary schools—e.g., the English grammar school, the French *lycee* and the German *gymnasium*—have long been viewed as providing an appropriate education for academically able students and constitute governmental policy regarding that population.

United Kingdom

On the basis of a year-long study some three decades ago, Passow (1961) found that the term "gifted" was rarely used in England. At the time, the grammar schools for which youngsters were chosen through the "Eleven-plus" selection process and the three years of highly specialized study from age 16 on in the Sixth Form were seen as the ways in which England provided for its most intelligent, academic-achieving students. At the time, comprehensive secondary schools were coming into being, particularly in LEAs where the Labor Party governed.

By the 1980s, changes in the tripartite secondary school system, including the selection processes, brought significant changes regarding the education of the gifted or highly able. In the early 1980s, for example, 30 LEAs participated in a Department of Education and Science (DES) sponsored Schools Council Gifted Pupils Project, a project which created a cooperative network and produced curriculum and instructional materials. Noting that the English were beginning to talk about the top 10% as including the "able child" (rather than the "gifted child"), project coordinator Callow observed:

There is far more support both philosophically and politically for provision through a move towards a process based curriculum and teacher effectiveness than by specific programmes of extraction or acceleration. While both main political parties claim to support help for the gifted/able child they differ widely in their approach. Conservatives see the answer to the problem in the provision of assisted places at Private Schools while the left wing socialists would be against any form of recognition or help for the able. At least one very promising programme was shut down due to a political wrangle (Passow, 1985, p. 40).

A 1982 National Association for Gifted Children (1982) survey found that, of the 59 LEAs that responded to the questionnaire, 54 supported the principle of enabling teachers to acquire skills and understandings

needed to work with gifted, 35 had established working parties on educating gifted and 20 had published guidelines on their provisions for able children. Several LEAs had appointed program coordinators.

Freeman (1992) points out that currently 35 of the 108 Local Education Authorities have at least one person responsible for the highly able and that for more than a decade "bright children can receive enrichment in many subjects; mostly offered out of school, in weekend and summer courses, either provided free by the Authority or privately at about 12 centres across the country" (p. 60). Nevertheless, Freeman reports that "there is no specific overall educational policy for the gifted in Britain where teachers prefer keeping able children in the regular classroom and are wary of any form of 'elitism', whether of wealth or ability, and are unhappy about categorizing children into ability groups" (p. 67). She observes that teachers prefer low-cost provisions such as acceleration or pullout enrichment programs because they worry that gifted programs will take scarce resources away from other children.

Clearly, the most significant governmental policy change in British education in recent years was the passage and implementation of the 1988 Education Reform Act, incorporating for the first time a National Curriculum. The National Curriculum requires that every child study the core subjects of mathematics, English, science, history, geography, music, art and physical education, as well as foreign languages at the secondary level. Each subject has ten defined levels of attainment which teachers are to assess. Freeman (1982) describes the issue the policy of a National Curriculum poses for the gifted child as follows:

In theory, the needs of the individual are given the highest priority, each child working through the level from its own starting point, at its own pace, and to the extent that it is able. This ought to be a truly differentiated approach, but it may restrict the ablest. For example, because the assessment of attainment is defined by a national age average at 7, 11, 14 and 16, it may concentrate teaching those prescribed standards, as though they were the limit of what might be expected at those ages. As a result, teachers may not realise that the attainments of some children could be well beyond them (p. 59).

Interest in the gifted had been growing steadily, Freeman noted, subsequent to issuance of the 1989 Annual Report of Her Majesty's Inspectors of Schools which had asserted that, in most schools, able students were simply not being sufficiently challenged. The following April, the Department of Education and Science convened more than 100 senior U.K. educators to examine ways of adapting the National Curriculum for the highly able. There is now, Freeman points out, a policy of official acknowledgment of a need for enrichment opportunities for both fast and slow learners. Ways of implementing the policies and meeting the issues posed by a National Curriculum are being seriously explored.

Germany

Policies regarding the gifted in Germany are promulgated on two levels—the federal and the *lander/states*. Educational policies are complicated by the need to integrate the “two Germanies” which had operated drastically different school systems.

At the opening session of the Sixth World Conference on Gifted and Talented Children in Hamburg in 1985, Minister of Education and Science Dorothee Wilms (1986) expressed the view that “the Federal Republic of Germany cannot shun the responsibility to give talented children more recognition and increased support” and considered “it an urgent educational task to make up the scientific leeway in this field and, after prolonged neglect of gifted education, to create an educational climate which enables an unemotional discussion to be conducted in this country too” (p. 17). The forum of the World Conference was viewed as providing a platform for discussion of the issues and as a stimulus to policy and program development in Germany.

Blanke (1992) has pointed out in planning support for the gifted, the national government has several basic premises: “participation is voluntary; development of academic and social abilities; early identification and support; constant counseling; inclusion of the parents; no exclusivity; variety of measures and sponsors; opportunity for private initiatives” (p. 14). The federal government now provides support for competitions, school academies and other extracurricular areas; vocational training in institutions for the promotion of talent; university scholarships for graduate study; and research. This policy has led to the federal government’s initiating research on early identification, differentiation and expansion of program support and inclusion of groups of gifted who have been underrepresented to date.

According to Knauss (1992), the ministers and senators of culture for the various German *lander/states* have declared their “agreement that it is the task of the schools to provide each student [including the gifted] with appropriate education according to their abilities” (p. 76). The various states employ three basic models for educating especially gifted students: (a) Enrichment Programs, (b) Acceleration Programs, and (c) “creation of special classes or schools with special performance demands and educational concepts” (p. 77). Together with the Federal Republic, the Standing Conference of Ministers and Senators has declared support for a number of country-wide competitions aimed at locating and nurturing special talents in specific areas of giftedness.

Since the school year 1984–5, the policy of the state of Baden-Wurttemberg has been to nurture giftedness through more than 500 work groups which focus on especially challenging and interesting topics and which operate outside regular classes and are independent of the school curriculum. These work groups are supplemented by state competitions as well as seminars. In four locations, Baden-Wurttemberg has also recently been

experimenting with gymnasia with an eight-year course in which especially motivated and talented students can save a year of schooling, graduating in eight years with a college preparatory degree without experiencing any loss of quality in their education.

On the other hand, Bavaria operates four parallel school types as well as differentiations within these types—e.g., there are gymnasia that focus on ancient languages, modern languages, music, business and social science. In addition, in order to nurture special talents, the state supports vacation seminars for especially talented and interested 11th and 12th graders; optional “plus-courses” which are not linked to specific grade levels and which help prepare students for competitions; the practice of grade-skipping of one year through school or vacation seminars; and the provision of scholarships for all-round highly gifted gymnasium graduates. Similarly, the policy of the state of Saxony has been to support special schools for the nurturing of mathematically, scientifically and musically talented students. After 1989, these schools were changed to *gymnasien*, each with a special profile. In addition, the state supports competitions which are particularly relevant for talent searches, including mathematics and science olympiades (Berenbruch, 1992).

Thus, in Germany the recent policy of the federal government is to support gifted education but implementation of that policy is limited to the policies of the states because of the federal structure of education. The Standing Conference of the Ministers of Culture of the States, a group consisting of ministers and senators from all of the states or *lander*, has taken a stand in support of gifted education as well. However, since, as in the United States, each of the German states/*lander* operates its own schools, there is diversity in their operating policies.

South Africa

In 1988, the Work Committee on the Education for Highly Gifted Pupils submitted its 442-page report titled *Education for Gifted Pupils* (1988) to its parent-group, the Human Sciences Research Council (HSRC), expressing the belief that its recommendations would make a valuable contribution toward developing gifted education in the R.S.A. Provisions for the gifted in the Republic of South Africa have been complicated by the separate and unequal school systems operated under *apartheid* and by the relationship of the provincial governments to the national government. The Work Committee’s study focused largely on the education of white students.

A 1964 National Advisory Education Council had recommended that primary school gifted students should be grouped homogeneously and “be educated accordingly”; that if there were too few gifted students, they be provided with individualized instruction in an

intra-class group; that acceleration and enrichment be introduced to make it possible for gifted students to progress at their own tempo; and that the curriculum content be revised to pose a challenge to gifted pupils. At the secondary level, the Council recommended the following fields of study—technical, commercial, agricultural, natural science and art—be offered at different specific secondary schools including general secondary, technical, agricultural, commercial and art (ballet, art and music).

A 1981 study by the HSRC Committee found that the implementation of the 1964 recommendations had been minimal: the Cape Education Department had organized a decentralized form of enrichment and pull-out within the ordinary school systems; the Transvaal Education Department had established extracurricular centers for the highly gifted; and the Natal Education Department gave special attention to identification and provided special education programs.

The HSRC Work Committee surveyed programs and practices in the R.S.A., reviewed a body of research literature from abroad and sought to lay down guidelines regarding all aspects of the gifted: definition, identification, educational programs, educational facilities, underachievers, school guidance, attitude development, curriculum development, handicapped and teacher training. The committee concluded: "If the educational authorities take note of these guidelines in the planning of education for gifted pupils, these pupils should come into their own in the educational system" (HSRC, 1988, p. 321). Political developments focusing on elimination of *apartheid* and other problems created by the separate school systems have seriously impacted on the implementation of the guidelines proposed by this quasi-governmental research and policy group. Each of the provincial governments continues to implement policies already in place and the policy recommendations of the Human Science Research Council are, for the most part, held in abeyance. The Cape Province has declared the aim of education to be that of offering each pupil opportunities to develop his/her potential and asserted it to be "the responsibility of the school and the community to create opportunities in academic, sport and cultural fields for developing and nurturing the potential and proven giftedness of their children" (Cape Education Department, no date, p. 1).

Australia

Like the U.S.A. and Germany, schools in Australia are operated by states and territories with some policy direction from the Commonwealth national government. Writing about gifted education in Australia some three decades ago, Radford (1961) observed that there was little concern expressed about what constitutes the "best education" for the gifted in that nation

because "most of the courses in secondary schools have in the past been written with the needs of the more able part of the student population in mind" (p. 227). Nor did Radford find "much evidence of informed concern about giftedness in the fields of art, music, literature, sculpture, drama or creative dance" (p. 227). Radford noted that a few special programs could be found such as "Opportunity C Classes" in New South Wales, "Scholarship Classes" in Victoria and "Terman Classes" in Western Australia and that some schools practiced streaming and acceleration. Radford was convinced that the increasing interest of the community for more secondary and tertiary education might lead to making "money available to encourage able persons to teach and to use educated gifts when they are available" so that hopefully "the gifted child will receive his due—not in a separate class or institution or with a totally different approach, but through developing his individual gifts within the framework of present organization" (p. 235).

In a comprehensive study, Braggett (1985) has traced the series of events between 1940 and 1975 that had reshaped and reformed education in Australia to widen its scope and "to cope with all levels of interest, ability and talent and to promote the social purposes of an egalitarian society" (p. 298). He observed that in the early 1970s: "Provision for gifted and talented children was not a popular cause to espouse in a nation that decried special attention to academic precocity and equated giftedness with privilege" (p. 1). In 1972 and 1975, the Federal Labor Government had attacked what it viewed as social injustices, had funded projects aimed at assisting the disadvantaged and had designed programs to equalize education for all. The prevailing attitude of the federal government—reflected forcefully in its policies—was "to assist disadvantaged children within an egalitarian framework, and gifted children were not acknowledged to be needy or handicapped. Any realignment of policy in favor of gifted children might be denigrated as elitist" (p. 1). When, in 1974, a survey was conducted to determine the attitude, as reflected in policy, of each of the states toward gifted education, it was clear that few long-term plans existed leading the authors to conclude that "children of high intellectual potential were not seen as a group worthy of any special consideration by teachers or education departments" (Braggett, 1985, p. 2).

At a 1976 meeting of all the Australian Director-Generals of Education, reports from each of the eight states and territories together with a paper from the Commonwealth Schools Commission were reviewed. In general, the states reported no official policies on the education of the gifted and few programs. The Commonwealth Department of Education's paper welcomed placing the topic of giftedness on the agenda, regarding it for a variety of reasons as "an important one worthy of special attention at this time" (Braggett,

1985, p. 2). The papers detailing the policies of each of the states and territories showed diversity but, for the most part, lack of support for gifted education. For example, Victoria noted that suggestions that something be done for the gifted inevitably triggered accusations of elitism and intellectual snobbery and, although there was no official policy on education of gifted children nor any official programs, "teachers were becoming increasingly aware that giftedness might be disguised behind underachievement, lack of motivation, and behaviour problems, and some were seeking advice on methods of catering for such youngsters" (p. 3). The Australian Capital Territory reported no specific system programs nor any attempts to identify gifted children and noted that since the 1960s, there had been a move away from ability grouping toward "deliberately homogeneous groupings with an emphasis on individual development and progression" (p. 3). Tasmania reported very few classes for the gifted and the occasional use of enrichment and recognition of individual differences. The reports of the other states and territories added to "striking evidence of the low priority afforded the education of gifted children in Australia in the mid-1970s" (p. 5). Braggett observed that the Labor Party's policy and the Schools Commission's direction during its early years had contributed to a trend against gifted education.

Prof. Miriam L. Goldberg of Teachers College, Columbia University, visited Australia in 1978, inspected a number of schools and institutions in five of the states and prepared a report—the first on gifted and talented children in Australia—in which she examined "Australian ambivalent attitudes to egalitarianism and excellence and explored the issues of definition/assessment, the criteria for judging appropriateness of special programs, various organizational alternatives, and the problems of staffing pertinent program initiatives" (Braggett, 1985, p. 305). At the invitation of the Schools Commission, Goldberg returned in 1980 to review and critique developments since 1978. This time she visited all states and territories. Her report was subsequently published by the Schools Commission and apparently influenced their deliberations (Goldberg, 1981).

In the 1980s, a shift in attitudes toward the gifted began to occur. The Australian Schools Commission issued a discussion paper titled *The education of gifted students* (1980). The Commission reviewed a number of issues which had framed the debate within Australia and which had contributed to the general ambivalence towards the education of gifted students. These dealt with a wide range of issues including definition, identification, appropriate means of delivering education, curriculum, staffing, teacher education, administrative arrangements and evaluation procedures. The report ended with the suggestion that Australia needed to openly address three important questions with policy implications:

—Can the provision of special educational services for the gifted be seen as consistent with the goal of schooling being socially comprehensive?

—Can extra provision for gifted students be regarded as equitable in terms of equality of opportunity and the encouragement of all children to achieve their potential?

—Are students with special talents really held back by the way their schooling is provided? (Australian Schools Commission, 1980, p. 40).

The Schools Commission recognized that these are not easy questions and expressed its interest in working with other agencies and education authorities "in activities which will provide a leading edge to thought and practice in the area" (p. 40). Braggett maintains that the Schools Commission:

has proved a vital factor in the development of policies and projects designed to enhance the cause of gifted education within Australia. It has fully supported moves to broaden the concept of giftedness, to cater for an increasing percentage of the student population, and to foster a diversity of gifts and talents. Ideally it would prefer this to be accomplished within existing organizational frameworks and with a recognition of "a wide range of special abilities and talents not simply defined in cognitive terms" (p. 306).

A First National Conference on the Education of Gifted and Talented Children took place at the University of Melbourne in August 1983. The group planning the conference envisaged an Advisory Committee, but this failed to materialize when three of the major Victorian teacher unions and both state parent organizations declined to participate. Nevertheless, the conference was successful and well-attended. A 516-page conference proceedings consisted of the plenary session addresses and the texts of 82 presentations.

By the time the Second National Conference took place in 1985, an Australian Association for the Education of Gifted and Talented and state groups had been formed. The conference theme was "Gifted and Talented Children—A National Concern". In the opening address, the Queensland Minister of Education, I. J. Matheson (1986), described that state's policy asserting that: "Provisions for gifted children must always be viewed within the context of the principal aim of education in State schools in Queensland . . . The schools are then committed to individualizing and differentiating their offerings to accommodate all children, including the gifted" (p. 1).

Between 1978 and 1985, with the exception of Victoria, all states and territories had issued policy statements on educating gifted and talented children. These varied in "emphasis and thrust and in the practical support they afford . . . some have concentrated on intellectual giftedness, some have sought to accommodate the six categories of the Marland Report, others have been

heavily influenced by Renzulli's Model, while others have developed an eclectic quality" (Braggett, 1986, p. 15). While the State of Victoria had issued no policy statement, a group of educators and the Victorian Catholic Education Commission had issued their own statements supporting gifted education.

Braggett (1986) observes that: "In one sense many of these new documents are not true policy statements at all: some are *philosophical* statements which stop short of policy ramifications and refrain from committing resources" (p. 15). He argues that the statements must be "judged within the context that some educational leaders are not in favor of providing additional system-support for such students. In such a climate, the mere existence of a policy is an important achievement" (p. 16). Braggett also notes that gifted education is a politically sensitive issue and that some policy statements are promulgated strictly for political reasons.

The success of the Eighth World Conference on Gifted and Talented Children, held in Sydney in July 1989, opened by the Governor-General of the Commonwealth of Australia and well-attended by participants from all over the country, indicated that, while there was still considerable unevenness among the state policies and provisions, education of the gifted had made great strides over the past two decades. Clearly the policies of the national and state governments had changed in support of gifted education.

Israel

A relatively small nation with a centralized school system, Israel provides an example of policy development through efforts of its Ministry of Education and Culture. With a few exceptions—mainly orthodox independent schools—the Ministry has central responsibility for all primary and secondary schools. The socialist ideology of the government from the establishment of the State of Israel in 1948 "until 1977 stressed social equality and disapproved of the establishment of special programs for the gifted" (Burg, 1992, p. 217). The need for nation-building, for absorbing newcomers from dozens of countries who did not know Hebrew and for providing a basic education for a wide range of academic ability—all took high priority for policy makers and educational planners.

In the late 1960s, a group of university professors offered after-school enrichment classes, first for high school students and then to junior high and elementary pupils. Responding to this initiative and to a changing public opinion regarding able children, the Ministry of Education appointed a study commission in 1970–71 to recommend policies regarding the education of gifted children. The study commission made two major recommendations: (1) that the Ministry of Education create a Department of Gifted Education to initiate new directions and programs and to coordinate activities on behalf of the gifted nationally, and (2) that financial

and logistical support be given to universities to aid them with programs already in operation.

The Ministry's Department for Gifted Children was created in 1973. Considering program possibilities, the Department rejected special schools for socio-political reasons and opted instead for expanding the after-school enrichment centers. By 1981, more than 5,000 students—an estimated 30–40% of the potentially gifted population—was being served by the centers which were funded on a shared-cost basis by parents' tuition, the Ministry of Education and the local sponsoring agency. The centers focus on mathematics and science with computer-based and laboratory experiences plus offerings in art, music, literature, history, philosophy creative writing and journalism. The Department also established experimental pullout classes in Jerusalem and Tel-Aviv to develop special curricula.

The renaming of the department as the Department for Gifted Children and Science Oriented Youth indicated a policy shift on the part of the Ministry to give special attention, in addition to the gifted, to those students who were gifted in science and mathematics. Currently, the Department is responsible:

for all matters relating to gifted pupils, supervising the implementation and operation of all associated programs including the pedagogical, organizational and budgetary aspects. The staff maintains contact with the principals of schools in which programs for the gifted are offered. Regular visits are made to these schools and meetings with pupils and parents. The department staff also coordinates enrichment programs with local educational authorities, professionals and colleges and universities in Israel and abroad. The Department's policy is to develop the gifted pupils' individual ability for themselves as well as their contribution to the society in which they live (Burg, 1992, p. 218).

The Ministry of Education funds identification of the gifted nationwide, administering the same test to all pupils. Those who score at the top then take an additional group test and the top 1–3% (IQs of 140+) are then chosen for the program. Currently, more than 20,000 students are in programs for the gifted—one day per week enrichment pullout classes and afternoon enrichment classes in 25 cities and towns. There are acceleration programs but these are not generally encouraged by the Department. In cooperation with the Committee for the Advancement of Science Education and the Department for Gifted Children, institutions of higher education offer courses in science and mathematics.

In 1990, a three-year residential high school (grades 10–12) for youths gifted and talented in science, mathematics or the arts was established with private funding. Tuition is charged on a sliding scale, depending on family income. The Ministry of Education provides the same level of funding for the Israel Academy for Arts and Science as for other secondary schools. The first year,

124 students from some 68 Israeli communities were admitted. The IASA is considered an experimental school in terms of designing curricula and providing instruction which other schools can adapt.

In the rural northern part of the country, the Department supports a program at a regional college for gifted students from a number of communities who come in one day a week for enrichment opportunities.

As Burg (1992) has pointed out, "the education of the gifted has undergone many changes during its eighteen years of its existence. During that period improvements in programs and provisions were introduced. No doubt additional changes will continue to take place in the future" (p. 221). Throughout, it has been the national Ministry of Education and Culture's policies which have guided and controlled the direction of Israel's programs for the gifted and talented.

Some Asian Nations

The policy of Asian countries varies from government-promulgated policies in support of gifted education to the absence of policy for egalitarian reasons. Roldan (1992) surveyed the status of gifted education in eight Asian nations and reported that the governments of Indonesia, Singapore, Taiwan and the Philippines had "enshrined in law [the belief] that the gifted/talented must be allowed to develop and fully maximize their potentials and that these students have the right to an education that is appropriate for their special abilities and talents" (p. 2). This commitment is embodied in Indonesia's State Policy of 1988, Singapore's 1984 Gifted Education Project, Taiwan's Special Education Law of 1984 and the Philippines' 1987 Constitution. Although Korea has no law, in 1988 official approval was given to the Council of Education Development and Innovation to design such programs.

Because of its egalitarian perceptions of education, the government of Hong Kong has no official policy regarding gifted education. There are some isolated enrichment programs and the Extended Learning Committee of the independent Hong Kong International School has designed some enrichment programs. Extra-curricular science programs as well as summer camps have been set up.

In Japan, major reform programs initiated first by the Allied Occupation Forces after World War II and then by the Japanese government in 1955 established a hierarchical secondary school system. The result has been that gifted education has been under a virtual ban insofar as formal government programs are concerned. Special classes for the gifted are non-existent; special provisions, such as acceleration, are very rare. Such special programs would be perceived as contrary to the prevailing egalitarian philosophy. It has been reported that teachers prefer "hard working" children to gifted children. After-school clubs and classes do exist and these provide enrichment opportunities for all

students who choose to participate, including those who are gifted. The *juko* classes, independent after-school tutoring classes, prepare youngsters for the competitive admissions tests for the highly regarded and extremely selective secondary schools.

Because gifted education occurs within the context of a nation's total schooling effort, a governmental commitment does not necessarily mean that programs will be developed and implemented. For example, Indonesia's Seven-year Plan for Educational Services for the Gifted and Talented in both urban and rural areas was formulated in 1982. The plan was to give special attention to development of programs in science and technology in 1982-86, followed by programs in the humanities and social sciences in 1985-89. Despite Indonesia's official policy that a citizen who is gifted or talented has a right to receive an appropriate education, in practice, special education for the gifted does not enjoy a high priority because of the lack of budget resources for education in general.

Singapore

The Singapore Ministry of Education began implementing its Gifted Education Project in 1984. Anticipating public objection and criticism, the Ministry prepared a background paper for the Singapore Schools Council which presented a rationale, philosophy and need for gifted education. The program began with 100 primary and 100 secondary pupils in eight classes of 25 pupils each. The existing curriculum was used but teaching methods were to differ. Since then, the program has expanded to include four elementary and three secondary schools. The program focuses on the intellectually gifted although the Music Elective and Art Elective Programs aim at catering to the musically and artistically gifted children.

The Singapore Ministry of Education's Gifted Education Unit has designed a curriculum which, while anchored in the regular curriculum, provides for extensive breadth and depth and emphasizes higher level thinking skills while preparing youngsters for "O" and "A" Level examinations. In 1988, the Ministry's Science Enrichment Program included a science camp at the National University of Singapore, a Mentorship Attachment which links scientists to students working on research projects and a Research Congress at which the project findings are shared.

Taiwan (Republic of China)

At the Republic of China's Fourth National Education Conference in 1962, a plan was adopted to provide gifted education in Taiwan (Wu, 1992). The government's attention to the gifted and talented is part of its overall effort to extend educational opportunities to

all children. When compulsory education was extended from six to nine years in 1968, the legislation stipulated that special provisions would be made for both gifted and handicapped children. In Taiwan, the term "gifted" is used to encompass the academically able and "talented" includes children with potential in the fine arts, music, dance or athletics. The 1984 Special Education Law stipulates that programs be provided for the gifted and talented in all these areas.

As Wu has pointed out, the long-term goals of gifted education in Taiwan include "the establishment of programs for academically talented students in all areas of the country in order to meet the national need for well-educated leaders" and, in addition, a "broad program of talent development is envisioned by both the nation's communities and leaders to foster the growth of Chinese culture and a general view of Western culture" (Wu, 1992, p. 280).

Over the past 30 years, there has been a rapid increase in special classes and resource classrooms together with an increase in the number of special class teachers trained for those classes. Self-contained classes and resource room classes both emphasize enrichment. A variety of acceleration procedures—"early entrance, grade-skipping, early graduation, telescoping of grades, exemption from entrance examinations, etc." (Wu, 1992, pp. 279-280)—are also employed.

Acknowledging that "any innovative program needs the encouragement and material support of the government and people to become successful", the Taiwan Ministry of Education employs a variety of strategies including curriculum design, teacher training, resources and research" (Wu, 1992, p. 280).

The Philippines

A commitment to gifted education was written into the 1987 Constitution of the Philippines, ten years after the then-President Marcos in his proclamation opening the Decade of the Filipino Child (1977-87) stated that:

there should be a program of identification for the specially gifted and a program for the development of their special gifts within the formal and non-formal systems of education. Children from the lower income classes or depressed areas should be provided the proper environment with enough challenge and stimulus for the development of their talents (Sutaria, 1983, p. 1).

One of the first important steps in gifted education occurred much earlier when the Philippine Science High School was opened in 1964, following passage of a bill in Congress recognizing the importance of identifying and nurturing the academically talented. There are now several special high schools for science or the arts supported by the Philippines government.

The regional governments vary in the nature and

extent of services actually provided. For example, Metro Manila established Silahis Centers in a half-dozen elementary schools in various districts which provide various acceleration and enrichment opportunities for the gifted/talented. Most of the thirteen regions provide some special classes and special programs, including accelerated programs, mainly in schools in the larger population centers.

The fiscal and political situations in the Philippines have had a serious impact on the support of gifted education. The strongest support for gifted education comes from such non-governmental organizations as TAG Philippines (Talented and Gifted Philippines) and Gifted Philippines, Inc. (GPI).

Eastern European Nations

The political, economic, social and philosophic conditions which came with the break-up of the Soviet Union and the Eastern European Bloc have had a strong impact on gifted education. As Sekowski (1992) has put it: "The political system which has been governing Middle East Europe since the Second World War has not positively influenced the atmosphere around the research on giftedness or on the educational work with gifted persons" (p. 104). Driven by a particular notion of egalitarianism, Sekowski asserts, official doctrine was that the talent would emerge on its own and that special provisions were discordant with the prevailing socialist ideology.

Similarly, Dockal, Laznibatova, and Kovac (1992) observe that: "During the time of the 'socialist build-up' in Czechoslovakia it had not been possible to examine the topic of special talents in children, as school policy was focused on 'averaging out' the population" (p. 177). It was only during the Soviet-American competition for primacy in space in the 1960s that programs for the gifted were openly discussed and established.

Yet, in a 1978 study titled *Paths to excellence and the Soviet school*, Dunstan (1978) tried to dispel common misunderstandings regarding Soviet socialist ideology. His study focuses on high-ability children, shows why they came to receive special attention, examines how they are provided for, and discusses problems of differentiation and selection which many of these forms of provision entail (p. 11). Dunstan described curriculum differentiation in the secondary general school; special schools for the arts, sports and circus, foreign languages, mathematics and physics; mass schools with special profiles; differentiation within mass schools; extracurricular activities in academic subjects and various olympiads. All of these programs and provisions functioned, of course, only with the official sanction and support of the central government. Dunstan concluded that during the two decades of 1958-1976, Soviet secondary education became increasingly differentiated: "The need to compete successfully with the West and to sustain the onward march towards communism in an

epoch of unprecedented scientific and technological advance . . . lent urgency to the quest of identifying young talent and the search for more efficient ways of subsequently exploiting it" (Dunstan, 1978, p. 246). However, these thrusts and programs operated in the midst of ideological controversy.

Sekowski (1992) argues that the political and economic changes presently occurring in Middle East Europe make it difficult, if not impossible, to find common trends amongst the newly independent former Soviet nations. Education in these nations is undergoing significant reform and gifted education is part of this change process.

Brazil

Brazil is a federal republic in which the states are responsible for providing elementary and secondary education and the federal government cooperates technically and financially. In 1987, the Federal Education Council approved a work group report titled *The hour of the gifted: A Federal Education Council proposal* which recommended a broad definition of giftedness, the employment of comprehensive identification procedures, the design of alternative programs and provisions, incentives for universities to promote studies and undertake research on the gifted, and the participation of the family, school and business community in the provision of "opportunities and means to involve and integrate gifted children into the Brazilian society" (Brito da Silva, Genio, & Ancona-Lopez, 1988, p. 18).

The Ministry of Education published some basic directives regarding working with the gifted: (1) With the exception of identified geniuses, gifted children should attend regular classes and be provided with suitable enrichment; (2) In the regular classes, not only should attention be given to nurturing individual talents but also to "the harmonious development of [the gifted child's] personality"; and (3) Based on individual needs, the special treatment should include "a more enriched school curriculum and/or the possibility of accelerated studies . . . , or the two may be combined" (Brita da Silva et al., p. 19). With the adoption of the Federal Education Council proposal and the creation of a Ministry of Education Office of Special Education, it was hoped "that helping gifted children in Brazil [would] acquire new dimensions without neglecting the efforts necessary to universalize elementary education for all Brazilians" (Brito da Silva et al., p. 19).

Because of the federal structure of government, it was left to the states to establish their own strategies and standards although the Ministry of Education advanced some model programs and procedures for guidance. The states have responded to this challenge differently, depending on the general education problems each faces and the nature of the resources available. For example, the Federal District (Brasilia) established guidelines in its Education Plan which resulted in the initiation of

"some activities to identify and specific procedures to work with gifted or talented students" (Brito da Silva et al., p. 20).

Not subject to Ministry of Education or state directives or guidelines is an independent educational complex, the *Objetivo Educational Center*, with preschool, elementary, secondary and college level programs in 23 states, serving more than 150,000 students. Serving mainly students from middle- and upper-middle-class families, this organization has been concerned with gifted students since 1973 and has carried on research and development activities which have been shared with the public sector.

In Conclusion

Programmatic efforts to identify talent potential and nurture it to talented performance are affected by governmental policies. How these efforts are affected depends on a number of factors such as the structures and relationships between governmental levels and the provision of resources to schools. Whether such policies are clearly stated or only implied and whether they are of a directive or discretionary nature, they impact on all aspects of gifted education, promoting and facilitating or impeding or preventing programs.

In the United States, at the state level where responsibility for providing schooling rests, it is through legislation, rules and regulations that policy is expressed, directly or by implication. Rules, regulations or legislation constitute the state's "statement" that may mandate that local school districts create programs for the gifted or support discretionary efforts initiated at the local level, depending on the nature of the state-local education relationships—the kind of funding and accountability, curricular and instructional direction, supervision or monitoring, etc. that the state requires from or provides for its local districts for education and schooling in general. Because of these different relationships between SEAs and LEAs, there is no single model shaping the policies, regulations, rules and guidelines in the 50 states. Nor is there a consistent pattern as to which policy—one that mandates or only permits programs for the gifted, providing greater or lesser specificity, clearer or less clear standards, more or less detailed directives, rules or guidelines—results in gifted programs which are "better", more stable and have greater continuity.

There is a broad range of policies in the illustrative examples of policies in other countries—from strongly endorsing efforts on behalf of the gifted and talented to antagonism toward such endeavors. In the case of the latter, it is often the socio-political context and a particular concept of the egalitarian ethic which creates the hostility toward the gifted and talented. Education and schooling do not take place in a vacuum.

The passage of legislation or the formulation of regulations which express a government's policy occur as part of a complex social, economic, political, philosophical

and educational context. Increasingly, advocates of gifted education—whether they be educators, parents, politicians, community leaders or other interested parties—have come to understand the importance of policies which attempt to identify and provide appropriate experiences for individuals with potential for outstanding achievement in socially valuable areas.

PART II

Conceptions and Development of Giftedness and Talent

Structural Tendencies and Issues of Research on Giftedness and Talent

KURT A. HELLER

University of Munich, Germany

Introduction

During the last few decades a change has been taking place in the concepts of giftedness and talent as they are featured in research literature. Whereas until ten or fifteen years ago the field was dominated by one-dimensional giftedness concepts and corresponding IQ measurements, a large majority of more recent models are based on multidimensional or multifactorial psychometric concepts of intelligence—e.g., Gardner's (1985) theory of multiple intelligences—on approaches from information theory and cognitive psychology—e.g., Sternberg's (1985) triarchic intelligence model. Other models still include elements from socialization theories, e.g., Mönks' (Mönks et al., 1986) extended Renzulli model. Furthermore, I agree with Sternberg's demand that (1990, p. 96): "We need to think in terms not only of multiple components of giftedness, but (also) of multiple kinds of giftedness".

"Giftedness" is thus defined as the individual cognitive and motivational potential for—as well as social and cultural conditions of—achieving excellent performances in one or more area such as in mathematics, languages, or artistic areas with regard to difficult theoretical vs practical tasks (Heller, 1989, 1992). "Talent" can be defined as a domain-specific gift or ability, e.g., "scientific ability" as the competence for scientific expertise in the fields of psychology, medical sciences, or physics. However, the differentiation suggested by Gagné (1985) between "giftedness" and "talent" is infrequently maintained in the literature. In many languages—as in German—both concepts are used more or less synonymously. For this reason, no semantic differentiation was insisted upon in this handbook between "giftedness" and "talent". When this makes sense in individual cases, the differentiation is explicated in that context. This also holds true for related terms, such as intelligence, creativity, or (high) ability, that are not independent of the theoretical basis in which they are found.

In addition, the definition of giftedness etc. is dependent on the intended use, for example, on the type and tasks of school programs, the aims of enrichment vs

acceleration programs, on empirical investigation goals and theory-based hypotheses, etc. Moreover, the term "giftedness" or "talent" is influenced by social norms and considerations (Tannenbaum, 1983, 1991; see also Sternberg in this handbook, Chapter 11). Last but not least, the definition of giftedness will be determined by the choice of measurement instruments, i.e., by the operationalization of the experimental variables examined (cf. Feldhusen & Jarwan in this handbook, chapter 13).

A differentiation between descriptive and explanatory terms is also relevant when looking at research strategies. Whereas the *descriptive* term is linked to the psychometric paradigm, the *explanatory* term needs an experimental design in the cognitive science paradigm. For example, on the one hand the psychometric intelligence structure theories enrich the ability phenomenology substantially, on the other hand the cognitive psychological (experimental) studies make it possible to explain the mechanism of cognitive processes and their individual sources. This also corresponds to the various identification strategies: status vs process diagnosis (see Part III of this handbook). Both descriptive and explanatory terms are necessary for theoretically and practically efficient conceptualizations and measures.

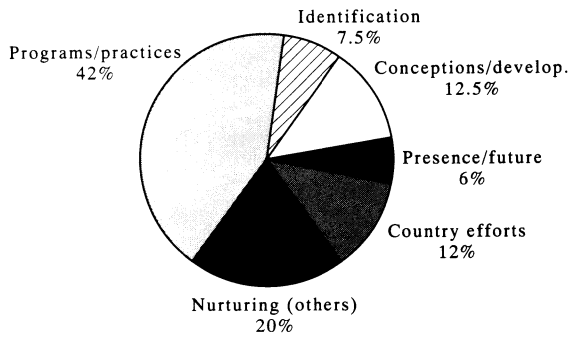

FIGURE 2. Percentages of the main topics of the WCGT conference proceedings (1975-1991) according to the structure of this international handbook.

FIGURE 3. Classification of the papers published in the WCGT conference proceedings (1975-1991) according to psychological subdisciplines.

International Trends and Topics of Recent Research on Giftedness and Talent

The state of the art of research on giftedness and talent to be presented here is based on content analyses of (a) the previously published nine volumes of proceedings from the World Council for Gifted and Talented Children (WCGT) and (b) four or six relevant field journals. For more details see Heller and Menacher (1992) and Heller (1993a). Supplementary to this, additional journal analyses and literature searches by Pyryt (1988), Rogers (1989) and Carter and Swanson (1990) are reported.

The conference articles from the WCGT since 1975 are shown in Fig. 1. The first of the biennial WCGT conferences was in 1975. The articles are classified according to seven main topics. It becomes apparent that the categories "Educational/Instructional Processes and Programming" with a median of 35% and "Personal Characteristics of G/T" with a median of 25% have the most entries, relatively speaking. These are followed by the categories "Development" and "Social Issues" with 12.5% each. An additional 7.5% of the published articles are concerned with "Identification" problems, 5% with "Learning and Perception" and only 2.5% with "Physical and Mental Conditions" (median of each calculated from the nine previously published conference proceedings). This picture does not change much if we redefine the categories somewhat. If one prefers to use the structural concept from this handbook, then we find the division as shown in Fig. 2. Once again, we find a clear dominance in the area "Education and Nurturing Problems" (see Fig. 2).

The following analysis results are very informative about the psychological subdisciplines which contributed to the WCGT conference proceedings: Approximately 70% of the contributions stem from Educational Psychology (including Education); 7% of the topics are Social Psychological Problems of giftedness. Develop-

mental Psychological contributions and Individual Differences are each represented in 5% of the contributions and an additional 5% are from related disciplines (e.g., Sociology or Psychiatry); cf. Fig. 3. Thus, there is an emphasis on applied topics in conference proceedings.

This impression is confirmed in the analysis results presented in Fig. 4. The 20% theoretical and only 5% basic research (mainly experimental) contributions can be contrasted with 20% databased (empirical) studies in the sense of applied research as well as 55% more or less related to gifted education in practice (cf. Fig. 4). The WCGT conferences mainly meet practical needs in gifted education. Real research contributions, i.e., those based on hypotheses, make up approximately one quarter of all conference papers. An even smaller percentage of theoretical papers can be added to this. But hardly a third of the contributions would meet the usual scientific standards. This estimation holds true when the category "Theoretical Papers" includes not only "Review and Survey" articles, but also "Opinion Papers".

FIGURE 4. Classification of the papers published in the WCGT conference proceedings (1975-1991) according to research vs practice reports.

TABLE 1
Age Groups and Sample Sizes in the Data Based
Contributions to the WCGT Conference Proceedings
(1975–1991)

Age groups	3%	preschool
	13%	primary education
	45%	elementary/secondary education (grades 4–8)
	23%	later secondary education (grades 9–12)
	3%	higher education
	13%	adulthood
Sample sizes	42%	$n =$ under 100
	42%	$n =$ 101–500
	10%	$n =$ 501–1000
	6%	$n =$ 1001 and more

When we analyze the databased studies which make up about 25% of all contributions in the WCGT conference proceedings according to methodological aspects, then we obtain the following information: The most frequently studied group are students from grades 4 to 8 or 12, with mainly small to mid-sized samples (Table 1). With 71%, the interview is clearly the preferred instrument of analysis. Cross-sectional designs were used in 67% of the studies, whereas longitudinal studies are found—as expected—in only 10%. This is probably due to the high demands on such studies (Table 2).

The type of research represented in the proceedings corresponds somewhat with the results from Pyryt (1988), Rogers (1989) and Carter and Swanson (1990), who undertook content analysis of relevant journals. Here, too, the more practically oriented applied research dominated, generally using more simple statistical analysis methods. There is an enormous need to “catch up” in the area of experimental research on giftedness.

This has already been emphasized by the information presented in Figs 3 and 4 above. One rapidly forms the assumption that the research represented by the WCGT conference proceedings is heavily influenced by educational psychologists, educational scientists, and teachers. These individuals are, of course, more interested in solving practical problems of gifted education, programming, and identifying, counseling and guidance problems than in the development of scientific methods for identification and program evaluation or even theoretical questions and developing models.

With regard to a theoretically based identification and nurturance practice as is repeatedly called for by experts (e.g., Gallagher, 1985; Shore, 1986), a greater representation at conferences by researchers from various disciplines is desirable and useful. Before I make a few recommendations about this, the most important journals in the field should be analyzed with regard to their content. According to most recent literature searches by Hany and Hany (1992, p. 237)—source: PsycLit 1986–1991; descriptor “gifted”—the following

journals have the most frequent contributions on giftedness (the total frequencies are in brackets): *Gifted Child Quarterly* (126), *Roeper Review* (119), *Journal for the Education of the Gifted* (88), *Gifted Education International* (22) as well as *Psychology in the Schools* (22) and *Journal of Counseling and Development* (21). In our content analysis, we therefore considered the first four journals supplemented by two others: *Exceptional Children* and the *Journal of Educational Psychology*. These two journals were selected as a “control group”, since they also publish articles about giftedness but do not specialize in this field and also contain articles on other topics. The most recent 10 or 12 volumes were used in the content analysis; we only had the *Roeper Review* volumes from the year 1987 to present available to us. In order to be able to compare the articles published in the journals with those in the conference volumes from the WCGT proceedings, we also used the categories seen in Figs 1 and 2. The most important results are summarized in Figs 5–8. Here the following questions were asked:

(1) Which topics are most frequently dealt with in the giftedness-related journals?

(2) Are there differences between the four journals that are giftedness related and the two journals in the control group?

(3) What types of articles appear in these journals?

(4) Furthermore, these findings are to be compared with the results from the WCGT conference proceedings analysis. The question which interests us the most, is whether the results to be found in the WCGT proceedings on the situation of research in the field of giftedness can be confirmed by this second content analysis of the most important journals in the field.

Independent of the category system used for analyzing the journals, the following picture is found (cf. Figs 5 and 6): The topics “Gifted Education” and “Programs and Nurturing” are most frequently represented in all four giftedness-related journals (between 30% and 60%). The topics “Characteristics of the G/T” are relatively more frequently dealt with in JEG (30%) and GCQ (28%). The corresponding values in RR are (21.5%) and GEI (19%). “Social Issues” is most frequently found in GCQ (13%); “Identification” makes

TABLE 2
Measurement Techniques and Research Designs of the Data
Based Contributions to the WCGT Conference Proceedings
(1975–1991)

Measurement techniques	71%	interview
	5%	observation
	19%	(quasi) experiment with intervention
	5%	(quasi) experiment without intervention
Research designs	23%	single-age group
	67%	cross-sectional
	10%	longitudinal

FIGURE 5. Percentages of the main topics in the four analyzed gifted field journals (1980–1991).

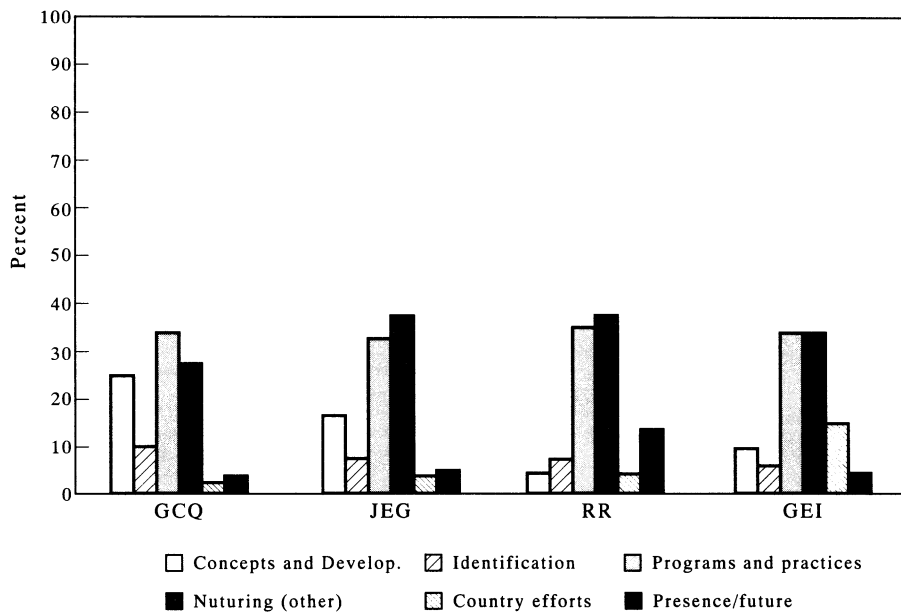

FIGURE 6. Percentages of the main topics in the four analyzed gifted field journals (1980–1991) according to the structure of this international handbook.

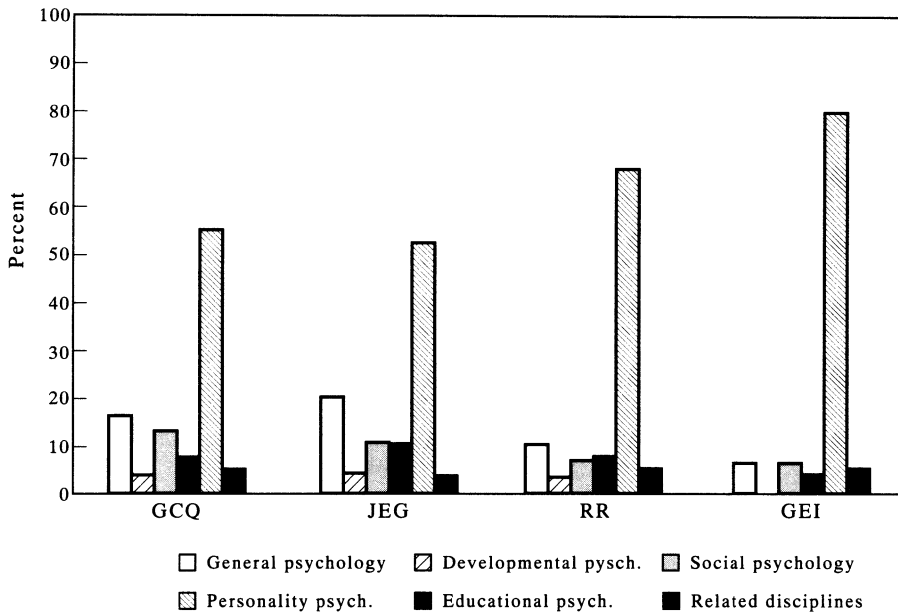

FIGURE 7. Classification of the articles published in the four analyzed gifted field journals (1980–1991) according to psychological subdisciplines.

FIGURE 8. Classification of the articles published in all (six) analyzed journals (1980–1991) according to research and practice.

up 7.5% each in GCQ and JEG. The percentages for "Learning and Perception" as well as "Development" are astonishingly low in all journals (Fig. 5). Solely, the broader category "Concepts and Development" obtained higher values in GCQ (27%) and JEG (16%); (Fig. 6). These results generally confirm the findings from Rogers (1989) and Carter and Swanson (1990).

If one compares the individual journal profiles, GCQ and JEG on the one hand, and RR and GEI on the other hand can be joined in more homogeneous subgroups. The obvious emphasis of both RR and GEI is the category "Gifted Education", followed at a clear distance by the topic "Characteristics of the G/T". The profiles of GCQ and JEG show a more balanced content structure. This picture is even clearer when we analyze the contributing psychological subdisciplines (cf. Fig. 7). Indirectly, one can conclude from this that the profile in GCQ and JEG (cf. Pyryt, 1988; Vockell & Conard, 1992) is more strongly research oriented and in GEI and RR more practically oriented.

The journals chosen as control group, EC and JEP in Table 3, have a more balanced content structure as compared with GCQ and JEG even when using the identical categorical system. It should be pointed out, however, that the relationship of giftedness-related articles to the total number of articles is negligibly small in the profiles of the control group journals (percentages in brackets). The number of contributions found by using the descriptor "gifted" in PsycLit 1986–1991 is 14 in JEP, 10 of which are all to be found in the year 1990 (special topics issue). Between 1986 and 1989, and in 1991, absolutely no relevant contributions were published (Hany & Hany, 1992, p. 237).

Thus we again see the need for special journals in the field of giftedness and talent. On the other hand, this specialization of publications makes *interdisciplinary* work more difficult. This is reflected in extremely low quotas of giftedness-related articles in the journal control group (see Table 3, percentages in brackets). In order to recognize the research percentages of the analyzed journals better, the following categorical system was used for evaluation:

- (a) theoretical papers,
- (b) contributions of basic research,
- (c) contributions of applied research,
- (d) papers concerning gifted education,
- (e) practical reports.

The information from Fig. 8 can be summarized as follows:

Reports of databased research are represented by about 40% in GCQ and JEG; the results from RR (27.5%) and GEI (10.5%) show definitely lower median values. This corresponds to a research proportion of approximately one-third of all articles which were published in one of the four journals in the field of giftedness during the last decade. This also corresponds relatively well to the content analysis of the literature on giftedness by Rogers (1989). Rogers considered 2680 citations

during the period from 1975 to 1986 (searches of the ERIC, ECER, PSYC, and Child Development Abstracts; descriptors "gifted" and "creative"). These were evaluated in 15 categories; the results are presented in Table 4.

Our agreement in the analysis of GCQ was even better with the findings of Pyryt (1988), where we found 39.5% of the articles of applied and 3.5% of the articles of basic research whereas Pyryt found 39.7% research articles—abstracted in the ERIC system over an eight-year period—for GCQ. The almost negligible percentage of *basic* research articles in all four analyzed gifted journals also agreed with the values found by Pyryt (1988) with JEG and GCQ (about 3%) achieving the highest values. According to this, multivariate statistical techniques or more complex designs are employed relatively infrequently.

Rogers (1989) as well as Carter and Swanson (1990) came to very similar conclusions; see Tables 5 and 6. We calculated a median of 24% (quasi) experiments in the WCGT conference papers published in the proceedings; see Table 2 above. In contrast, the percentage of the databased research articles in the two journals of the control group are much higher. In the JEP more than 95% of all publications were databased (cf. Fig. 8, above).

Complementary to this, the GEI has the relatively highest percentage of gifted education or practice-related publications, followed by RR. The lowest quota is found in JEP; however, one should not forget the quite low percentage of giftedness related articles in total in this journal.

The content analyses of both the WCGT conference proceedings (1975–1991) and the most important journals in the field of giftedness and talent during the same period showed a number of similar results. The most important can be summarized in three statements.

(1) The main focus of the recent literature in the field of giftedness and talent is on practical problems of *gifted education* and related questions.

Half of the articles published in JEG and GCQ and even two thirds of those published in GEI and RR and those papers published in the WCGT conference proceedings contain information about practical problems of educational and instructional issues, programming, and nurturing the gifted/talented. In contrast, the minimal consideration of basic research questions and those theoretical-innovative considerations related to these is remarkable. There have been repeated warnings in the literature about the disadvantages for both applied research and for improving the practice of gifted education, e.g., from Gallagher (1986), Feldhusen (1989) or Passow (1989). Obviously, not much has changed with regard to this recently. The summary made by Carter and Swanson (1990) at the end of their analysis of the most frequently cited gifted journal articles since the Marland Report holds true without limitation for the results presented above. I quote:

TABLE 3
Percentages of Main Topics in the Journals of the Control Group (JEP, EC)

		<i>Journal of Ed. Psych. (JEP)</i> 1980–1991		<i>Exceptional Children (EC)</i> 1980–1991	
I	Learning and Perception	14.5%	(0.5%)	12.0%	(0.4%)
	Identification of G/T	9.5%	(0.2%)	4.0%	(0.1%)
	Development of G/T	5.0%	(0.1%)	16.0%	(0.5%)
	Personal Characteristics	47.5%	(1.0%)	28.0%	(0.9%)
	Physical/Mental Condition	—	—	8.0%	(0.3%)
	Educ./Instructional Processes and Programming	9.5%	(0.2%)	24.0%	(0.8%)
	Social Context and Influence	14.5%	(0.3%)	8.0%	(0.3%)
II	Conceptions and Development	28.5%	(0.5%)	24.9%	(0.8%)
	Identification of G/T	14.5%	(0.3%)	16.0%	(0.5%)
	Programs/Practices of Nurturing G/T	5.0%	(0.1%)	28.0%	(0.9%)
	Other Components of Nurturing the G/T	47.5%	(1.0%)	20.0%	(0.6%)
	National Efforts, Policies, and Programs, etc.	—	—	4.0%	(0.1%)
	Presence and Future of G/T Education	5.0%	(0.1%)	8.0%	(0.3%)

I = Classification according to the categories in Figure 5.

II = Classification according to the categories in Figure 6.

“One of the most perplexing findings from this study is the infrequent use of psychological theory to study the concept of giftedness or to develop programming for the gifted. Certainly theories on intelligence/cognition (e.g., Davidson & Sternberg, 1984; Flavell, 1977; Shore, 1986, 1987; Sternberg, 1981, 1985) and human development (e.g., Bullinger & Chatillon, 1983; Carter & Ormrod, 1982; Horowitz & O'Brian, 1985; Janos & Robinson, 1985) can contribute much to our understanding and can lead to the improvement of practical concerns that have continued since the Marland Report (e.g., identi-

fication procedures, programming approaches, and curriculum development)” (Carter & Swanson, 1990, p. 122).

New recognitions with regard to the research content are, of course, also dependent on new methodological innovations. We call for not only more multivariate statistical techniques and complex designs, but also longitudinal studies instead of the usual cross-sectional designs. A current overview of longitudinal studies in the field can be found in Subotnik and Arnold (1993); also see chapter 9 in this handbook.

TABLE 4
Category Frequencies and Percentages for Research and Non-Research Based Publications According to Rogers (1989, p. 81)

Category	Research Based Publications		Non-Research Based Publications		Total
	<i>n</i>	%	<i>n</i>	%

In addition, the cooperation of researchers and practitioners needs to be increased. Once again, I quote Carter and Swanson (1990, p. 122):

“These efforts should focus on (a) identifying key issues and concepts, (b) synthesizing the literature around those issues and concepts, (c) conducting meaningful, theory based research, and (d) extending and elaborating research findings to both theoretical and practical settings”.

The interaction of theory and practice in the area of nurturance of the gifted was reduced by Julian Stanley (cf. George et al., 1979) to the well-known formula of three Ds: Discovery, Description, and Development. In addition see Mönks and Heller (1993).

(2) Basic and applied research in the field of giftedness and talent should be supported by *interdisciplinary approaches*. This should provide information about the developmental conditions surrounding giftedness and talent and also improved solutions to practical problems, such as identification and nurturance of giftedness inside and outside school.

Interdisciplinary cooperation in the area of research on giftedness is primarily necessary between educational specialists and psychologists, but also within these disciplines, e. g., between the various psychological subdisciplines, as they are presented in Fig. 7. Above and beyond this, other related disciplines are called upon to cooperate, such as neuroscience, genetics and brain research, artificial intelligence or expertise research. As experience in other areas has shown, surprising theoretical insights can be obtained due to the change in perspective and sometimes different methodology in interdisciplinary cooperation. In addition creative solutions to practical problems can be expected. Although the existence of specialized journals seems to be quite justified based on the content analyses (and their resulting in greater research vs practical emphases meeting current interests), one should not lose sight of the

danger of isolation from other related disciplines and journals. The interdisciplinary cooperation is more or less blocked rather than increased by such an approach. Perhaps we should consider how the contributions from other disciplines can be more frequently won for gifted journals. A further possibility is to publish interdisciplinary special issues, etc. In addition, the program of the WCGT conferences should include interdisciplinary symposia or workshops so that the research on giftedness does not become too isolated from important related disciplines, especially from the mainstream of psychological and educational research (cf. Jackson, 1993).

Furthermore, a close relationship with regard to information and experiences should be sought between researchers and practitioners. The demands sketched out here can most easily be met in interdisciplinary research groups. These should include especially qualified and research-oriented practitioners. Of course, alimentation problems could interfere with this idea greatly. A national system like that recommended recently by the American National Research Center on the Gifted and Talented—at the University of Connecticut in Storrs—could be used as a model. Presently we do not know how well organizations, such as those primarily concerned with practical problems of identification and gifted education could deal with this kind of system. I am thinking here of the programs from the *Study of Mathematically Precocious Youth* (SMPY) or the *Center for the Advancement of Academically Talented Youth* (CTY) at the Johns Hopkins University in Baltimore (U.S.A.), the *Talent Identification Program* (TIP) at the Duke University in Durham (U.S.A.), the *Center for Gifted Education* at the University of Calgary (Canada), and the *Center for the Study of Giftedness* at the University of Nijmegen (The Netherlands). They can certainly stimulate the international scene in research on giftedness and talent.

(3) *Cross-cultural studies* emphasize not only the worldwide importance of research on giftedness and talent, but are also important for examining theoretical assumptions of universality or specific cultural influences on the development of giftedness and are thus also necessary.

Factor analysis studies	16	2
Total	870	100

The degree to which development and socialization theory assumptions for explaining individual differences are actually universally valid, can only be determined by cross-cultural studies. There are already individual psychological approaches examining the relationship of culture or subculture and individual development of abilities (e.g., Haensly, Reynolds, & Nash, 1986; Csikszentmihalyi, 1988). Current studies in giftedness also seem to emphasize cultural influences on the development of creativity (Hany, 1993; Hany & Heller, 1993).

The research on creativity is unsatisfactory both in terms of measurement instruments and in its theoretical basis. This is probably due primarily to incorrect universality assumptions. This refers to the neglecting of domain-specific factors of giftedness and also cultural socialization conditions. In view of current research on creativity (cf. Weisberg, 1986; Simonton, 1988; Sternberg, 1988; Glover et al., 1989; Runco & Albert, 1990; Sternberg & Lubart, 1991), most of the previous training methods for increasing creativity can be considered obsolete. Innovations in creativity research and creativity nurturance as in other areas of gifted education are primarily to be expected (according, for example to Gardner, 1989) from cross-cultural studies and are substantiated by impressive examples (see also Winner & Martino in this handbook, chapter 14).

Psychometric Versus Cognitive Psychological Paradigms: Different Tasks and Functions

The current situation in the research on giftedness and talent is characterized by two contrasting paradigms: the psychometric and the cognitive science paradigm. This is especially apparent with respect to basic research. Both paradigms, however, should be viewed less as competing but rather in terms of how they complement each other. Whereas the psychometric structural theories or correlation studies, for example, greatly enrich the giftedness *phenomenology*, cognitive psychological (experimental) studies are expected to provide information about the mechanisms of cognitive *processes* and their individual causes. In the former case, the *descriptive* function dominates, and in the latter the *explanatory*. Thus, this corresponds to the differentiation in personality research to *nomothetic* (psychometric) versus *idiographic* (cognitive psychological) approaches. For new theoretical recognitions about high ability *and* for practical giftedness models we need both paradigms. This is documented by the various contributions in this handbook. For an overview of the various conceptions and models of giftedness, see the following chapter.

Despite this demand, it should not be overlooked that quantitative differences in the *psychometric* approach have thus far been better confirmed than qualitative differences in the *idiographic* or cognitive psychological approaches, i.e., qualitative differences in the learning and thinking of the gifted versus non-gifted individuals

(Jackson & Butterfield, 1986; Rogers, 1986; Waldmann & Weinert, 1990). Therefore, a scientifically elaborated ideal conception of giftedness is not yet available, although there are promising attempts (see chapter 10 of this volume). Whether or not the status quo can be positively rated is not clear. Still, the historical discussion of genius becomes superfluous when we consider the contemporary state of knowledge.

An additional misconception should be cleared up at this point. In the psychometric approach, not only one-dimensional definitions of giftedness are possible, i.e., the g-factor of intelligence (based on IQ), but also multidimensional conceptions of giftedness. An example of this is Gardner's (1985) Theory of Multiple Intelligences, Gagné's (1985, 1991) Differentiated Model of Giftedness and Talents or the Munich Model of Giftedness (Heller & Hany, 1986; Heller, 1991c; Perleth & Heller, 1993; Perleth, Sierwald, & Heller, 1993). In contrast to the usual practice of a single IQ value being used for identification (see the overview by Rost, 1991, or Tannenbaum, 1992, as well as chapter 1 of this volume), the necessity of a multifactorial or multidimensional or rather typological model of giftedness is recognized here in agreement with the majority of more recent concepts of giftedness. This demand holds not only for the theoretical conceptualization of giftedness but also for practical purposes of identification and education of gifted youth.

On the other hand, the influence of general ability on academic achievement, especially in grade school, should not be underestimated—as shown by Cronbach and Snow (1977), Thorndike (1985) or more recently Rost (1991). In recent studies on school, university or professional success predictions for gifted youth, the usefulness of multidimensional or typological concepts of giftedness could be proven (summarized e.g., in chapter 17 of this volume). At the secondary school age and in adulthood, differential approaches to identification with consideration of measurements of domain-specific demands have been proven to be much superior to single dimensional IQ definitions. The fact that identification of the gifted nevertheless often takes place in adolescence using IQ measures, is probably primarily due to less energy necessary for measurements with traditional IQ tests and not justified by any methodological arguments. The proven superiority of IQ tests over creativity tests cannot be used as an argument against considering creativity characteristics in the identification of the gifted as long as the combination of intelligence *and* creativity predictors leads to a better prognosis of outstanding achievement than an IQ test alone (Hany & Heller, 1991; see also chapter 11 in this volume). Above and beyond this, the usefulness of typological identification approaches must be emphasized with a view toward practical needs in gifted education in current literature (for an overview see chapters 12 and 13 as well as 18 of this volume). There is still no substitute for the psychometric approach for reliable and valid talent searches within the framework of enrichment courses

or for individual academic achievement predictions. This also holds true for developmental psychologically oriented longitudinal studies of giftedness (see chapter 9 of this volume).

However, purely psychometric identification procedures do have a number of obvious limitations. Interindividual differences in giftedness can be measured in this way, but this does not explain *how* they came into being. Such explanatory knowledge can only be obtained by means of cognitive psychological or rather experimental diagnostic strategies. In other words: Status diagnosis (psychometric) needs to be supplemented by process diagnostic (cognitive psychological, experimental) paradigms to provide theoretically and practically satisfactory information about gifted children and adolescents.

According to Facaoaru and Bittner (1987, p. 194), the following analytical units are characteristic for the research subject in the *cognitive psychological* paradigm:

Individual and developmental or age-related test achievement differences are not explained by global structural units or common achievement factors as within differential intelligence theories—i.e. by verbal or quantitative abilities—but rather through elementary process units such as information processing components. It is assumed that the so-called basic parameters of intelligence make up the individual thought processes. In Sternberg's component analysis, the speed of information processing, information selection and storage, the accessibility of available knowledge, etc. are taken into consideration. Corresponding taxonomies of cognitive components have been presented, for example, by Carroll (1976, 1981), Sternberg (1977, 1979, 1982, 1986), Rose (1980).

Whereas traditional intelligence theories within the *psychometric* paradigms study mental structures, the approaches to research of the gifted in the *cognitive psychological* paradigm study the mental components upon which the cognitive activities are based. The focus here is on the internal cognitive conditions and mechanisms as well as changes in the internal structure of knowledge, problem solving processes and thinking strategies, metacognitive competencies, etc.

The task division principle is typical of such component analyses. The well-known—and well-structured—intelligence test items are artificially divided into elementary components before they are again presented serially (Sternberg, 1977, 1986; Klix, 1983; van der Meer, 1985). As an alternative, test items can be employed together with successively presented information which is relevant for solving the problems (cf. Davidson & Sternberg, 1984; Davidson, 1986).

"In contrast to the traditional psychometric approaches where solely the number of test items

solved within a certain time period is counted up, within sequential information processing approaches, the speed (time necessary for each individual step in the solution process) and also the exactness (number of errors) and the course that problem solving takes (value of the independently produced intermediate solutions) are recorded. The individual steps are either recorded in writing or automatically using a computer simulation" (Facaoaru & Bittner, 1987, p. 195; free translation from German).

Waldmann and Weinert (1990), whose literature search provides a good overview of the current stand of research on thought processes of the gifted, expect the differential thought psychology to contribute heavily in the cognitive psychological paradigm to the development of theories in this context. A basic problem, however, is the extreme (inter- and intraindividual) variability of behavior in the gifted. A double risk results from this: unjustified generalizations versus inflationary model development, e.g., for explaining the problem solving behavior of gifted individuals. Waldmann and Weinert consider the development of a "theoretically well-founded, even if always provisional taxonomy of tasks and problem classes" to be an important task for future research from the general as well as differential psychological aspect. This cannot, however, be equated with a taxonomy of cognitive processes in problem solving. The enormous number of empirically identified cognitive processes makes it difficult to isolate task-invariant and non-domain-specific achievement predictors as was the long dominant research tradition. Waldmann and Weinert (1990, p. 179) believe that the flexibility of processes in problem solving is very great and that compensatory effects between various cognitive determinants are the rule rather than the exception.

"A basic problem of the psychometric approach was that similar and invariant ability patterns are postulated as independent of the giftedness quality (if one does not consider the theoretical variation of the differentiation hypothesis for the gifted). It is, however, certainly clear in the research tradition of the cognitive paradigm that higher thought processes play a decisive role in the explanation of exceptional abilities. One has to, therefore, cast doubt on the assumption that the research of giftedness is simply a specific variation of population-oriented differential cognitive psychology or whether it is not a search for specific structure and process characteristics of learning and achievement behavior in the gifted" (loc. cit.; free translation from German).

This again approaches the question of *qualitative* differences in the gifted vs non-gifted.

In an analogous fashion, more recent creativity research (e.g., Facaoaru, 1985) has been able to prove that both divergent and convergent thought processes are necessary for solving complex difficult problems—for example, in natural sciences and tech-

nology—in a creative way. This means that only the simultaneous employment of both divergent and convergent processes connected with adequate domain-specific knowledge increases problem-solving productivity (cf. Weisberg, 1986; Heller, 1991b, 1993b; Facaoaru, 1992). In addition to higher intelligence and the ability to use knowledge flexibly, Waldmann and Weinert (1990) claim that impulsive, fluid styles of thinking together with persistence and high intrinsic achievement motivation favor creative problem solving in demanding, challenging situations. In fact, more recent studies, primarily in the area of natural sciences, technological and mathematical giftedness, have been able to isolate a number of problem solving characteristics in the gifted that can be interpreted as *qualitatively* different from those in average individuals. For example, we can refer here to the experiments from Klix (1983) and van der Meer (1985) or Sternberg (1977, 1985, 1991). Linked to such cognitive psychological studies is the expectation that not only theoretically relevant explanatory knowledge will result from them, but also important information for the practice of raising and educating gifted individuals and nurturing the necessary knowledge of change.

Expert–Novice Paradigm, Cross-Cultural and Other Approaches in the Field of Giftedness Research

From a developmental psychological or instructional psychological perspective, it is especially interesting to see how the relatively general abilities and thinking competencies establish themselves. The learning processes necessary for this stretch over many years and are effected by many various internal (cognitive and motivational) and external (socialization and situational or context) variables. Because of these and possible compensatory effects, long-term predictions of outstanding achievement are difficult in early childhood (see chapters 15 and 27 in this volume).

In addition, the relative importance of *general* intellectual potential for explaining achievement variance decreases with age, and elaborated domain-specific knowledge bases for explaining expertise increase in importance. Long-term *individual* achievement predictions in childhood and adolescence with a certain degree of reliability are thus limited, i.e., to comparable situations. Modern knowledge psychology in the *expert–novice paradigm* is especially interested in those learning and knowledge acquisition processes which make it possible to achieve outstandingly in the sense of expertise. Accordingly, nurturance approaches for gifted students are thus directed less at ability constructs or predictors of giftedness in a narrower sense, and more at *learning* competencies. Some representatives of knowledge psychology (e.g., Gruber & Mandl, 1992) even suggest that one should not speak of the gifted but rather of experts, i.e., exchange expertise for the concept of giftedness. This would not

only take frequently neglected criteria problems from traditional intelligence research into consideration better than previously, but also approach more closely a social psychological definition of giftedness (e.g., Tannenbaum, 1983). On the other hand, a number of educational problems in the nurturance of giftedness, especially for so-called underachievers and gifted handicapped persons (cf. chapters 37 to 41 in this volume) would be mostly neglected in this approach. As useful as expertise research would appear to be in many cases, in other instances of fostering giftedness deficits become apparent.

New recognitions can be expected from expertise research, i.e., the comparison of beginners or novices with more experienced or expert individuals. This will primarily be found in the area of knowledge acquisition in *complex* domains which should compensate for a disadvantage of many ability-oriented (psychometric) studies. It is well-known that external or ecological validity is a major problem in measurements in the trait or factor approach. Expertise research could, thus, contribute to the description and analysis of domain-specific competencies in “natural”, complex demanding situations. At the same time, an attempt could be made to relate more closely various positions of learning and thought process research positions. Through the focus of learning theory questions about the *acquisition* of expertise and cognitive psychological *application* aspects on problem solving, they complement each other with regard to research on giftedness.

Empirical studies on the relationship of expertise and giftedness have been primarily carried out in the areas of music, sports and chess. For example, Gruber, Renkl, Schneider, and Kuhn (1992) examined the development of expertise in children and adolescents in a three-and-half year longitudinal study. In addition to the analysis of developmental courses in adolescent experts and novices in chess, predictors of various degrees of performance development were to be determined. Domain-specific short-term memory was measured. In addition, intelligence test values and results of biographical data were evaluated. The degree of expertise was defined by external criteria.

“The domain-specific memory performance from the first measurement was found to be a good predictor of unfavorable expertise development. It was well-suited to the identification of those who were identified during the first measurement as experts whose development would progress at a slow rate. It is probable that dispositional factors, such as memory capacity or intelligence, are responsible for the unfavorable expertise development. For the ‘entrance’ into an expert career, no person-specific predictors could be determined. In subjects who were novices at the first measurement and became experts, this was probably due to external experiences (e.g., entrance into a chess club based on corresponding peer relationships). . .

The superiority of practice-related variables versus

dispositional variables can be interpreted in two ways: On the one hand, it is possibly the expression of a *compensation* through practice comprehensible, which lets the expertise development appear to be independent of disposition when a certain degree of expertise has been achieved. On the other hand, one can express some doubt about the *validity* of measuring dispositional factors" (Gruber et al., 1992, p. 67; free translation from German).

The latter interpretation probably holds especially true for complex tasks or areas. For the initial explanation, which can utilize corresponding results of validity studies on school success predictions (Heller, Rosemann, & Steffens, 1978; Heller, 1984, 1991a), one should not overlook the confounding of cognitive learning abilities with learning activities. As a whole, representatives from expertise research seem to tend to underestimate the role of intellectual abilities in knowledge acquisition. The attempt is frequently made to support this with inadequately domain-specific intelligence test results. On the other hand, believers in the psychometric concepts of giftedness may be in danger of underestimating non-intellectual and situational prerequisites for learning. In this way, both paradigms can complement each other. An extensive valuation of the expertise approach as well as a detailed presentation of various methodological problems can be found in chapter 16 of this handbook.

With few exceptions (e.g. Amabile, 1983; Tannenbaum, 1983, 1991), *social psychological* aspects have been greatly neglected in the conceptualization of giftedness. This theoretical deficit is related to the psychometric research tradition where status diagnostically determined test scores (e.g., IQ scores) are considered to be—relative to corresponding (age) groups—invariant measures across the life span. Modern cognitive component approaches are also affected by this individualistic misinterpretation according to Waldmann and Weinert (1990). Cross-cultural cognitive psychological research provides, however, enough proof for the interaction hypothesis. According to this, personality characteristics as well as giftedness continually need to be seen as a product of interaction between individual factors and social-cultural determinants.

Attempts to describe such interaction processes need to include not only cognitive and non-cognitive (motivational) competencies, but also individuals' social abilities. These make it possible for a person to activate a potential gift in concrete social situations—particularly in the family, school and peer group (see chapters 4 and 5 in this volume). On the other hand, these activities are influenced by the quality of the learning environment. The development of corresponding systemic models of giftedness should be a rewarding research task. From a practical standpoint, the newly developed pentagonal model from Sternberg (chapter 11 in this volume) is of particular interest.

Cross-cultural studies cannot only provide important

information about social and cultural influences on the development of giftedness as well as nurturing and restraining socialization factors about gifted children and adolescents. Cross-cultural studies are also indispensable for examining the universality assumptions of many theories.

Cross-cultural research approaches to giftedness research can be expected to provide information about various cultural influences on individual developmental and educational processes (cf. Eckensberger & Krewer, 1990). This goal is to be achieved by specific research strategies making it defined not by its object but by its method (Petzold, 1992). Three comparative forms are relevant (a) cross-national, (b) cross-cultural, and (c) cross-societal. In the present context, cross-cultural studies are of interest. The systematic comparison of psychological variables or results obtained in various cultural conditions should help to identify culturally caused behavioral differences in individual development. This is a main problem in empirical cross-cultural research. Based on such research designs, universality assumptions of relevant developmental, educational and/or learning/instructional theories can be examined. This is something that Wilhelm Wundt emphasized at the turn of the century in his ethnological psychology.

This is also the approach taken by modern so-called *etic* (from *phonetic*) approaches in cross-cultural research on the universality of human behavior characteristics (universalism hypothesis). In contrast to this, the so-called *emic* approach (derived from *phonemic*) tries to determine cultural socialization influences within particular cultures (culture-relativism hypothesis). Corresponding culture-specific and valid measurement instruments which are also culture-fair make it difficult to really compare cultures. Thus, in more recent ecological psychological models (e.g., Berry, 1980), an attempt was made to overcome the dichotomy between "emic" and "etic" in an integrative conception (cf. Petzold, 1992, pp. 311–312).

Comparative cultural studies can provide new recognitions about social-cultural conditions in the development and nurturance of gifted children and adolescents because they force us to change our perspective. This could increase the variety and variance of nurturing ideas. This is not only of practical use, but tolerance and understanding of other cultures can be increased by cross-cultural research cooperation (Gardner, 1989).

To avoid or remove undesirable differences in the development of giftedness, both from the competence and performance points of view, a corresponding knowledge of change is necessary. This grows from the explanatory knowledge as it is obtained in experimental or quasi-experimental studies. For understanding sex-related and other giftedness and achievement differences, it is insufficient to carry out quasi-experiments in the social sciences, so that *interdisciplinary* research approaches can mediate furthering knowledge including neuroscientific and

biological research methods (see chapters 6, 7, and 40 in this volume).

Desiderata in the Research on Giftedness and Talent

The research on giftedness includes not only basic scientific research, but also technological and practice-oriented questions, i.e., tasks of applied giftedness research. In this context, possibilities for improvement related to the identification and practical nurturance of gifted children and adolescents increase in importance, reflected in the content structure of this handbook.

The applied research of the gifted is more or less based on reliable recognitions from basic research, e.g., from the area of experimental psychology. These are, however, still inadequate or provide, in part, non-uniform or contradictory results corresponding to the theoretical explanations. With regard to the "pressure to act" that practical research often feels from practitioners, a dilemma often arises: On the one hand, they should attempt to solve practical problems in a scientific and serious manner; on the other hand, this is impossible without adequate basic research and is hard due to the complexity of many practical fields. This often makes it necessary to compromise in applied research—also in the area of giftedness—while scientific methodological standards dare not be substantially impinged upon.

The model shown in Fig. 9 should clarify important relationships in research on the gifted and practical necessities of gifted education. Inasmuch as one considers formal nurturance of the gifted to be a function of individual personality development, a relationship exists, as shown in the model, between giftedness research and practical tasks in the identification and nurturance of the gifted, including evaluation of identification and nurturance measures.

A few exemplary research desiderata from the perspective of basic vs applied research are provided in the following (Heller, 1993a).

Deficiencies in the Field of Basic Research

—Lack of combined approaches of general and differential psychological perspectives for developing specific structure and process models for experimental designs in order to explain achieving excellence, expertise, etc.

—Few analyses of the development of metacognition, general vs specific knowledge bases etc.

—Little study of developmental courses of the highly gifted during the second half of the life span.

—Few system-theoretical analyses of individual and social components in the socialization process.

—Almost no cross-cultural studies in the field of high ability in order to verify or falsify theories, i.e., for testing hypotheses of universality.

—Lack of (quasi-)experimental studies aimed at causal

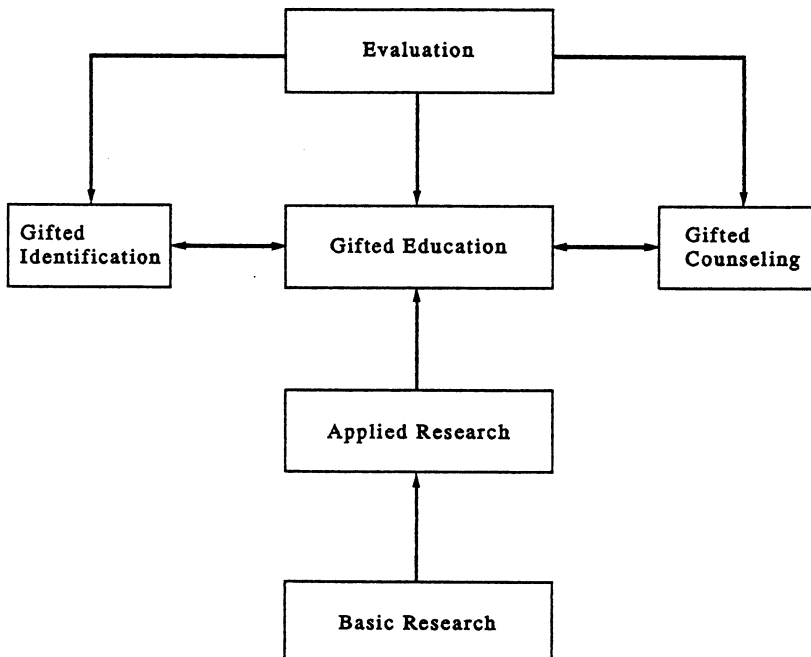

FIGURE 9. Relationship between giftedness research and practical tasks of gifted education.

analyses, e.g., of gender-specific differences, especially in the fields of mathematics, sciences and technology.

Deficiencies in the Field of Applied Research

—Very few multidimensional approaches and sequential strategies in the diagnosis of highly gifted and talented children and adolescents.

—Little process diagnosis (complementary to the so-called “status diagnosis”) in the field of high ability.

—Lack of intervention (and prevention) programs for balancing out gender-specific differences in competence and, above all, in performance, especially in the fields of mathematics, “hard” sciences and technology.

—No metacognitive and general problem-solving development programs as well as domain-specific knowledge-based programs for highly gifted students.

—Lack of evaluation of school programs and extra-curricular (enrichment vs acceleration) courses for the gifted and talented youth.

—Lack of expert systems for school psychologists, school counselors and study advisers in connection with problems related to high ability.

This list is incomplete and could go on forever, as one sees from the topics in this handbook. Among others the following research topics seem important to me with regard to *gifted education*.

Desiderata in the Research on Gifted Education

—Development of instruction concepts of talent didactics; didactic possibilities of differential, i.e., talent-oriented, instruction regarding cognitive instruction/learning contents.

—Curricular development for special academic courses, special classes or even special high schools for certain acceleration groups and for enrichment courses with extracurricular support of the gifted, including their evaluation (cf. Scriven, 1980, 1983; Wottawa & Thierau, 1990; Brandtstädter, 1991; Buchanan & Feldhusen, 1991).

—Longitudinal studies of the gifted including analyses of the life environment over a whole life span.

—Study of leisure-time activities of talented adolescents and their influence on personality development.

—Career problems of talented girls and women; especially in the fields of mathematics, natural sciences and technology.

—Analyses of metacognition, causal attribution (achievement motivation) styles, action control, the self-concept of talented adolescents, including sex-specific differences and problems, e.g., regarding situation orientation vs action orientation (Kuhl, 1981, 1987), self evaluation of heuristic abilities (Dörner et al., 1983).

Problems in *gifted identification* and *gifted counseling* have to be considered together. In consideration of

high risk groups, e.g., disabled talented girls or children of minority groups, the difficulties of differentiation in instruction and education require special attention. Despite a number of useful attempts over the past few years to identify and support talented children and adolescents, there is a lack of convincing evidence of the validity of many techniques, especially those which experts judge as innovative. Here, requirement-oriented diagnosis and support concepts (cf. Heller, 1984) could be useful, especially when they are linked to recent results of applied problem-solving research and knowledge psychology. On the other hand, possibilities of psychometric identification, e.g., in the aptitude testing paradigm, have by no means been exhausted (cf. Trost, 1986). There is often a considerable discrepancy between theoretical (multidimensional) identification and stimulation strategies (see Rost, 1991; Hany & Heller, 1991; Mönks, 1991). Independent of such controversies, the following topics for improving identification and support can be regarded as urgent (Heller, 1992).

Desiderata in the Research on Gifted Identification and Counseling

—Advisory aids for talent-orientated education, especially at preschool and primary school age.

—Advisory concepts for talented students, their parents and teachers.

—Early identification and support of the talented disabled.

—Identification and support of gifted girls (especially in the fields of mathematics, natural sciences and technology).

—Identification and support of gifted underachievers.

—Construction of process diagnostic identification instruments and their validation.

—Construction of domain-specific counseling tests for talented adolescents.

—Academic stimulation of creativity, in general and also in specific areas.

—General vs domain-specific thought training programs.

—Work training programs (e.g., for gifted underachievers).

—Quasi-experimental intervention studies for counseling and supporting gifted children and adolescents.

Evaluation

The *evaluation* of gifted education as well as of gifted identification and counseling takes on two functions, which are expressed in summative and formative evaluations in the sense of Scriven (1967). The *summative* evaluation is directed at measurements of effects (e.g., the effects of various gifted education programs or intervention effects), the feasibility of the corresponding measures is evaluated.

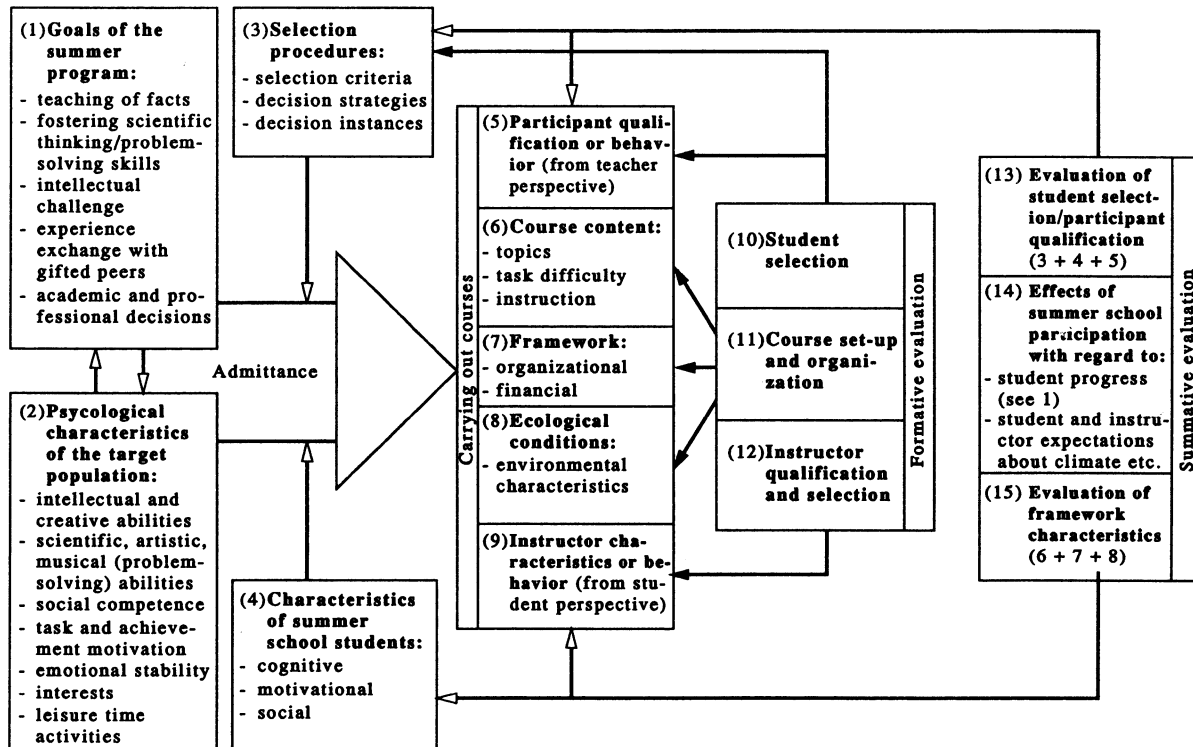

FIGURE 10. Evaluation model for a nationwide summer gifted program.

The *formative* evaluation is more or less directed at the optimization of nurturance and counseling measures, in the sense of action research. Since during the model project, the feedback of relevant evaluation results is given and effects the treatment, dysfunctions that may occur can be recognized, systematic errors eliminated and thus an attempt made to improve the treatment. Corresponding summative evaluation data at the end of the (quasi-) experiments can, however, no longer be interpreted as “independent” judgments. As long as the (formative) evaluation is intended to optimize the treatment, this is no disadvantage. If, however, two or more treatment concepts or models are to be compared with regard to their various advantages or disadvantages, only an independent summative evaluation (without a formative evaluation) can provide objective results. Thus, both forms of evaluation complement each other with regard to their various functions and can frequently be combined. This not only allows a *scientific* evaluation of treatment results but participants can be provided with important support during the trial phase by formative evaluation.

In the area of gifted education and also in the area of gifted identification and counseling, evaluation studies with scientific standards are still relatively rare. Also see Buchanan and Feldhusen (1991) and Callahan in chapter 34 of this handbook. Till now there has been an emphasis on case studies, essay reports or data (collected by those involved in the treatment themselves) which can hardly provide objective judgments. The model shown in Fig. 10 of the evaluation of a nationwide Summer Gifted Program (Summer School in Germany) exemplifies important elements of *scientific* model evaluation.

Research on Giftedness and Responsibility

Finally, the relationship between research on giftedness and the individual vs social responsibility will be discussed from several points of view. The following five aspects are to be especially emphasized here:

(1) Contributions from research on giftedness to improving practical considerations in the identification and nurturing of the development of gifted children and adolescents. Related questions are the prevention of individual behavioral problems, social conflicts, inappropriate upbringing and educational practices, encouraging counseling and intervention for maintaining or developing learning environments appropriate to various types of giftedness. The tasks described here belong to *applied research* on giftedness.

(2) The efficiency of applied research depends on the quality of *basic research* which can be seen in other scientific areas as well. This relationship holds true for research on giftedness and thus also for practical nurturance of giftedness. We can name as examples here innovative approaches from cognitive psychology or research on expertise. These have both provided

important impulses for applied areas such as problem-solving research or practical knowledge acquisition.

(3) The recognition that the development of competence and knowledge acquisition takes place in social-cultural contexts has consequences for the research on giftedness. Theoretically conceived universalities and methodological demands for validity need to be examined in *cross-cultural research*. Above and beyond this, cross-cultural and/or cross-national cooperative research projects serve not only to exchange information and experiences, but also can be expected to provide the flexibility necessary through the change in perspectives. The contribution to peacekeeping efforts is only marginally noted here.

(4) The development of a group of *elites* in the sense of elite achievers is a legitimate democratic desire. This makes for a double responsibility: to the individual and to society. The *society* has a duty to provide every young person with adequate developmental and educational opportunities. This is anchored in most democratic constitutions. This also has a double meaning: Equalizing of chances as a social component and equal opportunity as an individual component. The nation or the society needs to make sure that equal developmental chances are available to every young individual, i.e., also to the gifted. This postulate includes the necessity of equalizing opportunity in single instances and also the co-responsibility of socialization agents (especially parents and teachers). An *individual responsibility* grows out of the social responsibility for individually nurturing educational and upbringing opportunities. This is a responsibility to actually use the academic opportunities or nurturing socialization offers. This individual responsibility is first related to the responsibility of each person with regard to his/her own personality development (developmental psychologists refer to this as “developmental tasks” in the sense of Havighurst, 1952), at the same time, however, the individual’s responsibility to society is also meant here. This is the individual’s responsibility to make an appropriate contribution to the social well-being. There is an expectation that the gifted will generally be able to contribute more than weaker or handicapped individuals. This includes contributions to securing a social net or “human resources” in highly developed social systems.

(5) Finally a *mutual responsibility of society and the research community* exists. This does not question the freedom of researchers to choose their own topics and methods, but their responsibility to a society which—directly or indirectly—subsidizes their research must be emphasized. This basic demand is no less important in the research of giftedness which is in danger of isolation (and not only from scientific community). On the other hand, researchers in the field of giftedness have the same right as other qualified researchers to demand adequate research conditions, in order to scientifically research those areas considered desirable or necessary both from the point of view of basic research and in the practice of nurturing the gifted.

Constructs and Models Pertaining to Exceptional Human Abilities

FRANÇOYS GAGNÉ

Université du Québec à Montréal, Québec, Canada

Children and adults who manifest exceptional abilities and obtain superior performances in any field of human activity are designated by a large variety of labels. Terms found in the language of experts and lay persons alike include “gifted”, “talented”, “able”, “genius”, “prodigy”, “precocious”, “excellent”, “expert”, “competent” and “proficient”. Because of their centrality in the literature, the present chapter will focus on the constructs of giftedness and talent.

Definitions of giftedness (and talent) abound in the literature; rare is the textbook without a chapter devoted to a review of existing definitions followed by a new proposal by its author. Indeed, an entire book (Sternberg and Davidson, 1986) was published to bring together many of the more popular definitions and models of the 1980s. So numerous are the definitions that Stankowski (1978, cited in Davis & Rimm, 1985) found it necessary to extract a more synthetic view through a classification system in five categories: (a) *after the fact* definitions focusing on adult prominent accomplishments, (b) *IQ* definitions specifying a particular threshold score, (c) *talent* definitions emphasizing outstanding performance in specific artistic and/or academic fields, (d) *percentage* definitions varying from a generous 20% or more to a strict 3% or less and (e) *creativity* definitions stressing original and productive accomplishments in a particular field. These categories are by no means exclusive; many of the better known definitions and models of the last twenty or thirty years would belong to more than one of the above categories. Stankowski's system emphasizes the two general components implicitly or explicitly present in most definitions and models: (a) a “what is” statement pertaining to the core nature of the construct, its central or prototypical elements and (b) a “to whom” or “how many” statement about the size of the population targeted by the label. These two statements correspond to the usual distinction, in logic, between the *comprehension* of a concept and its *extension*; these two components will be examined separately in the following pages.

The Constituents of Giftedness and Talent

As a first step in this discussion of the concepts of giftedness and talent, here follows a chronological sample of definitions and models which have been cited with somewhat more frequency in the gifted literature of the last three decades.

Survey of Recent Definitions and Models

Among the numerous definitions published during the 1950s, two have withstood the test of time and appear regularly in historical surveys of the gifted movement. First, Witty (1958) considered as gifted any child “whose performance in a potentially valuable line of human activity is consistently remarkable” (p. 62). Witty's list of “lines” was fairly extensive and went well beyond the traditional high IQ and academic excellence. DeHaan & Havighurst (1957) proposed a definition which was somewhat similar to Witty's, but specified six domains of excellence: intellectual ability, creative thinking, scientific ability, social leadership, mechanical skills and talents in the fine arts. Tannenbaum noted that both definitions did not value strictly “skills that are rewarded for social service of some kind (. . .) but included abilities that are personally gratifying to their possessors and that provide uncommon pleasure to others” (1983, p. 64).

Inspired by the work of Guilford (1956) and his Structure of Intellect, Taylor (1967) developed his Multiple Talent approach as a means to promote the development of various creative abilities in the classroom. His pool of six talents, some of them far different from those recognized at the time, were labeled: Academic, Productive thinking, Communicating, Forecasting, Decision-making and Planning. He described them as follows: “the set of talents included one non-thinking way of reproducing and thereby acquiring knowledge, plus five thinking ways of actively processing and working with knowledge in order to acquire it” (1986, p. 316). This model became the backbone for a teaching program called Talents Unlimited (Schlichter,

1986). Taylor subsequently (1986) added three more talents: Implementing, Human relations and Discerning opportunities.

Probably the most often cited definition appeared in the U.S. Commissioner of Education's 1972 report to the Congress of the United States, commonly called the Marland Report.

Gifted and talented children are those identified by professionally qualified persons who by virtue of outstanding abilities, are capable of high performance. These are children who require differentiated educational programs and/or services beyond those normally provided by the regular school program in order to realize their contribution to self and society. Children capable of high performance include those with demonstrated achievement and/or potential ability in any of the following areas, singly or in combination: (1) general intellectual ability, (2) specific academic aptitude, (3) creative or productive thinking, (4) leadership ability, (5) visual and performing arts, (6) psychomotor ability. It can be assumed that utilization of these criteria for identification of the gifted and talented will encompass a minimum of 3–5% of the school population (Marland, 1972, p. 5).

The above definition was slightly modified a few years later by the United States Office of Education (see Davis & Rimm, 1985), mainly by deleting the sixth category (psychomotor ability). Renzulli (1979) criticized this definition, specifically the absence of non-intellective (motivational) factors, the non-parallel nature of the six categories and failure by its authors to provide guidance against misinterpretation and misuse by practitioners. Reviewing the literature on the determinants of adult eminence in various professional fields, Renzulli brought to the fore what he claimed to be three recurring causal antecedents of exceptional productive performance; these became the constituent elements of his conception of giftedness. He synthesized his definition as follows.

Giftedness consists of an interaction among three basic clusters of human traits—these clusters being above average general abilities, high levels of task commitment and high levels of creativity. Gifted and talented children are those possessing or capable of developing this composite set of traits and applying them to any potential valuable area of human performance. Children who manifest, or who are capable of developing, an interaction among the three clusters require a wide variety of educational opportunities and services that are not ordinarily provided through regular instructional programs (1979, p. 23).

Over the years, Renzulli has kept his definition intact, defending it vigorously (see Renzulli & Owen, 1983; Renzulli, 1988, 1990) against various criticisms (e.g., Borland, 1989; Gagné, 1985; Gross, 1993; Jarrell & Borland, 1990; Jellen, 1985; Kontos et al., 1983a, 1983b).

Tannenbaum (1983) proposed a somewhat different definition. "Keeping in mind that developed talent exists only in adults, a proposed definition of giftedness in children is that it denotes their potential for becoming critically acclaimed performers or exemplary producers of ideas in spheres of activity that enhance the moral, physical, emotional, social, intellectual, or esthetic life of humanity" (1983, p. 86). Tannenbaum identified five factors that serve to link promise with adult fulfillment: "(a) superior general intelligence, (b) exceptional special aptitudes, (c) nonintellective facilitators, (d) environmental influences and (e) chance, or luck. The five factors combine in a rare blend to produce great performance or productivity" (1986, p. 34). Tannenbaum also subdivided developed talents into four categories: (a) *scarcity* talents comprising those exceptionally inventive people who are the architects of major breakthroughs in their field (e.g., science, medicine, social science and so forth), (b) *surplus* talents (mostly in the arts) that contribute to the beauty of our social environment, (c) *quota* talents, which refer essentially to specialized high-level skills—including the traditional professions—needed to provide goods and services and (d) *anomalous* talents which include practical domains of excellence (e.g., cooking, gardening), amusing ones (e.g., trapeze artist, memory expert, speed reader), "extinct" abilities (e.g., orator, stone cutter) and even socially disapproved skills (e.g., demagoguery, machiavellianism).

One of the more popular taxonomies of abilities introduced during the last decade is Gardner's (1983) theory of multiple intelligences. Each of Gardner's intelligences was chosen because it represented a culturally valuable and relatively autonomous set of skills for problem-solving, each with an identifiable basis in the human nervous system. He looked for signs of their existence in eight areas, presented here in decreasing order of importance: potential isolation by brain damage, manifestation in idiots savants or prodigies, an identifiable core set of operations, a distinctive developmental history, an evolutionary history, support from experimental psychological tasks, support from psychometric findings and susceptibility to encoding in a symbol system. Gardner identified in this way seven distinct "intelligences": the linguistic, the musical, the logical-mathematical, the spatial, the bodily-kinesthetic, as well as two personal intelligences: the intrapersonal and the interpersonal. To each of these intelligences corresponds a particular type of giftedness.

In contrast with Renzulli, Feldhusen has regularly made significant and even major modifications to his conception of giftedness. First, he proposed "that four major psychological components comprise giftedness: (1) superior talent and/or ability, (2) a high degree of motivation, (3) unique self-concept and perceptual characteristics, and (4) high-level creative capacities. Talents and abilities are diverse, ranging from the academic and artistic to the social and vocational" (1985a, p. 180). This model was soon significantly modified as follows: "Our composite conception of giftedness then includes (a)

general intellectual ability, (b) positive self-concept, (c) achievement motivation, and (d) talent . . . in focusing on these four aspects we are asserting that they constitute 'principal components'." (1986, p. 112). Feldhusen (1992) modified his position again recently. He presented a much more complex model, which assumes genetically determined abilities that emerge precociously. These are nurtured through the impact of community, family and school experiences, as well as emerging motivation and learning styles and create a functional knowledge base and metacognitive and creative skills. This last trio of elements finally produces various talents. He defined talent as "a complex of aptitudes or intelligences, learned skills and knowledge and motivations—attitudes—dispositions, that predispose an individual to successes in an occupation, vocation, profession, art, or business" (p. 5) and giftedness as "a complex of intelligence(s), aptitudes, talents, skills, expertise, motivations and creativity that lead the individual to productive performance in areas or domains or disciplines valued by the culture and time" (p. 5). Unfortunately, these two definitions overlap so much that giftedness and talent become almost synonymous. If giftedness is "a complex of talents", does it mean that talents are constituent elements of giftedness? If both include intelligences, aptitudes, skills and motivation, where is the difference? If there is no apparent difference, why take the trouble to produce two distinct definitions? Feldhusen's text does not answer these questions.

Sternberg, for his part, based his concept of giftedness on his triarchic theory of intelligence (1985) which brings together three subtheories, as follows.

The componential subtheory specifies the mental mechanisms responsible for the planning, execution and evaluation of intelligent behavior. The experiential subtheory further constrains this definition by regarding as most relevant to the demonstration of intelligence behavior involving either adjustment to novelty or automatization of information processing, or both. The contextual subtheory defines intelligent behavior as that involving purposive adaptation to, selection of, and shaping of real-world environments relevant to one's life (1986, p. 240).

Sternberg argued that giftedness could take many forms, corresponding to different combinations of the abilities typical of each of the elements of his theory. In his view, "the triarchic theory implies a notion of intellectual giftedness that is quite a bit broader than usual conceptions, event those that take into account creativity and motivation as well as intelligence" (p. 242). Davidson (1986) defined giftedness as insight ability, a complex of three distinct psychological processes borrowed from Sternberg's componential subtheory: selective encoding, selective combination and selective comparison. She found that measures of performance on insight problems discriminated clearly between intellectually bright and average children.

Finally, having described and discussed most of the above definitions and models, Borland (1989) proposed his own, which he deemed more functional or practical in the context of schooling. "For the purposes of education, gifted children are those students in a given school or school district who are exceptional by virtue of markedly greater than average potential or ability in some area of human activity generally considered to be the province of the educational system and whose exceptionality engenders special-educational needs that are not being met adequately by the regular core curriculum" (pp. 32–33).

The above citations and comments demonstrate that definitions and models of giftedness can incorporate a large variety of ingredients or components and that there is little consensus in the field. One common denominator of these definitions and models is their use of the concept of abilities as a central theme. For some authors, giftedness corresponds strictly to intellectual abilities (e.g., Sternberg, Davidson). Occasionally, these authors will mention that their definition concerns "intellectual giftedness" (e.g., Sternberg) implicitly acknowledging that other types of giftedness are possible; but, most of the time, these definitions contain no such qualification of the concept of giftedness. Some definitions, however, clearly include a variety of other abilities: leadership aptitude, physical abilities, artistic abilities (e.g., Witty, DeHaan and Havighurst, Marland, and Tannenbaum through his four types of talents). Even though he calls his various native abilities "intelligences", Gardner's taxonomy belongs in this second group, since he acknowledged that exact terminology was not a major issue in his taxonomy. He commented: "Call them all 'talents' if you wish; or call them all 'intelligences'" (Walters & Gardner, 1986, p. 175). Some definitions include human characteristics which are clearly outside the domain of abilities (e.g., Renzulli's task commitment, Feldhusen's self-concept, Tannenbaum's nonintellectual facilitators and chance factors). Some scholars reserve the label of "true" giftedness to adult accomplishments (e.g., Tannenbaum), judging children to manifest only "potential" giftedness. Some appear to reserve the term giftedness to a very small number of exceptionally superior performers or producers of knowledge (e.g., Tannenbaum's description of the adult gifted as "outstanding contributors to the arts, sciences, letters and general well-being of fellow humans": 1986, p. 33); others clearly mention a somewhat larger percentage of the population (e.g., Marland's 3% to 5%). In fact, most proponents of models and definitions do not specify the extension of their concept of giftedness or talent. Some definitions include the mention of special educational needs (e.g., Marland, Renzulli, Borland), while most do not. In a few definitions (e.g., Renzulli, Tannenbaum, Witty), giftedness is mostly associated with "socially valued" areas of human endeavor. Finally, most of these definitions focus on giftedness, without specifying how it differs, if it does, from talent. For instance, Marland clearly considers both terms to be synonymous—as do

most scholars in the field (Gagné, 1985). Tannenbaum appears to consider giftedness as a potential which actualizes itself in “developed talents”. Still, his definition implies that giftedness in adults corresponds to developed talent, a clear nondifferentiation between the two concepts. Taylor alone uses the label talent for his group of abilities; but he does not specify how these abilities are related to the concept of giftedness. Concerning the nature of the two central constructs of giftedness and talent, Gagné (1985, 1991) proposed a model which attempts to differentiate what types of abilities could be associated with each of them.

Gagné’s Differentiated Model of Giftedness and Talent

Gagné’s model associates giftedness with natural or non-systematically developed human abilities, called aptitudes and talent with systematically developed abilities or skills which constitute expertise in a particular field of human activity. More formally, “*Giftedness* corresponds to competence that is distinctly above average in one or more domains of human aptitude. *Talent* corresponds to performance that is distinctly above average in one or more fields of human activity” (1991, p. 66). The model specifies that the emergence of a particular talent results from the application of one or more aptitudes to the mastery of knowledge and skills in that particular field, mediated by the support of intrapersonal (e.g., motivation, self-confidence) and environmental (e.g., family, school, community) *catalysts*, as well as through systematic learning and extensive practice (see Figure 1).

APTITUDES

Aptitudes are “natural” human abilities; they have their origin in the genetic structures of the human organism; they appear and develop more or less spontaneously and are present in every human being, albeit with a large range of degrees, thus giving rise to individual differences. They can be observed in very young children in the absence of any systematic training or practice. When exercise and practice are controlled, they explain a major proportion of individual differences in talented performances. They are the main explanatory factor for the exceptional precociousness of children in school, of young musicians or chess players, of athletes who attain adult expertise at a very tender age. There has to be a genetic basis to each of these natural abilities for them to be defined as “gifts” or aptitudes; it is more than just having acquired some particular knowledge or skill which will make possible the acquisition of further knowledge. The main behavioral index for a high degree of a particular aptitude is easy and rapid learning of the knowledge and skills governed by that aptitude. Even though aptitudes have a significant genetic component, their growth is by no means controlled solely by maturational processes; environmental stimulation plays an equally important role through daily use and informal training (e.g., physical conditioning, problem-solving exercises in school, crosswords, creativity workshops, voluntary social work and so forth).

The model identifies five aptitude domains: intellectual, creative, socio-affective, sensorimotor and others. Intellectual aptitudes are by far the better known and more extensively studied. They could be subdivided into a few or many subcategories, depending on the

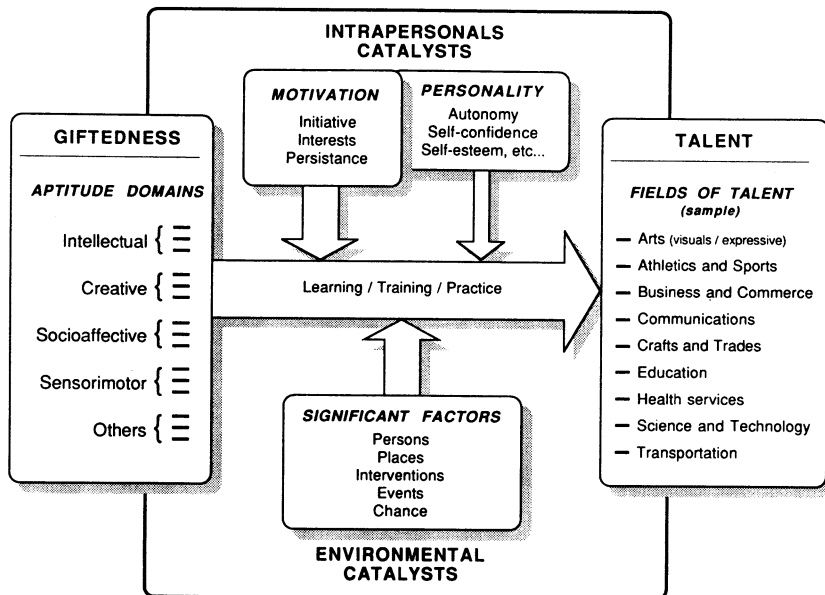

FIGURE 1. Gagné’s differentiated model of giftedness and talent.

theoretical system adopted. The identification of a separate category for creative abilities may not be equally well received by all scholars, some judging creativity to be little more than the exercise of intellectual abilities confronted with a problem-solving situation (Weisberg, 1988), others judging that there are as many creative abilities as there are fields in which original ideas can manifest themselves, at least qualitatively (e.g., Perkins, 1981; Runco, 1987). The category was maintained because there is a fairly large community of scholars who are convinced that there exists "an ability to respond *adaptively* to the needs for new approaches and new products. It is essentially the ability to bring something new into existence purposefully" (Barron, 1988, p. 80). Because it is presented as one aptitude category among others, creativity is given a more modest role in Gagné's model than in some others. Gagné (1985) points out that creativity is not a key ingredient of talented performance in many fields (e.g., athletics, musical interpretation, business administration, teaching, nursing and so forth). This position becomes a major point of divergence between Gagné's model and Renzulli's definition in which creativity is described as an essential component of giftedness. Similarly, Tannenbaum clearly distinguishes "consumers" of knowledge from "producers" of knowledge, only these last being judged "truly gifted" (1983, p. 86). He also points out that we may regard giftedness as "extraordinary promise for productivity or performance in areas of work that are publicly prized; it is not a facility for consuming knowledge in abundance or at a rapid pace" (p. 89). In direct opposition with this statement, if there is one characteristic that could be considered common to all domains of aptitude in Gagné's model, thus to all gifted persons, it is their facility and rapidity in acquiring new knowledge and skills and in generalizing this new knowledge to adjacent areas of the domain.

Socio-affective aptitudes have been explored much less; the mapping of subcategories in this very large domain is still quite deficient. A non-exhaustive list surely includes abilities useful in social intercourse, empathy or the ability to perceive the points of view and feelings of others, social influence (e.g., leadership), manipulation and so forth. Research (see Janos & Robinson 1985) suggests a clear distinction between social intelligence, corresponding to knowledge about adaptive social behavior, and social behavior itself. It appears that intellectually gifted children demonstrate precociousness in social intelligence, but not necessarily precocious behavioral abilities in their relationships with peers and adults. Sensorimotor aptitudes take many forms. On the sensory side are all the abilities related to each of the five senses: the visual acuity of the marksman, the sound discrimination of the musician, the odor recognition of the perfume maker, the taste differentiation of the wine specialist and so forth. On the motor side there is speed, endurance, strength, reflexes, dexterity, balance, etc. The last category, "others", acts as an "expansion port" for less recognized and studied

natural abilities (e.g., extra-sensory perception, gift of healing). Except for the "others" category, there is incontrovertible evidence concerning the heritability of the above aptitude categories (Gardner, 1983; Plomin, 1986, 1989). Scarr (1981) stated:

Not only my work but research by many others also supports the modest conclusion that we are different from one another on both genetic and environmental bases—not only in intellectual ability but also in personality, cognitive style, gestural and postural communication, linguistic style and probably all other measurable characteristics. I am hard pressed to think of any aspect of human behavior for which genetic as well as environmental differences will not explain part of the variability (pp. 526–527).

Plomin (1989) similarly commented:

The first message of behavioral genetic research is that genetic influence on individual differences in behavioral development is usually significant and often substantial. Genetic influence is so ubiquitous and pervasive in behavior that a shift in emphasis is warranted: Ask not what is heritable, ask what is not heritable (p. 108).

INTRAPERSONAL CATALYSTS

The model distinguishes two types of catalysts: intrapersonal and environmental. Intrapersonal catalysts include human characteristics which are outside the domain of abilities. The most visible of these catalysts, as observed by Renzulli, is motivation. But, Renzulli's task commitment is only one of the three recognized consequences of motivation on behavior; motives *initiate* or activate behavior, they *direct* and guide it and they *maintain* it in the presence of obstacles until satisfaction of the need. At least as important as task commitment for the development of talent is the directional energy, variously called curiosity, inquisitiveness, specific interests, or intrinsic motivation (Deci & Ryan, 1985). Not much appears to be known about the origins of interests (Schiefele, 1991); but recent research suggests that vocational interests have a genetic component (see Plomin, 1986). The third aspect of motivational energy, initiative, has not been the object of much study. There also appears to be no research concerning relationships between these three types of effects of motives on behavior. For instance, is it possible for some individuals to show high interest in some area without the accompanying persistence to pursue that interest with the commitment and doggedness that others would apply?

Many other human characteristics, besides motivation, have been associated in the literature with the presence of intellectual aptitudes and academic talents in children and adults. To name but a few, there are self-confidence, self-esteem, autonomy, locus of

control, as well as moral judgment, emotional maturity and general mental health (Janos & Robinson, 1985). Again, increasing evidence (Plomin, 1989; Bouchard et al., 1990; Neubauer & Neubauer, 1990) suggests that personality factors do not escape being under partial genetic influence. But, there are some reservations concerning the causal significance of these personality characteristics. First, most of the research has focused on comparisons between intellectually gifted (high IQ) children or adolescents and average age-peers; much less is known in other aptitude domains. Second, it is quite clear (see Roedell et al., 1980) that the observed differences do not explain a very large percentage of the total variance between groups; *within* group differences remain very important. Finally, the causal direction of influence is not always clear. For instance, does self-confidence cause talent, by supporting the individual during his process of skill development, or is it an effect brought about by the satisfaction of having achieved competence in a field of talent?

ENVIRONMENTAL CATALYSTS

Environmental catalysts can be subdivided into five distinct categories: (a) significant persons, (b) significant physical environments, (c) significant interventions, (d) significant events and (e) chance. The role of significant persons is one of the best documented sources of impact on talent development. The literature is replete with studies about the role of parents, siblings, teachers, trainers, public figures playing the role of identification models and so forth. This role was particularly emphasized in Bloom's (1985) study of national leaders in six talent fields: concert pianists and sculptors in the arts, mathematicians and research neurologists in the cognitive domain, olympic swimmers and tennis players in the psychomotor domain. It also comes out clearly in interviews with eminent scholars who obtained the prestigious MacArthur award in the form of "no strings attached" five-year grants (Cox et al., 1985). Physical environments are usually taken for granted, without realizing their significant role. For instance, children in rural areas or in developing countries often have less access to environmental resources for talent development. Even geographical features can play a significant role: there are few talented downhill skiers from the tropics or Netherlands, or talented sailors from landlocked countries.

The category of significant interventions covers community resources. Many of them do not harbor the label "gifted or talented program" (e.g., summer camps, math or science clubs, Saturday art courses, the international baccalaureate curriculum, selective high schools), but in fact respond in some degree to enrichment needs felt by gifted and talented youngsters. Programs can be classified along three main dimensions: content, setting, density. *Content* refers to the program's activities, hopefully related to the type of ability being nurtured: aca-

demically subjects, artistic activities, athletics, leadership training, etc. *Setting* refers to the insertion of enrichment programs in the regular classroom as compared to various forms of part-time or full-time ability grouping. *Density* refers to the presence or absence of accelerated progression (e.g., early entrance, grade skipping, radical acceleration); it is to be distinguished from curriculum compacting (Reis, Burns, & Renzulli, 1992) whereby the more rapid learning remains within the boundaries of the year's curriculum; accelerative alternatives may be introduced to fill the learning space created by the compacting. The fourth category, significant events, is related to specific moments in the life of individuals which have a lasting impact on their vocational decisions, or on the choice of a non-vocational investment in a captivating leisure activity or in some form of community service. This category has been borrowed from Walters and Gardner's (1986) "crystallizing experiences", which they define as follows.

A crystallizing experience, then, is the overt reaction of an individual to some quality or feature of a domain; the reaction yields an immediate but also a long-term change in that individual's concept of the domain, his performance in it and his view of himself. . . . Only retrospectively, after the individual's behavior in the postcrystallizing period has been observed, is it possible to single out an experience as having crystallized ensuing activities (p. 309).

Finally, chance as an environmental catalyst plays a role which is probably much more critical than is usually recognized in the literature, if not in personal testimonies. In fact, only Tannenbaum (1983) has examined in some detail the role of chance factors. He mainly presents Austin's (1978) hierarchical "quatuor" of chance factors: (a) the stroke of good luck falling upon a passive recipient, (b) the increased likelihood of being struck with good fortune through constant active exploration of the environment (the Kettering principle), (c) the luck of being the right person at the right time at the right place, but having the sagacity to grasp the significance of an unforeseen event (the Pasteur principle) and (d) the luck of those with "altamirage," defined by Austin as a facility for becoming lucky through a distinctive and uncommon lifestyle (the Disraeli principle).

TALENTS

No category system could do justice to the immense variety of talents manifested by children and adults in all walks of life. They do not only include the more traditionally mentioned fields of academia (humanities, social sciences, health sciences, physical sciences, mathematics) and those of the arts (drama, visual arts, music, dance, etc.), but also fields which are regarded as less elitist, like athletics and sports, technology, crafts, popular entertainment, business and administration and so forth. The classification systems of fields of talent

created for the Strong Vocational Interest Inventory (SVII) is one of the most comprehensive (Campbell, 1977). It is based on Holland's RIASEC system of six basic personality types (Realistic, Investigative, Artistic, Social, Enterprising, Conventional), to which are associated 23 basic interest configurations, like agriculture and mechanics (R), science and medicine (I), music and writing (A), teaching and social service (S), merchandizing and public speaking (E) and office practices (C). The RIASEC system serves also to label dozens of more specific occupations, professional as well as technical. The SVII's structure of fields is a more basic way of organizing talents than Tannenbaum's fourfold system (scarcity, surplus, quota and anomalous) mentioned earlier; in this last case the principle of classification is only indirectly related to the nature or content of the talent. Moreover, Tannenbaum's categories are not mutually exclusive, since scarcity talents are but the more creative and innovative expressions of quota talents.

The talent component of Gagné's model is totally compatible with Csikszentmihalyi's (1988) distinction between "domains" of knowledge and "fields" of human endeavor. His domains correspond to self-sufficient areas of knowledge (e.g., physics, literature, music, sculpture, engineering, history) embedded in a particular culture at a given time. The field corresponds to the social organization of the domain; it designates all the individuals who have attained definite competence or expertise in the domain, including those who have achieved clear eminence; among other things these people guide the evolution of the domain by acting as judges of the creativity and originality of their peers' productions.

LEARNING, TRAINING AND PRACTICE

This component of the model illustrates more than the others the longitudinal dimension of talent development. The growth of aptitudes and talents can be accounted for by four developmental processes: (a) maturation, (b) daily use in problem-solving situations, (c) informal training and practice and (d) formal training in a particular field of activity. The first two processes directly contribute only to the development of aptitudes. The third process can foster the development of both aptitudes and talents; its role in the development of aptitudes has already been emphasized. In the case of talent development, it is quite common to observe individuals learning by themselves to play a musical instrument or to master a craft or a sport, some of them achieving respectable levels of proficiency and expertise. Moreover, the administrative practice in some schools and colleges to offer credit by examination demonstrates that many individuals can develop their academic talents outside formal educational environments. Systematic and formal training is the usual way

to develop talents in any field, especially when aspiring to high level proficiency. Granted that many pupils can go through primary school and even high school without much studying; but the higher one goes up the educational ladder, the more effort will be needed to succeed. The apparent facility with which very talented persons perform their skills, be they scientists, artists, craftsmen or athletes, can easily make us forget the hundreds and thousands of hours which were necessary to build progressively that level of talent. And the higher the talent, the longer the investment in time and effort. This confirms eloquently Edison's famous comment about genius being 1% inspiration and 99% perspiration!

INTERACTIONS AMONG COMPONENTS

Each component of the model can have an impact on any of the others and it can be shown that these relationships are bidirectional. It would not be hard to find in the research literature support for each of these relationships. For instance, the link between intellectual aptitudes and academic interests, namely that more able students are more intrinsically motivated toward learning activities and school subjects, is well documented (Deci, Vallerand, Pelletier, & Ryan, 1991). Conversely, there is frequent mention—yet little research—that some interests emerge from a satisfying exercise of one's aptitudes in a particular field of talent. As Bloom said: "We believe an individual tends to like those activities which he believes he has done or can do successfully" (1976, p. 78). Concerning relationships between intrapersonal and environmental catalysts, it is recognized that parents (or teachers) will tend to be more attracted and give more support to youngsters who manifest intense interest and motivation in their field of talent. Again, the inverse causal relationship is equally plausible: support by parents can have an impact on the motivation and persistence of people actively pursuing excellence in a particular field of talent, as Bloom's (1985) study mentioned above has clearly shown. Most pairings could in the same way be documented with appropriate empirical studies.

Other forms of relationships between the components can be mentioned only briefly here (see Gagné, 1991, for more detail). First, relationships between aptitudes and talents are co-univocal; it means that a given aptitude can contribute to the development of many different talents; conversely, any talent can draw its underlying abilities from more than one aptitude domain. Second, in direct opposition to Renzulli's three-ring conception of giftedness, Gagné maintains that no aptitude can be considered a prerequisite for the emergence of every talented behavior. For instance, above average intellectual abilities are not essential to attain a fairly high level of excellence in many fields of talent (e.g., athletics, crafts, arts); yet, they might be required for

emergence among the most exemplary performers in a field. Similarly, creative abilities do not always play a central role. As Gagné (1991) argued:

What about celebrated athletes, whose accomplishments make international headlines; musicians of international repute; teachers or professors who have positively influenced their students; and many others who have attained a certain prominence, if not absolute renown, by means of interpretive performances or other skills, and not principally through creative aptitudes? (pp. 69–70).

Third, by definition, a talented person is also gifted, but a gifted person might not be talented, as evidenced by underachieving gifted youngsters. Finally, two persons can call upon different components to attain an identical level of talent. Some youngsters can cruise along in high school without any studying, little motivation and minimal parental support, if they have very high intellectual abilities. Friends in the same class might achieve at the same level, but they would have to make up for a lower level of native intellectual abilities with greater motivation, harder work and/or more intensive environmental support.

GAGNÉ'S MODEL IN HISTORICAL PERSPECTIVE

A close examination of the definitions sampled at the beginning of the chapter clearly shows that Gagné's model is not radically different from many of them. In fact, it is foreshadowed in many expressions used by their authors, especially the distinction between potentialities and their eventual confirmation in "developed" or fully-fledged abilities and skills. Marland's "those with demonstrated achievement and/or potential ability", Renzulli's "those possessing or capable of developing this composite set of traits and applying them to any potential valuable area of human performance", or Tannenbaum's "their potential for becoming critically acclaimed performers or exemplary producers" represent clear examples of such a distinction. It is also encountered in most discussions of the characteristics of gifted and talented persons. For instance, Renzulli (1979) criticized Marland's categories as follows:

Two of the six categories (specific academic aptitudes and visual and performing arts) call attention to fields of human endeavor or general performance areas in which talents and abilities are manifested. The remaining four categories are more nearly processes that can be bought [*sic*] to bear on performance areas" (1979, p. 7).

In this text Renzulli was in fact arguing for a differentiation between two of Gagné's fields of talents and four of his aptitude domains: general intellectual ability (intellectual aptitudes), creative and productive thinking (creative aptitudes), leadership ability (part

of his socio-affective domain) and psychomotor ability (part of his sensorimotor domain). Scholars have thus been struggling for some time with this duality of notions. One major hurdle to a more general acceptance of a distinction between natural and developed abilities before the 1980s was the "political incorrectness" of acknowledging the existence of "natural" abilities which had a genetic origin and, consequently, the partial hereditary foundation of observed individual differences among children and adults. In other words, the reigning environmentalism of the 1960s and 1970s totally refused to accept the existence of inequalities that could not be corrected by *any* form of social intervention. The weight of the evidence finally succeeded in bringing about a more objective view of the respective roles of nature and nurture in the development of human abilities, predispositions and traits.

Comments

It is time to examine some of the discrepancies signaled earlier between the definitions and models sampled. These will be discussed on logical grounds as well as in the light of Gagné's differentiated model of giftedness and talent.

GIFTEDNESS, TALENT AND ADULT ACHIEVEMENT

Some definitions and models of giftedness state, either explicitly or implicitly, that "true" giftedness is restricted to adult achievements; this corresponds to Stankowski's first category mentioned earlier. This tendency appears not only in Tannenbaum's "keeping in mind that developed talent exists only in adults", but also in the fact that most examples of gifted behavior describe the extraordinary accomplishments of historical figures in science (Einstein, Freud), arts (Mozart, Picasso), or the humanities (Kant, Gandhi). The impression one gets is that children manifest only "potential giftedness". Tannenbaum (1986) even says it explicitly in the following passages: "Children who are identified as potentially gifted" (p. 33), "because it excludes too many children who may grow up to be gifted" (p. 33) and "factors that link promise with adult fulfillment" (p.34). "Potential giftedness" is totally irreconcilable with Gagné's model. In the model, potential *is* giftedness in the sense that aptitudes, even though measured as performances on tests of (intellectual, creative, social, or physical) abilities, represent existing natural abilities which are called upon by an individual aspiring to master the skills of a particular field of talent. In fact, giftedness is *potential talent*, whether it is observed in children or adults. As defined by Gagné, giftedness can be observed in very young children, as well as in adolescents and adults, as long as the

term refers to the natural, partly inborn, abilities of individuals.

Talent itself can appear at a very early age, as confirmed by various forms of precociousness in school learning, arts and athletics. But, the developed skills of the talented usually manifest themselves from adolescence onward. Consequently, following Gagné's differentiated model, the adult accomplishments of eminent figures in any field should be labeled talents insofar as the products of their developed skills are the reason for their eminence; these individuals would represent instances of exceptional talent. Their giftedness would be implicitly recognized through their talents. Unfortunately, the label talent is rarely used in the case of extraordinary accomplishments. One possible reason might be an implicit hierarchy between the two terms in the mind of some scholars: giftedness would correspond to a superior level of abilities. Some have explicitly proposed such a distinction: Robeck (1968) applied the word talented to individuals with IQs in the 130–145 range, while IQs ranging from 145 to 160 received the label gifted. Similarly, when laypersons were asked to describe the difference they perceived between being gifted and being talented, some argued that giftedness was more exceptional, less common than talent (Gagné, Motard, & Bélanger, 1991). It is hard to assess how widespread this implicit, almost unconscious, vertical distinction is; but it can substantially affect the understanding and acceptance of Gagné's differentiated model.

GIFTEDNESS, TALENT AND INTELLIGENCE

By proposing five general domains of giftedness, Gagné's model radically differs from all models and definitions which restrict giftedness to cognitive abilities (Stankowski's second category). Such restricted definitions abound, going back to Terman's in the 1920s. Two have already been described: Sternberg's triarchic theory and Davidson's insight "subtheory"; two more appeared in Sternberg and Davidson's (1986) book. Jackson and Butterfield (1986) proposed an apparently large and encompassing definition of gifted performance: "A gifted child is one who demonstrates excellent performance on any task of practical value or theoretical interest" (p. 155), adding that they saw "no reason to exclude from our definition skills that are predominantly physical, artistic, or interpersonal" (p. 155). But, they went on to explain these performances strictly in terms of cognitive constructs: cognitive efficiency, knowledge base, strategy use and metacognition. Borkowski and Peck (1986) described a very similar explanatory model of gifted behavior, based on the Campione–Brown model of intelligence (Campione & Brown, 1978). It posits two hierarchical levels of intellectual processing, namely an elementary *architectural* level of perceptual efficiency and a higher *executive* level calling upon a knowledge base, a set

of strategies for learning and problem solving and a metacognitive component.

All these strictly cognitive models of giftedness would be totally compatible with Gagné's model if they specified that they attempt to circumscribe *intellectual* giftedness. Unfortunately, it is not always clear that their concept of giftedness allows for other forms of natural abilities besides intelligence. As soon as one accepts to associate giftedness with natural abilities, it should follow "naturally" to recognize that these abilities extend well beyond the cognitive domain. If we disregard their name, Gardner's seven "intelligences" correspond to such a list of natural abilities, the more so when taking into account their eight selection criteria. It can be seen that they are closely related to Gagné's aptitude domains. Gardner's linguistic, spatial and logical-mathematical intelligences would all become subcategories of Gagné's intellectual aptitudes domain; the musical and bodily-kinesthetic intelligences would fall in his sensorimotor domain; the two personal intelligences (intra/inter) would become subcategories within his socio-affective domain. In short, if intellectual giftedness is but one form of giftedness, then the general concept of giftedness must be defined in such a way as to include all manifestations of giftedness in all domains of human behavior. A reduction of giftedness to superior intelligence is identical to a reduction of human abilities to intellectual ones, as so many scholars have done in psychology and education (e.g., Lohman, 1989; Horn, 1976; Guilford, 1985). One wonders if this "cognocentrism" might not be an indirect form of elitism: could non-intellectual abilities be overshadowed, sometimes even ignored, because they are *felt*—more than judged—to be less noble than intellectual ones?

GIFTEDNESS, TALENT AND JURISDICTIONS

According to Davis and Rimm (1985), the United States Office of Education decided to remove psychomotor ability from the list of performance domains because "artistic psychomotor talents (for example, dancing, mime) could be included under performing arts, and athletically gifted students are already very well provided for" (p. 11). This was an unfortunate decision from the point of view of the defining process. General definitions of concepts should never be limited or influenced by practical or political considerations. Definitions and applications are two distinct operations. Program conceptors could well decide to consider and implement only certain aspects of a broadly defined concept; there is no need for a procrustean modification of the definition to make it fit a particular context. In a similar fashion, Borland (1989) specified that gifted children had to demonstrate their superior ability "in some area of human activity generally considered to be the province of the educational system" (p. 33). To be completely fair, it must be pointed out that

Borland qualified his definition by stating at the outset “for the purposes of education”. Still, it would have been preferable first to define the full concept of giftedness, then to specify which subpopulation would be considered in a particular context. For example, it is quite easy to specify that a given program addresses the special needs of the subgroup of mathematically talented youths, as Julian Stanley did in the Study of Mathematically Precocious Youth (Stanley et al., 1974); there is no need to restrictively define the talented as those who manifest mathematical abilities.

Borland’s restricted definition evolved from his criticism of “disjunctive multitrait” definitions of giftedness (e.g., Gagné, Gardner, Marland, Witty), which he found difficult to operationalize because they generated numerous subgroups of gifted children. “One need only imagine the complexity of the identification and programming plan that would have to be put into effect in a school district” (1989, p. 12). This argument raises at least two objections. First, the complexity of a problem should never be an argument to abstain from addressing it; most problems our technological societies now face are very complex indeed (e.g., environmental issues, international trade accords, civil wars and other disputes between nations); should we decide not to address them for such a reason? Second, some schoolboards have succeeded in offering a large variety of services that cater to the needs of diverse groups of gifted and talented youngsters: special high school programs in science, literature, foreign languages, etc.; programs or special schools in fine arts, drama, dancing; music conservatories; special schedules for those active in athletics; and so forth. The diversity in available responses is there; schoolboards can draw from a long list of efficient and successful programs (see Juntune, 1986). In short, disjunctive multitrait definitions need not be an obstacle to effective programming; on the contrary, they open the door to more adequate and specific responses to the particular educational needs of the diverse subcategories *within* the population of gifted and talented children and youths.

GIFTEDNESS, TALENT AND PERSONALITY

Many scholars introduce in their definitions “non-ability” or personality factors; recall Renzulli’s task commitment, Tannenbaum’s nonintellective facilitators, Feldhusen’s self-concept and achievement motivation. These characteristics are referred to in the scientific literature by various labels: tendencies, predispositions, traits, temperaments, drives, motives, etc. Should such elements be part of a definition of giftedness or talent? *Definitions* of concepts focus essentially on their constituent elements; *descriptions* of concepts and constructs can include more peripheric information. If we accept that the core of the giftedness concept is natural abilities, then we must exclude all non-ability

characteristics. Indeed, intellectual giftedness will be assigned as a label if a person demonstrates—through an IQ test or any appropriate measure of intellectual functioning—intellectual competence which is markedly above average; no other criterion is necessary for the label to be correctly ascribed. It follows that any underachieving pupil who obtains an IQ of 130 or more should be considered gifted, even if that pupil displays no school motivation whatsoever, low self-esteem, a total absence of confidence and autonomy, etc. The IQ alone is sufficient evidence of intellectual giftedness. Similarly, if adults are assessed as to their physical condition and show superior strength, or endurance on a treadmill, or flexibility, they should be recognized as physically gifted, even if they had never practiced any sport or athletic activity, showed no interest whatsoever in such pursuits and suffered from major personal and/or social inadaptations. The superior natural ability *is* giftedness and nothing else is needed for the label to be appropriate.

Is the situation different in the case of talents? Not at all; the same distinction holds between definitions of talent as opposed to descriptions of talented persons. If we accept that talent corresponds to “performance that is distinctly above average in one or more fields of human activity” (Gagné, 1991, p. 66), then only the constituent elements of that performance, namely the developed abilities and skills, belong in the definition itself. Talent in piano playing is nothing but a level of performance that is distinctly above average; academic talent is nothing but a level of achievement that is distinctly above average; talent in swimming is nothing but a level of performance that is distinctly above average; and so forth. No doubt that talented persons in a given field exhibit some personal characteristics that differentiate them somewhat—on average—from those who are less talented in that field; hundreds of such comparative studies have shown statistically significant differences on a large inventory of personality constructs (see Janos & Robinson, 1985). But, these characteristics are not *constituents* of the talented performance; they may act as contributors, facilitators or catalysts in the development of talent, or appear and develop as a result of the talented performance. Talent development requires the support of these facilitators, probably the more so if the person aspires to a very high level of talented performance, but they are not components of the talent itself. Among the elements in Gagné’s model, only aptitudes come close to being constituents of talents, insofar as the developed skills result from the systematic training and exercise of natural abilities in a specific and restricted context. The musician’s dexterity on the keyboard, the neurosurgeon’s dexterity when operating, the dexterity of the potter or that of the graphic artist, all have their origin in a more general psychomotor aptitude. There is a proximity of nature between aptitudes and talents which is not found between catalysts and talents. Still, there remains a difference in kind between natural abilities and developed skills, a difference clear enough

to become the foundation of the distinction between gifts and talents in Gagné's model.

The description of Gagné's aptitudes and catalysts as contributors to talent development resembles Tannenbaum's presentation of the components of his star model as "five psychological and social linkages between promise and fulfillment" (1986, p. 34). If they act as linkages (Gagné's catalysts?), then none of them should be a constituent element of either "promise" (Gagné's aptitudes?) or "fulfillment" (Gagné's talents?). In fact, two of them—general intellectual ability and special abilities—are clearly described by Tannenbaum as intellectual aptitudes (general vs specific). The logical problem is that they cannot be at the same time constituents of the "promise" and linkages between promise and fulfillment. Apart from this problem in the structural organization of its components, Tannenbaum's model presents many close similarities with Gagné's differentiated model of giftedness and talent.

GIFTEDNESS, TALENT AND SPECIAL EDUCATIONAL NEEDS

Marland's definition specifies that gifted children "require differentiated educational programs and/or services beyond those normally provided by the regular school program"; both Renzulli's and Borland's definitions also include a very similar remark about gifted children's special educational needs and the imperfect response of the regular curriculum. This type of information should not be included in a definition of giftedness and talent for the same reason that personality factors were excluded: special educational needs are not constituent elements of either giftedness or talent. Moreover, this characteristic applies only to children. Such exclusion is not meant in any way to negate or attenuate their relevance and importance in the context of providing for the maximal development of each child's aptitudes and personality. It simply means that such needs should be introduced as part of descriptions of gifted children, but outside the definition of the concepts of giftedness and talent.

GIFTEDNESS, TALENT AND VALUES

Some definitions, mostly the disjunctive multitrait ones, call upon a value system to specify what types of superior performances will be labeled gifted or talented. For instance, Witty (1958) spoke of "potentially valuable lines of human activity", while Jackson and Butterfield (1986) used the much broader expression "any task of practical value or theoretical interest". Tannenbaum (1983) was probably the most explicit. First, he circumscribed giftedness to "spheres of activity that enhance the moral, physical, emotional, social, intellectual, or aesthetic life of humanity". Then, he introduced the four

categories of talents already described (scarcity, surplus, quota and anomalous). It is a very hierarchical system, with scarcity and surplus talents—judged equally valuable—at the top and anomalous talents at the bottom. When confronted with the definition, this taxonomy raises a few questions. For instance, if gifted (talented?) adults must become "critically acclaimed performers or exemplary producers of ideas", will these labels be restricted to those few exceptional individuals who are recognized as members of the scarcity and surplus categories? What becomes then of the talented in the two other categories? Will they be considered "just" talented, but not gifted, thus confirming our earlier hypothesis about a possible hierarchical relationship between the two terms? Moreover, if giftedness must appear in "spheres that enhance the moral . . . life of humanity", what happens to "anomalous" talents, which include "socially disapproved skills such as wily interpersonal behavior and demagoguery" (1986, p. 25). Are these to be labeled talents but not gifts? Values also creep up in less explicit ways. As mentioned earlier, scholars who choose all their examples in certain fields of human endeavor, usually the sciences, the arts and the humanities—the noble ones—are indirectly creating a hierarchy between these more desirable or highly valued talents and other less desirable ones (e.g., technology, popular arts, athletics and sports, business and administration).

The preceding discussion brings forth some of the problems generated by the introduction of values in the definition of gifts and talents. First, there is a logical problem similar to the one mentioned above in relation with jurisdictions, namely a confusion between definitions and applications. It was said that definitions should not be modified to take into account practical or political problems; what should be done is to select those aspects of the definition which are applicable to a particular context. The problem here is identical. The value system should not appear as part of the definition of gifts and talents, but be brought up instead when discussing which particular gifts and talents should be fostered and nurtured by the schools or the community. Modifying the definition to make it congruent with the values of a particular culture or societal subgroup is analogous to censure. Second, the value systems usually proposed definitely have an elitist flavor, inasmuch that they introduce a ranking of talents more congruent with the values of a certain intellectual elite, with science and arts near the top of the scale and everything else at a lower level (as is the case with Tannenbaum's quota and anomalous talents). These hierarchies only give lip service to more popular talents, like rock music, athletics and sports, crafts and trades, home activities (cooking, gardening, renovating, interior decorating, sewing and so forth). Why do scholars rarely describe the talents of popular singing stars, athletes in sports, talented landscape gardeners, chefs, teachers and so forth? Why analyze the lives of music composers much more frequently than those of talented performers? Why mention only the doctors who invent new techniques or

do research and never those who excel in diagnosing, in performing surgery, or in their socioaffective rapport with patients? Why never give examples of successful entrepreneurs, effective administrators, proficient salespersons and so forth? Why put aside the excellence of a top notch auto mechanic, a superior electrician, or a very talented social worker? A more "democratic" approach to the categorization of talent fields would undoubtedly allow many more individuals to feel that they deserve the label "talented", that it is not the exclusive preserve of a small group of more prestigious fields or subfields of human activity.

Finally, the inclusion of a value system automatically implies the exclusion of "socially reprehensible" gifts or talents. Does it mean that the sexual abilities of a Don Giovanni or a geisha, the social abilities of a Machiavelli or a con artist, the intellectual abilities of a Mafia leader or a successful drug dealer cannot be labeled gifts or talents? Negating their existence does not prevent them existing by any means. They can even be the object of much praise and respect in certain subcultures. There exist many areas of the underworld in which individual differences in ability can manifest themselves: pickpockets, counterfeit artists, robbers, swindlers, assassins, etc. The dexterity of a very talented pickpocket is no less a superior human ability than that of a talented neurosurgeon! Both should be considered equally talented in their respective fields. Similarly, how can we not acknowledge the superior intellectual and social abilities of dictators like Hitler, Stalin, Fidel Castro, Mobutu Sese Seko and so many others who succeeded in maintaining for years their power over their fellow citizens. Talent is a distinctly superior performance no matter what the field of activity is. Giftedness is superior natural abilities whichever way they will be developed, in the same way that a knife remains a knife whether it is used to cut bread or maim people. A value system is most useful to help us decide which talents we will promote and foster, but not to define their nature and extension to domains and fields of human activity.

In summary, it has been shown that the concepts of giftedness and talent can be clearly differentiated by grouping under the term giftedness the large diversity of natural abilities or aptitudes (intellectual, creative, socioaffective, sensorimotor, others) that humans from every culture manifest to varying degrees; the concept of talent encompasses for his part the complexes of developed skills that characterize the hundreds of areas of human activity in such larger fields as technology, crafts, science, arts, social service, athletics, business and so forth. It has been argued that the comprehension of both concepts is restricted to these two types of abilities. Definitions should thus *exclude* reference to any other descriptive characteristics, whether they be personality traits, special educational needs or particular values. These do not belong to the definitions of the concepts, but to more general descriptions of gifted and talented persons.

The Extension of Giftedness and Talent

The extension of a concept can be understood in two different ways. The more common meaning refers to the demarcation between the central constituents of a concept and other more peripheral elements which appear to be closer to the central constituents of another concept. This first meaning has already been addressed "extensively" in the preceding pages. The second meaning ensues from the *normative* nature of the concepts of giftedness and talent, which is given concrete expression by the words "distinctly above average" in Gagné's definitions of both concepts. Still, this expression is not very precise because of its qualitative vocabulary; its quantitative operationalization directly addresses the problem of the *prevalence* of gifted and talented individuals within the general population. In other words, it corresponds to a search for the *lower bound threshold* between those who do not qualify to be labeled as gifted or talented and those who do.

This is one of the most important questions in the field of gifted education. Not only is it among the first questions asked by media people and laypersons, but it also has a major practical impact through its role in the identification process: it determines the size of the subgroup who will benefit from any enrichment activities offered in the school. Strangely, in contrast with its presence among the main interrogations of the population, the question of prevalence has been among the least discussed by specialists in the field. Indeed, only Marland's definition among those described at the beginning of this chapter specified a prevalence estimate. Gagné (in press) observed that it is rarely discussed in textbooks; usually, one finds mention of the two most frequent cutoff scores: an IQ of 130 for intellectual giftedness and a percentile of 95 for academic achievement, both placing prevalence at 2% to 5%, like Marland did. Sometimes, much more "generous" thresholds are proposed. For instance, Renzulli (1986) stated that the Talent Pools of his Revolving Door Identification Model should include at least 15% to 20% of an average school's population. In the United States of America, state norms follow the more restrictive tendency of a 5% ceiling (Mitchell, 1988).

If explicit positions are rare on the subject of prevalence, implicit ones abound, mainly through the identification procedures adopted by program planners, school administrators and researchers. Laypersons also have their own opinions on the subject. In the only existing survey on the prevalence estimates of laypersons, Gagné et al. (in press) asked a heterogeneous sample of adults to quantify their perceptions of prevalence; one half of the sample was queried about "gifted" individuals, while the other half received the "talented" version of the question. Estimates ranged from 1% to 99% in both cases, with respective means of 19% and 36% for the gifted and talented versions, but with very large standard deviations of 18% and 30%. Three things stand out from these results: (a) there is a large diversity of opinions

among laypersons in terms of their perceived prevalence of gifted and talented individuals, (b) a majority of these popular estimates are higher than even the most generous values advanced by professionals and (c) there is a very significant discrepancy between estimates for gifted as compared to talented persons.

The Problem of the Threshold

The main obstacle to a more specific and consensual position on the subject of prevalence is undoubtedly the arbitrariness of any cutoff point placed on a continuous score distribution to mark the "end" of normal abilities and the "beginning" of gifted or talented performance. As Gagné (in press) comments:

To be sure nobody questions the talent of the top 1% in a population nor the fact that being just a bit above average—below the upper third for instance—is not sufficient to be recognized as gifted or talented. But, between these clear marks lies a large grey zone of disputable performances; the more strict or selective one will be, the higher the threshold will be placed.

How can this threshold be targeted more precisely within that large grey zone? Could additional criteria help pinpoint with more precision the threshold's position, for instance special educational needs or observed performance in an enrichment program? Such an approach brings forth the same logical problem already mentioned in connection with the comprehension of the concepts: scholars relying on such criteria would no longer be assessing the prevalence of gifted or talented persons per se, but of "gifted or talented persons with special educational needs", or "gifted and talented persons who benefit from special enrichment activities". Even if there was no such logical hurdle, other problems would restrict the usefulness of these additional criteria. For instance, the criterion of special enrichment needs, seen from the viewpoint of the potential beneficiaries, is not perfectly correlated with the level of intellectual (or other) abilities: personal observations and testimonies from program coordinators indicate that many children and adolescents who test in the top 5% of the population would consider themselves perfectly satisfied with the regular school curriculum. Moreover, a significant proportion of high IQ adolescents deliberately choose *not* to participate in local enrichment programs. The motives are diversified: it might be that their friends are not participating, or that their intellectual curiosity is not very high, or that they are put off by the heavier work load, or whatever. Similarly, playing with the contents of an enrichment intervention can significantly modify the percentage of those who would benefit from it. For instance, grade skipping is undoubtedly applicable to

a smaller percentage of pupils than the offer of a parallel curriculum in five years instead of six; because of its suddenness, the grade skipping would represent a greater challenge than the same gain of one year spread over the six years or so of elementary schooling.

These criticisms do not mean that such criteria are useless; on the contrary, they can be quite helpful in determining how many gifted and talented children would benefit from particular resources. Unfortunately, little research has been done on this particular subject. In fact, only one study was found that addressed this question empirically, comparing two "levels" of gifted children in terms of their performance in an enrichment program. Reis and Renzulli (1982) selected two groups of elementary school pupils to participate in enrichment activities; members of the first group scored in the top 5% on standardized tests of intelligence and achievement, while those in the second group scored from 10 to 15 percentile points below the top 5%. At the end of the program, judges independently assessed student products through a double-blind procedure. No significant difference in the quality of the products was observed between the two groups. The authors used these results as a case for a broadened conception of giftedness. Such thought provoking studies should be replicated with other forms of enrichment activities. Still, its results remain open to at least one alternative interpretation. Since the program's activities consisted of Type III personal projects, it could be argued that all children chose a project more in accordance with their personal cognitive strengths, strengths not differentially assessed by the more global selection criteria. If this was the case, the study would rather support a diversification of assessment measures than a lowering of the threshold on more global identification instruments. Even in the absence of an alternative interpretation of the results, this study should not lead to the broadened conception of giftedness proposed by its authors: the logical hurdle remains. The results should simply indicate that that particular program of enrichment activities was not specific to intellectually gifted children, as restrictively defined in that particular American state. Otherwise, the extension of the giftedness and talent concepts would become overly dependent on the fluctuating results of studies similar to the one described above. It seems preferable to adopt a definition that is as logically sound as possible and then examine empirically to what extent various enrichment activities specifically benefit the population so defined.

The above discussion demonstrates that there is no simple empirical solution to the problem of threshold; it suggests that the narrowing of the grey zone should be addressed logically. Since the problem has been presented as a search for a *lower bound* threshold, then the cutoff point must be placed as close as possible to the mean. The lowest point for an "above average category" corresponds to a score just beyond the limits of the confidence interval of an average score, in other

words a score reliably above average. For instance, IQ tests and standardized achievement tests, which are probably the most reliable among the instruments used to identify gifted and talented children, have 95% confidence intervals ranging from one third to one half of a standard deviation (see Sattler, 1988). On the other hand, the concepts of giftedness and talent designate a subpopulation with characteristics that are distinctly different from those of average ability children and adults. So, using as a criterion the “beginning” of the above average category would unduly dilute the meaning of both concepts. This is why the adverb “distinctly” is important in Gagné’s definitions. A convenient point which would satisfy these considerations is the +1 standard deviation, at the same time close enough to the mean to encompass a fair group of children or adults, namely approximately 15% of the population and far enough from the mean to save the normatively selective meaning of both concepts. Considering finally the omnipresence of measurement errors and the fact that these should not penalize the subjects, a *threshold zone* similar to a confidence interval should be used instead of a cutoff point. It follows from these remarks that an appropriate threshold zone between the gifted or talented and the general population could be described as “the top 15–20% of the population”.

One possible barrier to a more general acceptance of such a low threshold for giftedness and talent might be the reluctance of many professionals to lump together the more “commonly” gifted at the lower end of the range with those few who show exceptional precocity. If it was more generally recognized that there are levels *within* the population of gifted and talented persons, then it might be easier to accept a more generous lower bound threshold than the 3–5% modal cutoff. It is not that levels have never been proposed in the past (see Robeck, 1968) or even recently (see Chapter 25 by Miraca Gross in this handbook). It is more a problem of lack of consensus within the field concerning the number of levels to introduce, their position on a continuous score distribution, as well as the labels to attribute to each of them. Because the establishment of levels within the gifted/talented population is subject to the same problems discussed above with regard to the lower bound threshold, the solution proposed here builds on that lower bound threshold, simply extending the series of standard deviations toward the extreme of the normal distribution. The quantitative categories described in Table 1 include a specific threshold zone between each level. Beyond the +4 S.D. threshold, the prevalence becomes so small (1 in 50,000) that no further divisions are necessary. The general terms “gifted” or “talented” would describe the whole range; when referring to the lower level exclusively, the term “basically” gifted/talented would be used. There would be numerous advantages to using such quantitative subcategories within the gifted/talented population. They would increase the precision in the sampling of subjects for research or service purposes; they would bring a

TABLE 1

Subcategories within the gifted/talented population

Label	S.D.	IQ equiv.	%	ratio	
Basically	+ 1	± 112/115	15–20%	1 in	5 or 6
Moderately	+ 2	± 125/130	2–4%	1 in	35 (± 10)
Highly	+ 3	± 140/145	.001–.003%	1 in	600 (± 300)
Extremely	+ 4	± 155/160	± .00002%	1 in	500 000 (± 10 000)

more efficient targeting of enrichment activities aimed at specific subpopulations; they would also greatly facilitate comparisons between studies and put in better perspective differences in their results.

The Problem of Definitions

Even when the question of the threshold is finally solved in a satisfactory way, a few other problems need to be addressed in order to assess with greater precision the prevalence of the gifted and talented population. Probably the most important of them is the definition of the giftedness and talent constructs, a subject already discussed in the first part of this chapter. It should be evident that there is a lower bound threshold for *each* form of giftedness or talent. What then happens when one takes into account a large variety of abilities, natural ones in the case of giftedness and developed ones in the case of talent? How large can the population of gifted individuals become when the intellectually gifted, the creatively gifted, the socioaffectively gifted and the physically gifted are all counted? No doubt that the prevalence estimate would become even larger when subcategories are considered. For instance, how many could be labeled *intellectually* gifted if various forms of moderately correlated specific cognitive abilities were separately assessed: verbal intelligence, spatial intelligence, logical-mathematical intelligence, practical intelligence (Sternberg & Wagner, 1986) and so forth? Similarly, how many would deserve the label “socioaffectively gifted” if not only leadership abilities, but also empathy, adaptativeness and self-regulatory abilities (Zimmerman & Schunk, 1989) were independently assessed? If similar distinctions were made concerning fields and subfields of talent, the prevalence of the talented would also increase dramatically. As stated by Gagné (in press):

Could a majority of the population be considered gifted or talented in *at least one* of the numerous domains or fields in which abilities manifest themselves? The adverse proposition would be that a small minority of the population controls all forms of excellence, that all talents are in the hands of a small group of “jacks-of-all-trades”, of “good at everything” individuals. The plausibility of this adverse proposition is dependent on the level of the correlations between measures of abilities: the lower they are, the larger the population of gifted and talented persons will be.

A few empirical studies (see DeHaan & Havighurst, 1957; Feldman & Bratton, 1980; Hainsworth, 1978, cited in Tannenbaum, 1983) have addressed this question and shown clearly that as the criteria for gifted behavior are diversified, the percentage of those who deserve the label grows accordingly. Anastasi (1988) described a study in which army personnel were assigned to various occupational specialties, using a thirteen-test classification battery with subscores in various aptitude areas. Eighty percent of them got a score above the mean in their best aptitude area. Anastasi concluded: "This apparent impossibility, in which nearly everyone could be above average, can be attained by capitalizing on the fact that nearly everyone excels in *some* aptitude" (p. 193). Finally, Gagné (in press) analyzed a large data bank collected as part of the validation of a series of peer nomination forms for the screening of gifted and talented pupils. The pool of forty abilities from which different groups of twelve were chosen to make up experimental forms was inspired by his differentiated model of giftedness and talent. Each of the 2500 participating pupils in grades 4 to 6 received a score on a 100-point scale for nineteen different abilities, covering school subjects, technology, crafts, arts, physical abilities and social abilities. The three best (top 12% on average) in each of the eighty-eight groups were singled out for each ability domain. It was found that just over 50% of the pupils on average in each classroom were judged by their peers to excel in at least one ability domain. Similar results were obtained by analyzing teacher choices made on the same forms.

In summary, it is no longer defensible to maintain, as Marland did in his definition, that only 3% to 5% of the school population can be considered gifted or talented. It is possible to keep such a restrictive threshold in any given domain or field and still see the prevalence of the gifted and talented grow rapidly as more and more areas of excellence are taken into account. It must be again emphasized that the fact that a majority of the population can be labeled gifted or talented in no way dilutes the restrictive meaning of these concepts: in any one ability domain, the 15–20% threshold still applies.

The Problem of the Group Reference

The last problem examined here is the choice of an appropriate reference group for the various categories of gifts and talents. Why not simply use the general population? This simple solution is unacceptable for many reasons. For instance, most fields of talent bring together less than 10% of the population, which would make all their members automatically talented if compared to the entire population. Sometimes this point of view appears in everyday language: if someone in a small neighborhood participates in a marathon, however long it takes that person to complete it, he/she will

instantly become the neighborhood athlete, because the implicit comparison group will be all dwellers in the neighborhood, instead of the subgroup of joggers, or the even smaller group of marathon participants. Similarly, most persons who have never learned a particular skill will tend to perceive as talented anyone who has mastered that skill reasonably well. Still, the entire population could be a more appropriate basis of comparison for aptitudes than for talents. Indeed, while the developed skills of a talent area are found only in a relatively small subgroup of the population, aptitudes are characteristic of every human being. Except for a few individuals who have profound intellectual, emotional or physical handicaps, everyone is at least minimally apt to operate in the intellectual, creative, socioaffective or sensorimotor domains. For this reason, aptitudes must use the entire population as the basic reference group.

But, human aptitudes have also a developmental component; as mentioned earlier, they develop through maturation, everyday use and more systematic practice and training. Consequently, age must be taken into account in assessing the level of a given aptitude; otherwise only extremely precocious children would stand a chance to be labeled (intellectually, physically, etc.) gifted if compared to all age groups. It must be pointed out that the age parameter does not affect the prevalence estimates; it only distributes the 15–20% equally among age groups. Sex is an obvious choice as a second parameter for the differentiation of aptitudes; its impact is clear in some psychomotor aspects of the physical domain, notably strength and speed, so much so that most athletic disciplines segregate the sexes. There are also confirmed differences in some cognitive abilities (Deaux, 1985), but these have never been judged large enough to justify any differential standardization of measures according to sex. Ethnic or cultural membership might serve as a third parameter, if major differences in aptitudes could be shown. The over-representation of African Americans in many professional sports and athletic disciplines or of Jews and Asians in North American universities would suggest that such differences exist. These need not have a genetic origin; the impact of the environment on the development of aptitudes can produce significant intercultural disparities. As with sexual differences in cognitive abilities, ethnic or cultural differences in aptitudes have not been judged significant enough to justify separate standards of comparison.

The problem of the reference group is somewhat more complex in the case of talents. First, if talent corresponds to a performance which is "distinctly above average in a field of human activity", then members of a particular field must serve as the basic comparison group. As mentioned above, this statement somewhat contradicts the spontaneous reaction of laypersons, but is essential to prevent against inflated estimates of the prevalence of talented persons. The next question is the definition of membership. In most cases, the demarcation is relatively easy to make. Usually, trades, crafts

and professions have some form of certification that confirms membership in the field (e.g., chemists, electricians, teachers, comedians, computer programmers). Subdividing these fields into more specific subgroups (e.g., science teachers, math teachers, English teachers) will not affect prevalence estimates. A problem arises when the subgroups are related to levels of performance within a field. For instance, should a professional pianist be compared to all pianists, including those who have barely mastered the most basic skills in the field, to those who have obtained an academic diploma, or even those few who are actively pursuing a career as professional pianists? These three alternatives can be invoked to specify a particular population: the entire population of pianists, the qualified pianists and the professional pianists. But, it seems more appropriate to adopt a membership definition analogous to that of the lower bound threshold mentioned earlier, then use the labels proposed in Table 1 to qualify higher levels of talent. Such a definition is less likely to trigger accusations of elitism. With this lower bound definition of fields, the upper 15–20% of all persons having mastered at least basic skills in piano would be labeled talented in that field; among them progressively smaller subgroups of moderately, highly and extremely talented individuals would be identified. Similarly, in the case of the neighborhood marathoner mentioned above, the appropriate reference group would be all those who have chosen running as an athletic discipline, with the top 15–20% forming the basically talented group. Within that group, subgroups of moderately, highly and extremely talented individuals could be identified using the appropriate ratios proposed. No doubt that those who complete a marathon, whatever time it takes them, would be among the talented in that field. Their talent would also implicitly confirm their physical giftedness.

This proposal will probably not modify the well-ingrained custom of within-subgroup comparisons in most fields, according to which only the best within the subgroup are recognized as talented. For instance, most people actively interested in the field of music would describe as “truly” talented only those professional pianists who have won prizes in major competitions, are at least nationally renowned as soloists, or are members of well-known orchestras. Similarly, most ice hockey fans would restrict the label to only a minority of the 500 or so players in the National Hockey League, forgetting that all of them are at least *highly* if not *extremely* talented, having risen to the top from a pool of hundreds of thousands of youngsters who played in junior leagues but never realized their dream of becoming a player in the NHL. The same tendency exists in schools. The educational system is one of few fields through which most children have to pass, at least in industrialized countries. Some leave after primary school, others during or after high school, while a few go on to college and fewer still get a graduate degree. All students who obtain a college degree should be considered academically talented, simply because of the

small percentage of such people. In fact, almost all of them were probably among the two or three best in their group while in elementary school. Still, from the point of view of college students and professors, only the more performing are usually perceived as talented. This tendency to evaluate excellence from the top down instead of from the bottom up is very unfortunate insofar as it gives an overly elitist flavor to the word talented.

Should a field include only those active in it? The answer has to be positive, otherwise it would be unduly inflated with all those who have at one time or another tried to master the skills of the field, then stopped practicing because of failure, insufficient rate of progression, or competition from more interesting or absorbing activities. Is age a relevant parameter to circumscribe a field of activity? In many cases the question is not relevant since membership in the field presupposes adulthood (e.g., trades and professions); but in other cases (e.g., most artistic and athletic fields) excellence can manifest itself at an early age, normatively speaking. For the same reason given in the case of aptitudes, namely the recognition of precociousness, age must be taken into consideration when assessing the presence of basic, moderate, high or extreme talent. In other words, precociousness should be synonymous with giftedness *and* talent. Age is also important because some fields of talent have a developmental ceiling: they become almost obsolete after adolescence. The most conspicuous case in point is academic talent. It is no longer a relevant field of activity beyond early adulthood; indeed, as students leave the educational system academic talent becomes progressively superseded by the presence or absence of talent in the chosen career.

In sum, different bases of comparison have been proposed for giftedness and talent. Will the wider base for giftedness generate more gifted people than talented people? In itself, this criterion should not have much influence, since the wider base is offset by a smaller number of categories and subcategories. But, the structure of the model implies that there should be theoretically more gifted individuals than talented ones, since the absence of appropriate intrapersonal or environmental catalysts may hinder the transformation of gifts into talents. On the other hand, because gifts and talents are defined normatively, as the upper 15–20% of some particular reference group, then equivalent proportions are artificially created for both groups. This could mean that among those judged talented some would fall below the threshold zone of the relevant aptitude(s).

Conclusion

During the last two or three decades, the multiplicity of definitions of giftedness and talent has testified to the creativity of scholars intent on putting on markers

in a field in full growth and bubbling with new ideas. The time seems ripe now for a meeting of minds among scholars and professionals concerning the nature of the two major constructs: giftedness and talent. Such an agreement would confirm that the field is now progressing toward a new level of conceptual maturity. Gagné's differentiated model of giftedness and talent could serve as an initial proposal to be discussed, amplified, and/or modified. Not only is it the only existing model to offer a clear operational distinction between gifts and talents, but there are also signs that it has aroused widespread interest (Borland, 1989; Feldhusen, 1985b; Sattler, 1988). The above discussion already suggests ways in which Gagné's definitions could be modified to take into account the preceding discussion on the extension of the concepts. Here is how they could be rephrased.

Giftedness corresponds to a level of competence in the non-systematically developed abilities of at least one aptitude domain that places subjects among the upper 15–20% of their age peers.

Talent corresponds to a level of performance in the systematically developed skills of at least one field of human activity that places subjects among the upper 15–20% of the same age active members of the field.

Beyond the definitions themselves, agreement should be sought on a series of subsidiary questions, like the nature and categories of aptitudes, the relevance of the various mediating structures presented as catalysts by Gagné, the nature and "cartography" of fields of talent, the talent areas to be prioritized by the educational system, the levels—and their labels—to introduce *within* the gifted/talented population and so forth. Such an effort, if successful, would create a basic conceptual framework to be shared by most scholars. It would become a common node, progressively enriched and expanded, from which would radiate the various research questions and concerns. No doubt that it would help in creating closer ties and more intensive collaboration between scholars and professionals, not only at the local or national level, but also internationally.

Developmental Theories and Giftedness

FRANZ J. MÖNKS

University of Nijmegen, The Netherlands

EMANUEL J. MASON

University of Kentucky, Lexington, Kentucky, U.S.A.

Introduction

For generations psychologists have been debating whether development of an individual is determined more by organic or environmental factors. This nature-nurture issue is not only a concern for developmental psychology (Vernon, 1979). Education and socialization depend largely on theories and findings of developmental psychology. If proponents of the nature position predominate at a given time, human development is regarded as a process of maturation. If, however, the advocates of nurture are prevailing, the emphasis is on learning. Nowadays most developmental and educational psychologists hold a position somewhere between the two extremes.

The primary question in developmental research on the gifted is no longer whether nature or nurture is the most basic, but rather what kind of interaction between the two occurs, and how does this influence development. In other words, what results from the interaction of specific individual traits and experiences in a given social and cultural environment. Human development is generally regarded as a process of interaction between individual characteristics and environmental opportunities.

In this chapter, the authors describe and discuss prevailing developmental theories. In addition, the diversity of definitions of giftedness will be outlined. It will become evident that some versions of the nature vs nurture controversy remain. Existing and ongoing research demonstrates that only longitudinal studies can provide evidence about the relative contribution of nature and nurture to the development of gifted individuals. Finally, instructional and educational provisions will be discussed from a developmental perspective. In the present chapter, the authors treat the terms gifted, highly able, and talented synonymously.

Developmental Theories

The concept of development includes a complexity of processes and their organization. This complexity is

constructed from conceptual and empirical elements. A theory of development depends on the accentuation of aspects of this complexity. Theories are most meaningful when they enable description, explanation and prediction of diverse phenomena (Mason & Bramble, 1989). It has been suggested that the usefulness of a theory of giftedness should be established in terms of what it implies about the nature of the gifted child, education and programs for the gifted, its structure and framework, and the criteria of good theory (e.g., logical consistency, parsimony, etc.) (Cohen, 1988). According to Marx (1963), a distinction is necessary between four different modes of theory construction. They are arranged from relatively more conceptual to relatively more empirical.

Deductive theory refers to any logically or deductively arranged cluster of concepts. The empirical data are explained from a conceptual structure. Such a formally organized theory can give direction to research but findings contribute little to produce a new or better theory.

Functional theory refers to the interaction of empirical findings and conceptualization. Empirical and conceptual activities are emphasized and have equal status in theory construction.

Inductive theory refers to the kind of theory that is essentially a summary of empirical data; it contains a minimum of deductive logic. Essentially it is the contrary of a deductive theory.

Model is a term for any conceptual analog that can be used for empirical research. Such an analog is often of a mathematical or physical nature. A model that directs the process of finding an answer or solution is called a heuristic. The result of such a process can be a hypothesis and as such contribute to a better conceptualization. Models often have a descriptive or explanatory function. Such a model accentuates the most important aspects. For example, the machine or deficit model has often been used to explain the human aging (i.e., the functioning of a machine decreases over time, parts of the machine getting old, which affects the functioning of the system). This increasingly

disfunctioning model serves as an analogy for the human aging process. Thus, a model has value as a heuristic or tool. A model is not subject to the same kinds of rigorous demands for verification and falsification as a theory (Cook & Campbell, 1979).

Developmental theories can be grouped by their different perspectives. Divergent orientations will be presented to show the variety of explanations for human development.

Biologically Oriented Theories

In this context development is viewed as synonymous with evolution. Human development is mainly seen as growth and maturation of the organism, as unfolding of predispositions: i.e., heredity and temperament. In this view development is biologically determined. The environment plays a relatively unimportant role providing only the necessary ground for the growth of predispositions, comparable with a plant which needs favorable environmental conditions for its growth. Actually, development is a continuation of the genesis of the embryo.

Terman believed to his "dying day" that intelligence is a genetically determined trait that is stable over the life of an individual (Minton, 1988, p. 199). However, by the time he was 77, his own empirical genetic studies, the longest developmental investigation ever attempted, convinced him that many of his 1500 subjects had never made use of their superior ability. He concluded that factors other than intelligence, such as personality and environment, determine in an essential way whether or not an individual reaches "life success" (Terman, 1954). Nowadays, however, there are no serious proponents of this kind of theory.

Milieu-Oriented Theories

Learning and sociologically oriented theories belong to this group. The influence of the environment on the development of a person has a central position in these theories. Human development is seen as an ongoing social learning process.

Learning theories, although not identical, have a common feature that learning is viewed as a relatively stable change in the person's *disposition*. Disposition may be described as the potential to behave. Therefore, development means increase of potential to perform and to behave. Walking has to be learned, as does being with people, and thinking systematically. The potential to perform higher order activities is not the result of spontaneous organismic growth, but is the outcome of learning appropriate techniques. Therefore, the child learns to demonstrate milieu-specific behavior patterns.

It is important to search for the mechanisms that govern the acquisition and modification of behavior, but it is unknown whether this approach "actually looks for mechanisms of acquisition and modification or whether

it merely applies the preconceived notion that the growth of all behavior is caused by conditioning and thereby overlooks the actual mechanisms governing acquisition and modification" (Langer, 1969, p. 85). Evidently much of our behavior is learned and its acquisition, such as with language learning, often depends on our social environment. But these theories neglect the inborn abilities and the diversity of human characteristics. A single environment with specific learning opportunities is not the same for every developing individual exposed to it. One child may profit optimally while another is not at all affected.

Psychodynamic Theories

Psychodynamic theories and learning theories both portray the environment as having a strong impact on human development. They differ in that the socio-affective component of personality and its development is considered to be fundamental in psychodynamic theories but is not central in theories of learning. The socio-affective component essentially determines the dynamics of the developmental processes.

Within the psychodynamic group, the most prominent theory is the psychoanalytic. According to this view the child is born with two fundamental forms of biological energy: libido and aggression. These two conflicting yet complementary classes of instincts are operative from birth. Libido or Eros is constructive, positive and life seeking. Aggression or death instinct is destructive and life disturbing. The child is born with an id structure that is energized by libido and aggression. The id provides the child the energy to satisfy his or her passions, but the environment inhibits this process. The id structure is transformed by its interactions with the environment into an ego structure. The superego emerges under the influence of the social environment, especially the parents, to control the behavior of the ego and the demands of the id.

Psychodynamic theory is primarily a theory of socio-affective development. A problem with this theory is empirical validation of the id, ego and superego, and the stages of sexual development (which are not covered in this chapter). Findings are obtained by the clinical therapeutic method. The data are therefore confounded with the therapist's interpretation. "Thus, not only are the data not reliable, but it is also not always certain which theoretical assertions they are relevant to" (Langer, 1969, p. 49).

Erikson (1964) broadened the Freudian perspective. He introduced a relationship between psychological, educational, and cultural factors. Erikson took a life-span perspective and developed a framework of eight distinct stages. Developing individuals pass through those stages at specific periods in their lives. Each stage represents a conflict that must be resolved successfully for the person to be psychologically healthy. This approach stimulated research, especially in the infancy

and adolescent periods. However, questions remain about whether psychodynamic theory really can be considered as a scientific theory (i.e., is it falsifiable, testable, and can it be revised?).

Interactionist Theory

The theories discussed so far are rather limited because each emphasizes a single dimension. A synthesis of the various aspects is necessary. The interactionist theory used by the great majority of Western psychologists and educators provides such a synthesis. The German psychologist William Stern (1871–1938) was the first to propose such a theory and called it the *theory of convergence*. In his view human development is a process in which personality and environmental factors converge (Stern, 1916). Yet, Stern never directly participated in the controversy concerning nature vs nurture.

The former socialist countries favored the environmental theory. Human development was seen primarily as a mirror of the environment. According to Vygotsky, cognitive development is not a “natural” process, but is determined by culture (see Van Parreren, 1983). Therefore, Vygotsky’s position was that it is not necessary, as Piaget argued, to connect instruction in school with stages of development, but rather with the “zone of proximal development”, in other words, stimulate the child to do tasks that are just above his or her ability.

Like Langer, some authors view Werner and Piaget as proponents of maturation. The human being is viewed as an active agent and development as merely a self-constructive process. Development occurs from within. Werner characterized development as an orthogenetic process that is “directed towards increasing differentiation, centralization, and hierarchic integration of the child’s mental organization” (Langer, 1969, p. 9). On the other hand, Piaget (1967) characterized development as an equilibration process (i.e., development proceeds from relative disequilibrium to increasing equilibrium). The child will always function to achieve equilibrium. In doing so, the child changes and develops. Langer characterizes Werner and Piaget as *organic lamp* theorists. It is true that these theorists emphasize maturation of the organism as a central agent of development. However, development only then takes place when the child *interacts* with his environment.

Therefore, Piaget (1896–1980) can be regarded mainly as an interaction theorist. However, he emphasized only cognitive functioning and the related issue of moral development. According to Piaget, development is a continuation of embryogenesis. Development occurs in a sequence of stages which, when reached, permit the child to perform a higher level of cognitive operations. The development of a higher stage depends on *maturation, experience, and social transmission*. Education and language play roles in social transmission. The most central factor, however, is the spontaneous activity of the child, because this activity brings the child through

interaction between maturation and social environment to new forms of *adaptation*. This means the child is increasingly able to react adequately to the demands of the reality.

Piaget called the process of adaptation of the organism *assimilation*. If the organism has to adapt to new elements of the environment, the process is called *accommodation*. This last form of adaptation requires a new attitude in the individual, creativity of mental operations. As a process of establishing equilibrium, accommodation brings the child to a higher cognitive level and the child establishes a higher structure for thinking. Structure refers to the scheme developed by the individual to achieve equilibrium between the tendencies of assimilation and accommodation. The result is a new process of accommodation that is necessary to establish a new or higher kind of operation that will disturb the existing equilibrium. The process of actively breaking through the existing equilibrium to establish a higher structure of thinking is called equilibration by Piaget. This active form of achieving a new equilibrium is a kind of *self-regulation*.

Interaction refers to mutual or reciprocal action or influence between a person and other people, objects, processes, or other elements of the environment. This includes the notion that the acting and reacting individual shapes the environment (e.g., with family, friends, classmates, social class). On the other hand, the individual influences the environment through experiences. In short, the individual both is a product and a producer of the environment. The biological concept of *adaptation* introduced by Piaget has to be extended to emphasize the more active role of the individual. Sociologists use the term *emancipation*, to mean self-actualization, becoming an independent person, and detachment from inappropriate bondings.

It is evident that psychological development consists of more than cognitive development as emphasized by Piaget. Psychological development includes cognitive as well as social and personality aspects. Furthermore, it is a dynamic and life-long process; the interaction between the nature of the individual and the environment determines the motives that emerge and the kinds of behavior patterns that will become manifest. In short, psychological development is the result of interaction between the individual and his or her environment.

As was emphasized earlier, conceptualizations of psychological development influence research directions and educational and psychological practice. All the theories briefly summarized here have influenced theory and concepts of giftedness and will continue to do so. Knowledge of developmental theories is necessary to understand what “is behind” a definition.

Definitions of Giftedness

Defining giftedness is a task fraught with difficulty. A definition should give a formal and concise description

of the meaning of a concept or a construct. Giftedness or the synonyms high ability and talent can assume different meanings. Frequently these meanings are tainted by an emotionalism that seems to engulf the concept of giftedness. For example, in German the word for giftedness can be *Begabung* or *Hochbegabung*. The connotation of *Hochbegabung* can be value laden, associating giftedness with elitism. A similar situation exists in French (*doués* or *surdoués*). Such a connotation evokes emotional reactions and negative feelings that have hampered progress in programming for the gifted worldwide (Williams & Mitchell, 1989).

Further, a concise definition is almost impossible because the context in which the definition is made may refer to a process, key elements of giftedness, provisions for the gifted, or education of the gifted. In addition, it is not easy to separate theoretical and practical concepts, because one's theory of giftedness determines research and educational approaches. Finally, practical concerns seem more involved in definitions than in developmental theories.

According to Hany (1987), there are more than a hundred definitions of giftedness (and its synonyms). These definitions can be clustered in four distinctive groups. The first two of them refer to psychological constructs, a third focuses on achievement and accomplishment, and the fourth takes an environmental view. In the following section these four main groups of definitions of giftedness are presented.

Trait-oriented Definitions

The most prominent representative of the trait-oriented approach is Lewis M. Terman (1877–1956) who popularized the concept of IQ and played a prominent role in the history of social science and public policy. Terman believed that intelligence as revealed by intelligence tests is genetically determined and therefore stable over time. His belief in *biological determinism* was so strong that he only came to the conclusion in 1947 that "intellect and achievement are far from perfectly correlated" (Terman & Oden, 1947, p. 352). The new ideas that environmental and personality factors are significant determinants of "the extent to which a subject had made use of his superior ability" (Terman & Oden, 1947, p. 349) were most clearly spelled out in Terman's address at the University of California at Berkeley (Terman, 1954).

Another central issue of Terman's work was the idea that he had a *mission* as a psychologist to contribute to the shaping of American society. He advocated a society that was a *meritocracy*. More precisely, individual differences in ability should be reflected in the hierarchical structure of the society: the most responsible positions should be held by the most capable individuals (that is, those with the highest IQ scores). A meritocratic social structure based on the results of mental tests that identify native intelligence at school age is an unrealistic ideal,

not only because high intelligence is not isomorphic with high achievement, but human beings develop in a dynamic way and through interaction with the environment.

Terman's view of intelligence as a unitary inherited trait reappeared in modified form in Marland's well-known definition of giftedness proposed in 1972.

Gifted and talented children are those identified by professionally qualified persons who by virtue of outstanding abilities are capable of high performance. These are children who require differentiated educational programs and services beyond those normally provided by a regular school program in order to realize their contribution to self and society. Children capable of high performance include those with demonstrated achievement and/or potential ability in any of the following areas:

- (1) General intellectual ability;
- (2) Specific academic aptitude;
- (3) Creative or productive thinking;
- (4) Leadership ability;
- (5) Visual and performing arts;
- (6) Psychomotor ability (Davis & Rimm, 1985, p. 10).

There are at least two new elements in this definition: the definition goes beyond intelligence to other areas of high ability, and abilities as well as achievement are criteria for identification. However, the definition excludes non-cognitive factors (e.g., motivation) as well as clear operationalization of the different forms of giftedness.

Some time ago when Gardner (1983) proposed his theory of multiple intelligences, he argued "that individuals have a number of domains of potential intellectual competence which they are in the position to develop, if they are normal and if the appropriate stimulating factors are available" (p. 284). Furthermore, there are conditions and criteria which have to be taken into account to identify a specific kind of intelligence. Criteria of an intelligence are, for example, potential isolation by brain damage, support from experimental psychological tasks or support from psychometric findings. Gardner identified several intelligences related to a specific domain of potential (e.g., linguistic, musical, logical-mathematical, spatial and bodily-kinesthetic intelligence).

The description of multiple intelligences or traits is primarily based on anecdotal findings rather than empirical results. The important extension beyond Terman's approach is that giftedness results from inborn abilities in interaction with an appropriately supportive environment. The other point is that this definition goes beyond the opinion that giftedness is based on a single inherited trait. The main assumption of the multiple intelligences approach is that interindividual differences in test scores are determined by mental abilities that can be measured psychometrically. This approach at best describes the results but not the processes which form the basis for the results achieved.

The trait-oriented approach has led to and enriched empirical research. It has enabled extension knowledge concerning characteristics and conditions for the development of giftedness and has led to better understanding of the processes of achievement of gifted people. This can ultimately lead to means for better instruction of the gifted and nurturance of their talents.

Cognitive Component Models

Cognitive definitions focus on thought processes, memory and related skills. For example, Piaget was less interested in the outcome of a test than in the process of responding. Therefore, he emphasized clinical methods in which a single or small group of children were observed and interviewed while they were performing tasks rather than large-scale research in his approach. In his theory of knowledge, better known as genetic epistemology, Piaget preferred to investigate how children get and use what they know.

Proponents of the cognitive information processing approach have recently invested considerable effort in the direction suggested by Piaget's work. "The cognitive components approach is task analytic and attempts to directly identify the information processing components of performance on tasks that have been generally used to assess mental abilities" (Pellegrino & Glaser, 1979, p. 188).

Sternberg is an important proponent of this approach (Sternberg, 1985; Sternberg & Davidson, 1987). A central concept in Sternberg's experiential subtheory of intelligence is insight and response to novelty in task performance. Within this view a distinction is made between "three separate but related psychological processes" (Sternberg, 1985, p. 80): (1) *selective encoding*, i.e., sifting out relevant from irrelevant information; (2) *selective combination*, i.e., "combining what might originally seem to be isolated pieces of information into a unified whole that may or may not resemble its parts" (Sternberg, 1985, p. 80); (3) *selective comparison*, i.e., relating new information to that which was acquired in the past.

Insightful performance demonstrated as problem-solving skills or as knowledge-acquisition components are indicators of giftedness. The better these skills are, the more intellectually gifted a person appears to be. Moreover, according to the loci of information processing, Sternberg makes a distinction between three kinds of giftedness: analytic, synthetic, and practical abilities (Sternberg & Lubart, 1991). The forthcoming *Sternberg Triarchic Abilities Test* will contain seven subscores for the different kinds of abilities and processing, namely analytic, synthetic, automatization, practical *abilities* and verbal, quantitative, figural *processing*. Sternberg hopes that such a test with different age levels (from kindergarten to adulthood) and a broad scope of abilities and processes will measure giftedness much better than a single IQ-test.

Another approach that is promising but not yet fully

developed is that of R uppell (R uppell, Hinnersmann, & Wiegand, 1986). He proposes a complex model of information processing to explain thinking processes of gifted people that he summarizes with the slogan "QI instead of IQ". QI means Quality of Information processing. R uppel et al. (1986) argue that complex creative problem-solving goes far beyond the normal level of thinking and recalling; this kind of problem-solving requires extraordinary thinking skills and insight. A problem with the complex approach of R uppell and his associates, however, is that the concepts are changing and that the experimental approach in the laboratory does not reflect reality. Moreover, the complex test situation is difficult to analyze because of the multidimensional processes which occur during experimentation.

Thus far, the cognitive component approach is more theoretical or at best in a beginning stage of empirical verification. The existing models need to be tested thoroughly to become useful for development of applications. Until now, this approach has contributed little to the definition of giftedness, the identification of gifted individuals, and programs for the gifted. However, on the basis of current activity and interest in the field, it appears that as this approach matures, it will lead to useful definitions of giftedness based on mental processes.

Achievement-oriented Models

Even Terman, the most rigidly trait-oriented author, was convinced by his own empirical data that high intelligence was only a necessary but not a sufficient condition for highly able behavior. As a result he considered *achievement* as the observable output of giftedness. As early as 1916, the noted German psychologist William Stern considered high intelligence as a necessary but not sufficient condition for outstanding achievement. He considered personality traits like motivation and environmentally appropriate conditions important (Stern, 1916). However, his arguments were more supported by intuition than empirical evidence.

The most influential author in the achievement orientation category is Renzulli. His article "What makes giftedness?" (Renzulli, 1978) has had a long lasting impact on the field. A thorough literature review revealed that there are at least three traits or factors involved in gifted achievement: (1) above average ability, (2) task commitment, and (3) creativity. These three clusters of variables are brought together in Renzulli's "three-ring conception". According to him highly productive people can be characterized by these three clusters of traits. Recently, the research base of the three-ring conception was attacked by Jarell and Borland (1990) who argued that the research they reviewed does not support this conception. Moreover, the research is either irrelevant or contradictory to the triad.

The article by Jarell and Borland provided Renzulli

(1990) an opportunity to react in a constructive and convincing way. Most important, Jarell and Borland did not examine the most recent theory and research on the three-ring conception. Furthermore, the intention of Renzulli's conception is threefold: "(a) to call attention to the developmental nature of behaviors such as creativity and task commitment, (b) to highlight the dynamic interaction among behaviors that is necessary in order for gifted behaviors to emerge, and (c) to provide enough flexibility in selection procedures . . ." (Renzulli, 1990, p. 325). Giftedness has to be seen as a manifestation "of human potential that can be developed in certain people, at certain times, and under certain circumstances" (p. 324). Renzulli's overall intention in his approach is to be able to identify *and* to nurture giftedness appropriately. The multicomponent conceptualization of giftedness can be regarded as one of the better definitions.

However, a definition that strongly or exclusively emphasizes personality traits neglecting the interactive nature of human development does little justice to the dynamic interplay of developmental processes. A multidimensional approach, including personality and social components as determining factors, seems to be an appropriate framework. The following modification was made by Mönks working from a developmental psychology perspective in his Triadic Interdependence Model of Giftedness (see Mönks, 1992a, p. 191). This model consists of one personality triad and one environmental triad. Task commitment was replaced by *motivation* which includes task commitment, risk taking, future time perspective, anticipation and planning. Furthermore, the rather liberal above average ability criterion was replaced by *high intellectual abilities* because gifted behaviors are manifestations of potential which ranks in the upper 5–10%, rather than the upper 15–25% as Renzulli suggested. The new triad includes the main social areas in which the child and adolescent grow: *family, school and peer group*. Emergence and development of gifted potential depend to a great extent on a supportive environment. Intellectual peers or developmental equals are significant people who are needed for healthy social and psychological development. All children need peers to interact with and from whom to learn, and so it is with the gifted.

Authors working with an achievement oriented model make a distinction between potential and realized capacities. In serving the needs of underachievers it is important to know the potential of a person and how much of that potential has been realized. Knowledge of the discrepancy between potential and realized abilities provides opportunity for intervention. The advantage of achievement oriented models is not only in the interconnection of identification and education, but also that attention is paid to the processes involved in achievement and the recognition that there are other factors than intelligence scores that influence the realization of innate human potential.

Socio-cultural/Psychosocial Oriented Models

As was indicated earlier, the social microenvironment (family, school, and peers) has an impact on human development. The Triadic Interdependence Model of Giftedness can be characterized as a partially psychosocial model because it includes the micro- but not the macroenvironment. However, it is evident that the macroenvironment has also an impact on the development of each individual. The *Zeitgeist*, the economic situation, the political orientation, and the culturally dominant values and beliefs all have influence on human development and therefore on the development of the gifted. To a certain extent this orientation is the opposite of "ontogenetic stability". Extreme social learning theorists would even argue that gifted behaviors are entirely learned.

According to Tannenbaum (1983), outstanding achievements are determined equally by the following five factors: (1) general ability, (2) special ability, (3) nonintellective factors, (4) environmental factors, and (5) chance factors. Tannenbaum arranged these factors in the shape of a star, and thus the name *star definition* (see Tannenbaum, 1983, p. 87; Feldman, 1992). Society determines who is regarded as gifted. From the societal perspective, a distinction can be made between "scarce talents", "surplus talents", "quota talents", and "anomalous talents". A society always has criteria for the attribution of what is talented and gifted in terms of outstanding achievement.

Giftedness is not seen as a priority in the schooling of children in all societies. Policymakers determine whether and to what extent educational programs are provided for gifted individuals. Thus, emphasis on a socio-cultural (political) perspective implies that giftedness is defined and determined in the context of the existence of concern, and the availability of provision, for the highly able.

Definitions of, and perspectives on, giftedness give direction to research and practice. The interconnection and interdependence of the individual and society affect both the gifted and the nongifted. The detrimental effects of not serving the special needs of gifted individuals will affect society at large. Programs for the gifted are not special in the sense that they advocate giving to each individual what is appropriate for him or her.

Research on the Development of Gifted Children

A casual review of the literature suggests that definitions of giftedness are more influential than the theories on the research of gifted development. This may be the result of a practical and educationally-oriented grounding of the definitions. For this reason, research presented here is organized more along definitional than theoretical lines.

Trait-oriented Research

Although early interest in the trait of intelligence could be attributed to the work of Sir Francis Galton, Karl Pearson, Alfred Binet, and others, the beginning of formal scientific research in giftedness has frequently been credited to Terman for his development of a technically sound method of assessment of intelligence and his longitudinal studies of the trait. In these studies, Terman postulated that individuals developed within the limits of their genetically preordained abilities (Cravens, 1992; Grindler, 1990). Terman initiated and performed the longest developmental investigation in duration ever attempted. This longitudinal study, involving more than 1500 children and adolescents from 5 to 16 years of age, started in the 1920s, and is still ongoing. The group was selected based on an IQ score of 135 or higher as determined by the Stanford-Binet Test.

Because of the influence of Terman's contributions, much of the research on giftedness has taken a trait-oriented approach emphasizing intelligence testing, and other psychometric approaches to identification of intelligence as a general static trait that determines gifted capacity (e.g., Macmann, Plasket, Barnett, & Siler, 1991). However, more recent analyses have challenged the assumption that high IQ scores and general intelligence are: (1) genetically determined, and (2) necessarily required for, or reflective of, gifted performance (O'Connor & Hermelin, 1988; Silver & Clampit, 1990).

The trait-oriented view prevails in research looking for the multiple traits of the gifted child. In studies of the performance of gifted children, an IQ test is frequently used to identify the gifted sample. Such studies have investigated a wide range of traits of gifted populations in addition to performance and achievement. For example, the Shigaki and Wolf (1980) investigation of children's syllogistic reasoning; Carter's (1985) studies of Piagetian task performance; research by Derevensky and Coleman (1989) and Henderson, Gold and Clark (1984) on gifted children's fears and daydreaming, and various studies of personality and socialization (e.g., Altman, 1983; Keller, 1992; Luftig & Nichols, 1991; and Olschewsky, Kulieke, & Krasney, 1988).

In recent years, research that questions the validity of using IQ test scores for identifying present and future gifted performance in specific academic and skill areas has been increasing. Along with this focus away from the general trait conception of giftedness represented by the IQ score, interest has been directed to identification of giftedness in groups that had previously not been considered gifted such as handicapped, underprivileged, and ethnically divergent minority groups (Sekowski, 1992). This new interest in giftedness among nontraditional populations is leading to a broadening of criteria for identification. For example, Schack and Starko (1990) reported that teachers emphasized creativity, learning speed and ease, curiosity, and initiative in seeking one's own learning experiences as essential for academic giftedness, but more experienced teachers also emphasized

the IQ score. A trait model that emphasizes multiple intelligences like Gardner's is becoming more compatible with research evidence than the single trait models relying on IQ scores for identification of giftedness.

Cognitive Component Models

Much recent literature that comes under the influence of cognitive definitions seems to represent the trait of giftedness functionally rather than by intelligence test score. For example, numerous investigations of giftedness in mathematics emphasize mathematics performance as the criterion (e.g., Benbow & Minor, 1990; Davis & Benbow, 1990; Benbow & Arjmand, 1990). Facaoaru and Bittner (1987) have advocated diagnostic procedures for identifying the gifted using techniques and concepts from cognitive research such as procedural thought processing, spatial abilities, and problem solving. The analysis of thought processes determined by verbal comments recorded during problem solving has proven useful in identifying how gifted students learn (Shore, Coleman, & Moss, 1992). In a more extreme position, Mason (1992) has presented research advocating the identification of giftedness on the basis of analysis of task performance and cognitive skills. This focus on functionality and mental processing is a reflection of the increased interest in the cognitive orientation in recent years.

A factor leading to the increase of cognitive research in giftedness is the growth of the information sciences and computer technology. These advances in technology have been particularly influential on research in cognitive psychology (Beer, 1990; Thorndike, 1984). The new technology has greatly increased the ability to present complex stimulus and problem solving situations. It also renders the study of constructs like response time more plausible and accurate than was previously possible. In addition, computers have provided a model for human information processing (Ellis & Hunt, 1989). Cognitive psychology has focused on the study of such subjects as the nature of expert thinking, the formation of a construct, and elements and structures of productive mental processing. This approach is reflected in studies showing that mathematically gifted students were able to express verbal statements of quantity and relationship mathematically more readily than their peers or college students taking mathematics courses (Dark & Benbow, 1990), and that verbally gifted students excel in different cognitive tasks than mathematically gifted students (Benbow & Minor, 1990). Further, by focusing on mental processing, Borland (1989) found divergent thinking was associated with a "strict percept-strict concept" cognitive style. In addition, Carter (1986) reported that teaching students higher level thinking skills led to greater success among gifted students in learning the concepts and reasoning but not in leading the gifted students to reach higher developmental levels of thought. In addition, research emerging from a

cognitive orientation is beginning to shed light on the complex relationship between the brain, high level performance and ability, and biological, psychological, and social status (Clark, 1986; Petersen, Crockett, & Graber, 1990).

Achievement-oriented Models

Achievement-oriented research on the gifted tends suggest rather consistently that children who are identified as gifted at a young age tend to continue to be identified as having high ability and accomplishment later in life (Mönks, 1992b; Milner & Elrod, 1986; Benbow, 1992). For example, accelerated readers seem to maintain an edge over other students, but the difference is less as they get older. Further, in Western cultures boys are more likely to sustain gifted performance and interest in science and mathematics than girls. In addition, experience with the contents of the educational curriculum prior to studying it (e.g., through involvement with preschool or after school programs, hobbies, etc.), family characteristics such as parents educational attainment level, and attitudes toward education, students' interests and attitudes towards learning, and access to experiences all seem to contribute to one's being identified as gifted.

The importance of special programming for the academic development of the gifted has been shown. For example, Brown and Rogan (1983) have addressed the effects of maintaining gifted children in rigid reading programs design for a particular grade level. According to these authors, these children can become frustrated about independent reading because they already have skills above what they are being taught. This can lead to disillusionment and poor study habits and the paradox of poor levels of achievement by gifted students (Boyd, 1990).

Socio-cultural/Psychosocial Oriented Models

Socio-cultural and psychosocial models emphasize the effects of environmental influences on the development of giftedness. Research in this area has focused on the family and home environment of gifted children (e.g., Colangelo & Dettmann, 1983; Cornell, Callahan, & Lloyd, 1991; Cornell & Grossberg, 1987; Prom, Johnson, & Wallace, 1987; Green, Fine, & Tolleson, 1988). This research suggests that the family and home environment play an important role in the development of the gifted. For example, the research suggests that the home environment affects emotional adjustment, achievement satisfaction, and academic success with a tendency for the most cohesive, child-centered, and functional family environments to produce the most successful students. On the other hand, giftedness in creative expression seemed to be greater from the less child-centered and tenser family situations. Similar

findings for scholastic performance with low income minority families have been reported (Prom, Jackson, Johnson, & Wallace, 1987). Other researchers (e.g., Klein & Cantor, 1976) have found lower self-esteem levels in gifted children in kindergarten to fourth grade. It has been suggested from this finding that the gifted child was more sensitive to the environment and had greater need for approval from family and friends than his or her less able peers. This social sensitivity was supported by a study of gifted and learning disabled children which reported the gifted were more able to identify and label prosocial behavior (Abelman, 1991).

Peer relations and cultural influences also seem to play a significant role in gifted development. For example, subtle cultural values may have been influential in producing the findings of Luftig and Nichols (1991) that gifted boys tended to be the most popular students while gifted girls least popular in a group of fourth through eighth graders. Young gifted students have also been found to show a tendency toward choosing older (Janos, Marwood, & Robinson, 1985) and more popular (Schneider & Daniels, 1992) students and leaders to be their playmates and friends. In general, the social psychological literature seems to provide substantial support for the kind of model proposed by Mönks (1992a) which integrates Renzulli's three-part model with the family, peer, and school environments.

As was pointed out earlier in this chapter, cultural environment can determine whether or not a child is exposed to opportunities for the giftedness (Lowenstein, 1979; Merenheimo, 1991). Female students are often not selected to participate in gifted programs in societies in which male dominance is well established in the educational system (Ayles, 1992). In addition, research findings have suggested that children who come from different cultural backgrounds than the majority of their peers may experience reduced opportunity to become identified as gifted despite evidence that such children give a fairly good account of themselves when they are chosen to participate in gifted programs (Cooley, Cornell, & Lee, 1991; Baldwin, 1987; Robinson, Bradley, & Stanley, 1990; Smith, LeRose, & Clasen, 1991).

General Trends in the Research Literature

Certain general trends can be discerned in the research literature. First, research in this field tends toward descriptive and case study methodology rather than more complex designs and sophisticated statistical analysis (Carter & Swanson, 1990). As noted by Gallagher (1986), practical needs and realistic solutions seem more influential in the contents of the research literature than high level theories of the sort proposed by Erikson (1963), Piaget (1967), or Bandura (1986). Further, when theory-oriented research is done, it does not seem to have immediate or widespread influence on practice. Finally, as suggested by Horowitz and O'Brien (1986),

the developmental perspective should be given more attention in the research on giftedness. Better understanding of the processes of development to include learning, cognitive mechanisms, emotion and temperament, and social and environmental factors through the life span will lead to more effective identification and provision for the gifted.

Provisions Based on Developmental Psychology

A considerable portion of the research literature deals with how to teach gifted students (e.g., Horowitz & O'Brien, 1986; Milgram, 1980; Reis & Renzulli, 1989; Slavin, 1987; Swiatek & Benbow, 1991; Vaughn, Feldhusen, & Asher, 1991; Wang & Walberg, 1983; Whitlock & DuCette, 1989). As this literature would suggest, many forms of instructional practice exist to serve the special needs of gifted children. These approaches can include some form of ability grouping (between- or within-class), cooperative learning, or pull-out programs. A further distinction can be made between homogeneous and heterogeneous grouping. However, the content of the program rather than instructional practice is most important. Certain instructional practices enable gifted children to learn at their own pace and level of ability. On the other hand, the content of the program enriches and motivates students who are highly able. Close examination of the research indicates that the various programs do tend to have positive influence on achievement, creativity or critical thinking (see Buchanan & Feldhusen, 1991). However, there is no clear indication of what is the most effective means of serving the academic needs of gifted students. To be able to identify the best practice requires comparison of all practices. This kind of research is both rare and difficult to do. Another conclusion that might be drawn from the literature is that academic arrangements designed to provide differentiated learning experiences for students of different ability levels are more effective than traditional undifferentiated approaches. It is also clear that the educational effectiveness of a particular instructional practice depends on the personalities of both teacher and student, and on social and developmental factors. Certain methods are most beneficial in certain environments for particular students. Further, what is beneficial in grade 3 need not continue to be beneficial in later grades.

The most beneficial educational approach, however, is the approach that fits the developmental needs of the individual child. As was already said, Vygotsky did not regard cognitive development as a process of nature (see Van Parreren, 1983), thus suggesting that education and instruction need not be fitted to a particular developmental level or stage, as Piaget argued. Vygotsky's position is that instruction creates development (to a certain extent), because learning and development take place within the zone of proximal development. Tasks within the zone of proximal development are too

difficult for the child to do alone. These tasks become possible with guidance and assistance from adults or older children.

An opposing developmental position has been defended and elaborated upon by Maria Montessori, a person who played a leading role in the school reform movement in Europe. This movement greatly influenced schools to become institutions where children were accepted and treated as individuals. The reform movement started in the early 1920s. Child-centered education was felt to be most beneficial for the healthy development of children.

Maria Montessori (1870–1952) grew up as an only child in a family with a father who believed in traditional values and role patterns. She aspired to a technical career but a daughter in a “male profession” was beyond her father's conservative value system, and he could not accept his daughter's choice of study. Maria Montessori was a mathematical prodigy, and at the age of 26 became the first woman physician in Italy's history. Although not a trained pediatrician, she became famous as an expert in children's illnesses.

After 1901, Maria Montessori studied anthropology, psychology and pedagogy at the university to be better prepared for the education of children. Her educational philosophy advocated first educating the senses and feelings and then educating the mind. Additionally, her system included observation of the child to provide for its needs. This core of principles formed the basis of a program that became a worldwide tool for innovative practices. Programs like the one established by Helen Parkhurst (Dalton Schools) were modeled after Montessori. Montessori's inherent interest in programs for gifted education is not so well known because she originally intended to serve the special needs of retarded and extremely poor children.

Montessori's Contribution to Gifted Education

Little systematic research on the effectiveness of Montessori education has been done. This is true for other educational approaches as well. Any meaningful evaluation of the Montessori system should be mindful of the specific objectives and key concepts of Montessori's approach. Concepts like independence, self-composure, love of learning, and tendency to lose oneself in one's work are essential in a Montessori education.

A central component of the Montessori theory is the concept of *sensitive periods*, or genetically determined developmental periods during which the child is especially eager and able to master specific tasks, similar to critical periods. During these periods the child works with a high level of interest to improve these abilities. However, “if the child is prevented from enjoying these experiences at the very time when nature has planned for him to do so, the special sensitivity which draws him to them will vanish, with a disturbing effect on

development . . ." (Montessori as cited in Crain, 1980, p. 56). According to Montessori, the critical sensitive periods in early childhood are for order, details, the use of hands, and for walking.

The role of parent and teacher can be described as "facilitator". To be successful in this role, parents must be aware of the specific developmental needs of the child, not only during early childhood but throughout the child's developmental period. Therefore, *ongoing careful observation* is necessary to give to the child needed experiences.

Other central concepts of Montessori education are *prepared learning environment* and *freedom of choice*. The proper environment will contain materials and means that correspond to the inner needs of children. Observation of the child enables the parent and teacher to make the right choices of supportive materials for the individual's development. Freedom of choice is the opposite of teacher dictated learning. Once the child makes a choice to do something, however, he/she must complete it. The provision of stimulation and control in the classroom are of course legitimate measures for teachers and are not in contradiction with freedom for the learner.

The Montessori elementary school with its mixed age groups (normally more than one age group is found in a class) provides possibilities for independent as well as cooperative learning. Ability grouping is a normal instructional practice in the Montessori school. According to Maria Montessori the age graded class should no longer be in existence (Holtstiege, 1991). A school must provide the possibility for an individual to progress at his or her own pace and level of learning. This principle is at the core of all gifted education.

Maria Montessori emphasized what she called *cosmic education*, an educational practice that has been improved in recent years throughout the world. It is substantially similar to environmental education (education to save natural resources, respect the environment, and oppose pollution). Montessori introduced the idea of a "cosmic task" for each child in the kindergarten, to care for a plant in order to increase a sense of responsibility for the environment. Cosmic education continues to be central to the curriculum into the higher grade levels.

The Montessori school encourages children to become independent learners and productive thinkers, and to love learning. Forms that this independence can take are revealed by a 10-year-old very able child who moved to another city with his parents. He wrote a postcard to his teacher saying, "I thank you for never teaching me anything" (personal communication from a teacher). Another 5-year-old Montessori child when asked, "Who taught you to read?" answered, "Nobody, I just read the book to see if I could read." A regular school child answered the same question with, "My teacher" (Crain, 1980, p. 68).

A curriculum based on Montessori education principles provides for *qualitative differentiation*. That is,

children are allowed to proceed at their own pace according to their own interests and needs. A differentiated curriculum is a prerequisite for appropriate and effective gifted education. Evaluation of the Montessori approach should include examination of test performance as well as independence, originality and productivity, and self-composure. Analysis of the Montessori system with regard to the elements beneficial for gifted education would be useful and helpful to the field. We agree with Crain's statement that, "Montessori demonstrated, as much or more than anyone else, how the developmental philosophies of Rousseau, Gesell, Piaget, and others can be put into effective practice. She showed how it is possible to follow children's spontaneous tendencies and to provide materials that will permit them to learn on their own" (p. 72).

Summary

Theories of development contribute to our understanding of the gifted. These theories provide different perspectives on the constitutional, environmental, psychological, and biologically determined characteristics and tendencies affecting gifted performance. They also give structure to social and political elements in the environment, and determine the opportunities for recognition of giftedness. Developmentally oriented definitions of giftedness have broadened from the foundations laid by Terman and other early workers. Cognitive research is becoming more influential. Research in the development of the gifted seems more influenced by practical than theoretical concerns. Although she worked more than half a century ago with handicapped children, Maria Montessori provided a fairly complete model for education of the gifted.

Genetic Influence on Cognitive Ability

LEE A. THOMPSON

Department of Psychology, Case Western Reserve University, Cleveland, Ohio, U.S.A.

ROBERT PLOMIN

Center for Developmental and Health Genetics, Pennsylvania State University, Pennsylvania, U.S.A.

Introduction

A handbook on giftedness and talent would not be complete without consideration of genetic influence. This chapter focuses on genetic research on one type of talent, general cognitive ability, because more is known about the genetics of this dimension than any other in the social and behavioral sciences. By general cognitive ability, we refer technically to "g" which is an unrotated first principal component of diverse tests of cognitive abilities. Because IQ scores from general intelligence tests are reasonable indices of "g," we could have used the terms intelligence or IQ scores but we prefer general cognitive ability which is less loaded with unwanted connotations. Although general cognitive ability is important, so are specific cognitive abilities such as verbal, spatial, and memory abilities. However, less is known about the genetics of specific cognitive abilities (Plomin, 1988).

In this chapter, we review research on the genetics of general cognitive ability that converges on the conclusion that this dimension of behavior shows considerable genetic influence. We describe a recent study which is the first to show that genetic factors are important, not only for the normal range of variation in cognitive ability, but also for high cognitive ability. Genetic research on this basic question of the impact of genetics on cognitive ability also raises interesting issues about the environment. In addition, genetic research on cognitive ability has begun to go beyond the basic nature-nurture question concerning the relative effects of genetic and environmental influences to ask more sophisticated questions such as developmental and multivariate questions. The most exciting recent advance is that the power of molecular genetic techniques is beginning to be harnessed in order to identify specific genes responsible for genetic influence on cognitive ability.

Genetics and Ability

Before launching this overview of genetic research on cognitive ability, it may be useful to ask why genetics has

been neglected in contemporary discussions of giftedness and talent. For example, most recent books on high ability (e.g., Feldman, 1986; Howe, 1990; Simonton, 1990) pay scant attention to genetics (cf. Storfer, 1990). Indeed, genetics is not mentioned in most of the chapters in this volume. This is ironic because one of the earliest scientific books about ability is also the first book about human genetics. A year before Mendel's seminal paper on the laws of heredity, Francis Galton (1865) published a two-article series on hereditary genius that he expanded into the book *Hereditary Genius: An Inquiry into its Laws and Consequences* (Galton, 1869).

Why is genetic influence neglected? Recent discussions of this issue in relation to the behavioral sciences suggest several possible reasons (Goldsmith, in press; Rowe & Waldman, in press; Rutter, Silberg, & Simonoff, in press). A rudimentary problem is the failure to distinguish between the development of differences among individuals and the development of an individual. Genetic research does not address the development of a single individual. Nor does it address the origins of species-wide developmental themes such as the use of language in the human species. Rather, its focus is on variations (individual differences) on these themes, for example, why some children are delayed in their use of language and why some individuals are more verbally fluent or have larger vocabularies than others.

An historical happenstance also contributes to the neglect of genetics: Behaviorism in the behavioral sciences set the study of behavior apart from the other life sciences. The legacy of behaviorism was to make behavioral scientists uncomfortable with biology. Behaviorism led to environmentalism, especially in the United States. Environmentalism dominated the behavioral sciences for so long that some behavioral scientists still find it difficult to accept a more balanced view that recognizes genetic as well as environmental influences on individual differences in behavioral development.

In our experience, the major source of concern about finding genetic influence in behavioral development

is the mistaken notion that if a trait is influenced genetically it cannot be affected environmentally. This notion is wrong for at least three reasons. First, to recognize genetic influence does not imply that a trait is entirely due to genetic influence. Rarely does heritability exceed 50% for behavioral traits, which means that as much of the phenotypic variance is accounted for by nongenetic as by genetic factors. In this sense, genetic research provides solid evidence for the importance of nongenetic factors.

Second, even if all the variance of a trait can be explained by genetic differences among individuals (and we hasten to add that no behavioral trait begins to approach this hypothetical case), this only describes "what is," not "what could be" or "what should be." Heritability describes the extent to which genetic differences among individuals in a particular population at a particular time contribute to observed (phenotypic) differences for a trait. In this sense, heritability is a descriptive statistic, not a constant like the speed of light. The relative magnitude of genetic and environmental influences can change as the population described changes. For example, one counterintuitive example of change is that genetic differences among individuals would increasingly account for phenotypic differences to the extent that salient environmental factors are equalized. In the case of cognitive ability, this would be the expected outcome of attempts to equalize educational opportunities.

In other words, heritability describes "what is" in a population—the genetic and environmental provenances of measured differences among individuals as they exist in a particular population with its particular mix of genetic and environmental influences. Heritability does not predict "what could be" nor does it prescribe "what should be." If this is understood, the following statement, which is at the crux of concerns about heredity and talent, will not sound paradoxical: Cognitive ability can be highly heritable in a population and yet show dramatic change for an individual who undergoes intense training. Heritability denotes probabilistic genetic influence for a population, not predetermined programming for an individual.

A third reason why it is wrong to think that genetic influences are immutable is that a necessary connection does not exist between the origins of a trait and intervention. Descriptions of "what is" do not have a necessary relationship to "what could be." Specifically, intervention programs for the gifted can be effective regardless of the origins of giftedness.

These concerns coalesce in the seldom-discussed but often-felt issue of political implications. In a recent discussion of this topic, Goldsmith (in press) makes three important points. First, it is wrong to suggest that scientific understanding of certain issues should not be pursued, although care must be taken to avoid interpretations of genetic determinism and other oversimplifications. Second, the rationale for intervention

should be demonstrated effectiveness, not efforts to denigrate evidence of genetic influence. Goldsmith's third point questions the assumption that genetic research will make people more hereditarian:

It would seem crucial to know what the general public, as well as political leaders, *currently* believe about the relative influence of inheritance and experience in molding behavior. It is not so clear that the public embraces experience over inheritance. Some of my experience suggests that an accurate description of current behavior-genetic findings to public groups outside academia often moves them toward a *less* hereditarian position (Goldsmith, in press).

Our view concerning social and political implications is that finding genetic influence is compatible with a wide range of actions, including no action at all. Values come into play when decisions are made concerning what is to be done with such knowledge. For example, finding genetic influence on cognitive ability by no means implies that those rich in ability must be made richer. Depending on one's values, it could be argued that scarce educational resources should go to those who most need them to function adequately in our increasingly technological society.

If heritability describes "what is" rather than predicts "what could be," then what does it matter whether or not genetic factors are important? The answer to this question depends on the answer to another question: Important for what purpose? For applied issues such as identification and intervention, genetics is unlikely to be of much specific help to the educator confronted with a gifted child. Knowledge of the importance of genetics might be helpful in more general ways. For example, finding genetic influence might aid identification by taking into account familial loading. Knowledge about genetic patterns of strengths and weaknesses might be useful in designing programs tailored to children's needs. Understanding the role of genetics can also affect our interpretation of other research. For example, most research on the development of talent focuses on familial factors such as parental tuition and encouragement. However, in families in which parents are genetically related to their children, it cannot be assumed that such links between parents and children are due solely to environment (Plomin & Bergeman, 1991). Another point is that just as cures are not necessarily related to causes of diseases, understanding causes can lead to more rational cures. In this sense, knowing "what is" is likely to guide us in the search for "what could be." More broadly, although finding genetic influence bears no necessary implications for social action, better decisions ought to be made with knowledge than without it. Finally, identification of specific genes involved in ability, discussed later in this chapter, would add considerably to the practical value of genetic knowledge. Still, for the present, it must be said that applications such as programs for the gifted would proceed largely

unchanged whether or not heredity contributes to the development of ability.

It should be noted, however, that behavioral genetic studies can contribute a great deal to our knowledge of environmental factors that affect behavior. Traditional environmental studies confound genetic and environmental influences; behavioral genetic research can disentangle genetic and environmental main effects, environment-genotype interaction and environment-genotype correlation. Identification of specific environmental factors that affect behavior may provide the best clues for designing effective intervention programs.

The major reason for wanting to know about the origins of ability is the basic science goal of explanation with no promise of practical application. An important first step, although just a first step, in understanding the origins of individual differences in ability is to ask the extent to which genetic factors are involved. This basic science interest in origins is also largely shared by educators and parents in a sense of curiosity about why children develop the way they do. We know that ability runs in families, but does it do so for reasons of nature or nurture?

Evidence for Genetic Influence

Human quantitative genetic research relies on family, adoption, and twin designs. Family studies of human behavior assess the extent to which genetically related individuals living together resemble each other. Such studies cannot disentangle possible environmental sources of resemblance. This was the problem with Galton's 1869 family study of talent in which he interpreted familial resemblance as due to heredity. Separating genetic and environmental sources of familial resemblance is the point of adoption studies. Genetically related individuals adopted apart give evidence of the extent to which familial resemblance is the result of hereditary resemblance. Genetically unrelated individuals adopted together indicate the extent to which familial resemblance is due to shared family environment.

Twin studies also provide a kind of natural experiment in which the resemblance of identical twins, whose genetic relatedness is 1.0, is compared to the resemblance of fraternal twins, first-degree relatives whose genetic relatedness is .50. If heredity affects a trait, identical twins should be more similar for the trait than fraternal twins. As in any quasi-experimental design, these methods have possible problems, most notably, the equal environments assumption for the twin method and selective placement for the adoption method. However, these are empirical issues and research suggests that these are not major problems. Moreover, the assumptions of the twin method are very different from the assumptions of the adoption method and yet the two methods generally converge on the conclusion that genetic effects are important. Details concerning quantitative genetic methods and their application to

behavior are available elsewhere (e.g., Plomin, 1990a; Plomin, DeFries, & McClearn, 1990).

Family, adoption, and twin studies can be used to estimate the magnitude of genetic effects as well as their statistical significance. This is the descriptive statistic heritability. As mentioned earlier, heritability is an estimate of effect size given a particular mix of existing genetic and environmental factors in a particular population at a particular time. Heritability estimates the proportion of phenotypic variance (i.e., individual differences in a population, not behavior of a single individual) that can be accounted for by genetic variance.

Consider height. Correlations for first-degree relatives are about .45 on average, whether relatives are reared together or adopted apart. Identical and fraternal twin correlations are .90 and .45, respectively, regardless of whether they are reared together or adopted apart. These results indicate significant genetic effects. For these height data, heritability is estimated as 90%. This estimate of effect size indicates that, of the differences among individuals in height in the populations sampled, most of the differences are due to genetic rather than environmental differences among individuals.

When these same methods are used to investigate genetic effects on general cognitive ability, they yield evidence for less but still appreciable genetic influence. Correlations for first-degree relatives living together are similar to their correlation for height. In a review of the world's literature of genetic research on IQ scores (Bouchard & McGue, 1981), the weighted average correlation was .42 for 8433 pairs of parents and their offspring in 32 studies. The weighted average correlation was .47 for siblings reared together (26,473 pairs in 69 studies). Unlike height, adopted-apart first-degree relatives are only about half as similar for IQ as are first-degree relatives living together. The average weighted correlation for 814 pairs of parents and their adopted-away offspring is .22; for 203 pairs of adopted-apart siblings the correlation is .24 (Bouchard & McGue, 1981).

The fact that the correlation for adopted-apart relatives is less than the correlation for relatives living together suggests that shared rearing environment contributes to the IQ resemblance of first-degree relatives living together. This fits with another finding from the adoption literature: Genetically-unrelated parents and offspring and siblings are similar. The average correlation for adoptive parents and adopted children is .19 (1397 pairs) and the average correlation for genetically unrelated children adopted into the same adoptive families is .32 (714 pairs; Bouchard & McGue, 1981).

Thus, in very rough summary, "genetic" relatives adopted apart correlate about .20, "environmental" relatives correlate about .20, and "genetic-plus-environmental" relatives correlate about .40. These adoption results are consistent with a heritability estimate of about .40, about half that for height.

The twin method converges on this conclusion. The average twin correlations are .86 for identical twins

(4672 pairs) and .60 for fraternal twins (5546 pairs; Bouchard & McGue, 1981). Because identical twins are twice as similar genetically as fraternal twins, a rough estimate of heritability doubles the difference between the identical and fraternal twin correlations. This estimate of heritability is about .50. It should be noted that the correlation of .60 for fraternal twins exceeds the correlation of .47 for nontwin siblings, which suggests that shared environmental influences contribute more to the resemblance of twins than nontwin siblings.

One of the most dramatic adoption designs, reared-apart identical twins, suggests a higher estimate of heritability than these other designs, although the number of such twin pairs is small for obvious reasons. For several small studies involving a total of 65 pairs of identical twins reared apart, the average correlation is .72 (Bouchard & McGue, 1981). The correlation for identical twins reared apart provides a direct estimate of heritability. This high heritability estimate has been confirmed in two recent studies of twins reared apart. In one report of 45 pairs of identical twins reared apart, the correlation was .75 (Bouchard, Lykken, McGue, Segal, & Tellegen, 1990). In a report of 45 pairs of Swedish identical twins reared apart, the correlation was .78 (Pedersen, Plomin, Nesselroade, & McClearn, 1992). The latter study also included 88 pairs of fraternal twins reared apart whose IQ correlation was .32 and matched identical and fraternal twins reared together. A model-fitting estimate of heritability that incorporates data from the four groups of twins in this study was .81, and a follow-up study three years later yielded similar results (Plomin, Pedersen, Lichtenstein, & McClearn, 1993). A possible explanation for this higher heritability estimate for twins reared apart is that, unlike most of the other twin and adoption studies, these studies involve adults rather than children and adolescents. As explained later, heritability appears to be greater later in life.

Model-fitting analyses that simultaneously analyze all of the family, adoption, and twin data summarized in the review by Bouchard and McGue (1981) yield heritability estimates of about .50 (Chipuer, Rovine, & Plomin, 1990; Loehlin, 1989). The error surrounding this estimate may be as high as .20, so we can only say with confidence that the heritability of IQ scores is $.50 \pm .20$. Nonetheless, even if heritability is at the bottom of this range, it is a remarkable achievement to account for so much of the variance of a trait as complex as general cognitive ability.

If half of the variance of IQ scores can be accounted for by heredity, the other half cannot and is attributed to environment. In this sense, these same genetic data provide strong evidence for the importance of the environment. These data also indicate how the environment works. Some of this environmental influence appears to be shared by family members making them similar to one another. For example, as indicated earlier, pairs of genetically unrelated children adopted into the same adoptive homes yield an average correlation of .32. This

suggests that about a third of the total variance of IQ scores may be due to a shared rearing environment. The average correlation of .19 between adoptive parents and their adopted children suggests less shared environmental influence, although it seems reasonable that parents and their children share less similar environments than do siblings. However, when we consider these data from a developmental perspective, a very different picture emerges, as described in the following section.

Beyond Nature–Nurture

A survey of more than 1000 social and behavioral scientists and educators indicated that most had accepted the evidence for a significant effect of heredity on IQ scores, traditionally one of the most controversial areas in behavioral genetics (Snyderman & Rothman, 1988). General acceptance of the important genetic contribution to individual differences in *g* makes it possible to go beyond this most basic nature–nurture issue to ask more interesting questions. Three examples will be mentioned briefly. The first concerns development.

Developmental Genetic Analysis: Genetic Change as Well as Continuity

When Galton first studied twins in 1876, he investigated the extent to which the twins' initial similarity or dissimilarity changed during development. Other early studies were also developmental, but this developmental perspective faded from genetic research until recent years.

Two types of developmental questions can be addressed in genetic research (Plomin, 1986). First, does heritability change with age? It is reasonable to suppose that environmental factors increasingly account for variance in cognitive ability as experiences accumulate during the course of life. To the contrary, genetic research suggests that cognitive ability shows a nearly linear increase in genetic influence from infancy through early childhood (Cardon, Fulker, DeFries, & Plomin, 1992; Fulker, DeFries, & Plomin, 1988; Wilson, 1983) and perhaps continuing throughout the lifespan (McCartney, Harris, & Bernieri, 1990; McGue, Bouchard, Iacono, & Lykken, in press; Plomin & Thompson, 1987). For example, as mentioned earlier, a recent report of the first genetic study of older adults reports a heritability of 80% for cognitive ability using the powerful design of twins reared apart and twins reared together (Pedersen et al., 1992).

Not only does heritability appear to increase during the lifespan, but the effects of shared environment appear to decrease. Although genetic research suggests substantial influence of shared environment as discussed in the previous section, recent evidence suggests that shared environmental influence that affects IQ scores may be much less after adolescence (Plomin, 1988).

The strongest evidence for the importance of shared environment comes from the correlation for adoptive siblings, that is, pairs of genetically unrelated children adopted into the same adoptive families. As indicated earlier, their average IQ correlation is .32. However, these studies happened to study adoptive siblings in childhood. In 1978, the first study of older adoptive siblings yielded a strikingly different result: The IQ correlation was $-.03$ for 84 pairs of adoptive siblings from 16 to 22 years of age (Scarr & Weinberg, 1978). Other studies of older adoptive siblings have also found similarly low IQ correlations (Kent, 1985; Teasdale & Owen, 1984). The most impressive evidence comes from a 10-year longitudinal follow-up study of over 200 pairs of adoptive siblings. At the average age of 8 years, the IQ correlation was .26. Ten years later, their IQ correlation was near zero (Loehlin, Horn, & Willerman, 1989). These data suggest that shared environment is important for IQ during childhood when children are living at home and then fades in importance after extrafamilial influences become more important.

A second type of developmental question concerns genetic contributions to changes with age and continuity in longitudinal analyses. It is important to recognize that genetic factors can contribute to change as well as to continuity in development (Plomin, 1986). Although genetic effects on cognitive ability contribute substantially to stability of cognitive ability during childhood, what is more surprising is the extent to which genetic effects appear to contribute to change with age (Fulker, Cherny, & Cardon, in press). Particularly interesting is the suggestion of substantial new genetic variation during the transition from early to middle childhood.

Multivariate Genetic Analysis: Genetic g

A second example of research that goes beyond the basic nature–nurture question is multivariate genetic analysis, which extends the univariate genetic analysis of the variance of a single trait to multivariate analysis of the covariance between traits. Multivariate genetic analysis makes it possible to estimate the extent to which genetic effects on one trait overlap with genetic effects on another trait. Analyses of this type in the realm of cognitive abilities indicate that specific tests and group factors show some genetic effects unique to each test and factor (Pedersen, Plomin, Nesselroade, & McClearn, 1993). Nonetheless, much of the genetic effects are shared in common across diverse tests and factors (Cardon & Fulker, in press).

Another recent finding makes a related point: The heritabilities of cognitive tests are strongly correlated with their g -loadings, their factor loadings on an unrotated first principal component (Jensen, 1987). That is, the more a test measures g , the more heritable it is. For example, in the study mentioned earlier of twins reared apart and twins reared together, the correlation between heritabilities and g -loadings

was .77 after differential reliabilities of the tests were controlled (Pedersen et al., 1992).

School Achievement and g : Same Genes, Different Environments

The third example also involves multivariate genetic analysis, but it is especially relevant to the origins and development of ability. School achievement is interesting from a genetic perspective because it is widely assumed that achievement and ability are different, almost by definition. Achievement is what a student achieves by effort, whereas ability is thought to involve inherent talent. For this reason, achievement test scores are assumed to be environmental in origin. However, a neglected finding is that achievement and ability tests are moderately correlated, which raises the possibility of genetic overlap between the two domains.

Although several twin studies of scholastic achievement have been reported in adolescence, until recently no research was available in middle childhood. In the *Western Reserve Twin Project* (WRTP), specific cognitive abilities and school achievement were investigated for a sample of 146 pairs of identical twins and 132 pairs of fraternal twins aged 6–12 (Thompson et al., 1991). Although school achievement tests yielded significant heritability estimates, these estimates were much lower than heritabilities for cognitive abilities—about .20 vs about .70. Most important are the results of multivariate genetic analysis: The well-known correlation between cognitive abilities and school achievement tests is due almost entirely to genetic factors in common to the two domains, a finding that has been replicated in another study (Wadsworth, in press) as well as in two studies focused on reading achievement (Brooks, Fulker, & DeFries, 1990; Cardon, DiLalla, Plomin, DeFries, & Fulker, 1990). Conversely, ability–achievement discrepancies are exclusively environmental in origin.

Although ability–achievement discrepancies have not been studied for high cognitive ability from a quantitative genetic perspective, a study addressing this question could have important practical implications. For instance, would the environment completely mediate ability–achievement discrepancies for high cognitive ability as it does for the entire range? For high cognitive ability these discrepancies must be manifested as underachievement. Identification of specific environmental factors that lead to underachievement in an extremely talented group could lead to changes in educational practice that would minimize underachievement by talented children.

Quantitative Genetics and High Cognitive Ability

The research described above addresses the etiology of individual differences in cognitive ability in the normal range. Much less is known about the origins of high

ability. It cannot be assumed that the etiology of the extremes of a dimension is the same as the etiology in the normal range. For example, at the low end of the ability spectrum, severe retardation shows little familiarity in contrast to the rest of the distribution of cognitive ability (Plomin, 1991).

Galton's 1869 study of talent was a family study. Since there was no satisfactory way to quantify ability, Galton relied on reputation as an index. By "reputation," he did not mean notoriety for a single act, nor mere social or official position, but "the reputation of a leader of opinion, of an originator, of a man to whom the world deliberately acknowledges itself largely indebted" (1869, p. 37). The designation "eminent" was applied to those individuals at the rank of 1 in 4000. The majority of individuals Galton considered to be the cream of this elite group, ranked as one in a million, and were termed "illustrious."

Taking the most eminent person in each family as a reference point, the other individuals who attained eminence were tabulated with respect to closeness of family relationship. Galton's results indicated that eminent status was more likely to appear in close relatives, with the likelihood of eminence decreasing as the degree of relationship became more remote. Eminence was attained by 26% of the fathers of the 100 most distinguished men, 23% of their brothers, and 36% of their sons. Second-degree relatives such as grandfathers, uncles, nephews, and grandsons achieved eminence to a much lower degree (about 7%), but much higher than the overall incidence of 1 in 4000 (i.e., .025%). These results conflate abilities of many different sorts, not just cognitive ability. Moreover, as indicated earlier, such familial resemblance cannot be attributed to heredity as Galton did. Galton started the nature-nurture controversy by overinterpreting his results to conclude that "ability will out" regardless of environment.

It is surprising that during the past century very little research has addressed the issue of the genetic and environment origins of high cognitive ability. Oden (1968) reported that, in a sample of gifted individuals who all had IQs of over 135 in Terman's study of the gifted, the 1571 offspring of these individuals yielded an average IQ of 133. Another study reported parent-offspring resemblance in another reanalysis of the Terman data (McAskie & Clarke, 1976). The analyses included 559 gifted parents with IQs over 135 and their 1027 offspring. Interestingly, the parent-offspring correlation was not significantly different from zero ($r = 0.08$) even though as a group the offspring mean resembled their parents' mean, as seen in the Oden (1968) report. McAskie and Clarke's finding is most likely due to the extremely truncated sample which attenuates the parent-offspring correlation. This is a problem that is inherent in studies of individual differences in extreme groups.

These two studies illustrate an important distinction that must be made when genetic and environmental

influences on the origins of high cognitive ability are explored. The issue is whether genetic factors affect high ability and how the magnitude of this genetic influence compares to the magnitude of genetic factors that contribute to individual differences in the normal range. The issue is not the heritability of high ability in the usual sense of genetic contributions to differences among high-ability individuals. The reasons why one child has an IQ of 150 and another an IQ of 145 are less important than understanding why both children have such high IQ scores as compared to the rest of the population.

This question can be addressed using a new approach that leads to an estimate of what is called *group heritability*, in contrast to the traditional heritability statistic which could be called *individual heritability*. Group heritability refers to the genetic contribution to the average difference between a selected group such as children of high ability and the rest of the population. The typical approach to group heritability in genetic research on disorders is to establish a cut-off score as a diagnostic index of the disorder (i.e., normal vs abnormal). Concordances can be calculated and compared for identical and fraternal twins, or liability (tetrachoric) correlations can be used which assume a continuous distribution even though the data, as they are used, are discontinuous.

A far superior approach has been developed by DeFries and Fulker (1985) and has been called DF analysis after its developers (Plomin & Rende, 1991). DF analysis requires that the continuum be assessed rather than assumed. It assesses group heritability as the differential regression to the population mean of the co-twins of identical and fraternal twin probands for a quantitative measure. That is, IQ scores of co-twins of probands ascertained because of high IQ scores are expected to regress toward the mean of the unselected population. However, to the extent that high ability is due to genetic factors, the regression to the mean will be less for identical twin co-twins than for fraternal twin co-twins. DF analysis was first applied to reading disability (DeFries et al., 1987). Group heritability for reading disability was found to be only about half the magnitude of individual heritability for reading ability, suggesting that the disorder of reading disability may be different etiologically than the dimension of reading ability.

Is group heritability of high ability significant? What is the magnitude of group heritability for high ability? The WRTP twin sample was used to estimate group heritability (Thompson et al., 1993). The DF approach was applied to IQ scores from traditional intelligence tests (Wechsler Intelligence Scale for Children-Revised and the Peabody Picture Vocabulary Test) expressed as a composite standard score with a mean of 0.0 and a standard deviation of 1.0. High ability was operationally defined as IQ scores 1.25 standard deviations above the sample mean.

As a preliminary analysis, concordances were calculated

separately for identical and fraternal twin pairs in which at least one member of the pair scored 1.25 standard deviations above the sample mean. Probandwise concordances were used in which the total number of affected individuals in concordant pairs is divided by the sum of the total number of affected individuals in concordant and discordant pairs. The probandwise concordances were 62% (18/29) for identical twins and 25% (6/24) for fraternal twins, suggesting genetic influence for high ability.

These twin concordances suggest that group heritability for high ability is additive in that the DZ (dizygotic) concordance is roughly half the magnitude of the MZ (monozygotic) concordance. This finding for high ability does not contradict the hypothesis that rare genius may be epistatic (Lykken et al., 1992). The genetics of genius may differ from the genetics of high cognitive ability. For example, specific constellations of many genes may be required for genius. The hallmark of such epistatic interactions is resemblance for MZ twins but not for first-degree relatives.

DF analysis provides an estimate of the magnitude of group heritability using continuous IQ scores rather than dichotomizing the scores. The gist of the DF approach to group heritability compares the mean score of the co-twins of identical twin probands to that of the co-twins of fraternal twin probands. Group heritability is suggested to the extent that the mean score of the former group regresses less far to the population mean than does the mean score of the latter group. For the high IQ sample, the mean standardized score of the probands is 1.67 and the population mean is 0.00. The co-twins of the identical twin probands regress very little to the population mean—their mean score is 1.53. In contrast, the co-twins of the fraternal twin probands regress more than halfway to the population mean—their mean score is 0.76. This pattern of results supports the suggestion of group heritability for high ability that emerged from the comparison of twin concordances.

DF analysis employs an elegant regression model which tests the differential regression to the mean for identical and fraternal twin probands, taking into account mean differences between the probands. The analysis yields estimates of group heritability and provides standard errors of the estimates. The analysis, described elsewhere (DeFries & Fulker, 1985, 1988), estimates group heritability as $.67 \pm .24$ for high ability. This significant group heritability suggests that about two-thirds of the difference between the IQs of the children in the high-ability group and the average IQ in the sample can be attributed to genetic factors.

This estimate of group heritability is similar to the traditional individual heritability for cognitive ability obtained in this same sample (Thompson et al., 1991). Together these results suggest an hypothesis with far-reaching implications: In terms of genetic influence, high cognitive ability may be merely the extreme of the normal continuum of cognitive ability.

Molecular Genetics and High Cognitive Ability

We are at the dawn of a new era in which molecular genetic techniques will revolutionize genetic research on behavior by identifying specific genes that contribute to genetic variance in behavioral dimensions and disorders (Plomin, 1990b). We have begun to employ these techniques in our research in order to identify specific genes that affect high cognitive ability (Aldhous, 1992).

It was only ten years ago that the now-standard techniques of the "new genetics" were first employed to identify genes responsible for single-gene disorders. As described elsewhere (e.g., Plomin et al., 1990), the discovery of restriction enzymes, which led to recombinant DNA and the ability to sequence DNA, also produced thousands of new DNA markers, genetic differences among people that involve DNA itself rather than gene products such as the blood groups. These new DNA markers can be used to identify a chromosomal region and, eventually, to isolate a gene and a gene product for single-gene disorders.

Notable early successes include cystic fibrosis and Duchenne muscular dystrophy. These are dichotomous traits, like Mendel's smooth vs wrinkled seeds, in which one gene is necessary and sufficient to explain the observed difference. Although several thousand single-gene disorders, most very rare, have been reported, behavior is much more complex. Behavior reflects the functioning of the whole organism and it is dynamic, changing in response to the environment. Genes that affect behavioral traits are transmitted hereditarily according to Mendel's laws in the same way as genes that affect any other phenotype. However, behavior is special in three ways. First, unlike Mendel's smooth vs wrinkled seeds, most behavioral dimensions and disorders are not distributed in simple either/or dichotomies such as talented vs not talented, although in psychopathology we often pretend that a line exists that sharply separates the normal from the abnormal. Second, behavioral traits are substantially influenced by nongenetic factors: heritabilities rarely exceed 50%. Third, genetic effects on behavioral dimensions such as cognitive ability are likely to involve many genes of variable but generally small effect size. Each of these points applies to the dimension of cognitive ability and to the dichotomy of convenience that we call high cognitive ability. The challenge is to use DNA markers to find genes in these complex systems of behavior that involve multiple genes as well as multiple nongenetic factors. Such genes of varying effect size that contribute to quantitative traits are called *quantitative trait loci* (QTL).

Linkage

For a single-gene trait, linkage is a method guaranteed to find the chromosomal location of the gene, even when nothing is known about the gene product. Linkage traces

the co-transmission of a marker and a disorder within a family pedigree. The exemplar is Huntington's disease, which was the first disorder mapped to a chromosome using the new DNA markers. Huntington's disease has long been known to be a single dominant gene that is lethal later in life regardless of a person's other genes or environment. Other single-gene disorders are quickly being put on the genome map through the use of linkage.

The problem is that behavioral dimensions are different. Most importantly, they show no suggestion of simple single-gene inheritance. Linkage can only identify a major gene that is largely responsible for a disorder. For the analysis of behavior, reliance on linkage techniques that can only detect major-gene effects is an example of losing one's wallet in a dark alley but looking for it in the street because the light is better there. It is now generally recognized that no major gene for behavioral dimensions or disorders is likely to be found in the population. However, current linkage research assumes that a major gene can be found in certain families. For this reason, linkage studies focus on large pedigrees with many affected individuals in the hope of finding a major gene responsible for the disorder in a particular pedigree. In this view, multiple-gene influence is seen at the population level because different major genes are responsible for the disorder in different families.

The alternative view espoused here is that major genes will not be found for behavior either in the population or in a family. Rather, for each individual, many genes make small contributions to variability and vulnerability. In this view, the genetic quest is to find, not *the* gene for a behavioral trait, but the QTL that affect the trait in a probabilistic rather than predetermined manner. Although some sledgehammer effects of major genes may be found, it seems more likely that many other alleles nudge development up as well as down for many individuals and do not show dramatic effects as in the classical single-gene disorders.

The point is not that behavior is too complex to take advantage of the new DNA markers, but rather that we need to bring the light of molecular genetics into the dark alley. New strategies are needed to identify genes that affect behavioral traits, even when the genes account for only a small amount of variance, when nongenetic factors are important, and when the traits are quantitatively distributed. That is, we need to use molecular genetic techniques in a quantitative genetic framework.

Allelic Association

Given the breathtaking pace of technological advances in molecular genetics, the safest bet is that at the turn of the century we will be investigating multiple-gene influences for complex dimensions and disorders using completely different techniques from those in use today.

However, one strategy that we are using in the meanwhile is called allelic association. Linkage refers to loci rather than alleles—linked traits such as hemophilia and color-blindness do not occur together in the population. In contrast, allelic association occurs when a DNA marker is so close to a relevant gene (or it is part of the gene) that affects the trait that a marker allele is correlated with the trait in unrelated individuals in the population.

The best case is when the marker is the relevant gene itself. That is, the marker can be in the coding region of a gene and thus code for actual polypeptide differences among people. Some background information is necessary here. Most DNA involves noncoding regions between genes that are not transcribed into messenger RNA and thus are not translated into amino acid sequences. Moreover, much DNA in a transcribed gene is spliced out (so-called introns) and is not translated into amino acid sequences that form polypeptides. Of the thousands of known markers, only a handful are known to be in coding sequences (exons). An example of functional markers that happen to be in coding sequences are markers for two of the five types of dopamine receptors, D₃ and D₄ dopamine receptors. In the case of dopamine D₄ receptor, it is known that receptor binding differs for people with different marker genotypes. However, the vast majority of current markers are likely to be in noncoding regions because natural selection permits variation in nonfunctional DNA much more than in functional DNA. Finding such functional markers is a high priority for research because of the power they provide for identifying QTL (Sobell, Heston, & Sommer, 1992).

Allelic association makes it possible to use markers that are not functional themselves but are very close to functional genetic variation. A particular combination of a marker allele and a functional variation in DNA that happen to be on the same chromosome is rarely separated by recombination (meiotic crossing over of chromosomes) if their loci are very close together on the chromosome.

Allelic associations have been found between disease states and markers in the HLA histocompatibility complex (Tiwari & Terasaki, 1985). In other words, particular alleles in this complex increase risk for certain diseases. For normal variation, the best example of allelic association is serum cholesterol levels for which about a quarter of the variance can be explained by four apolipoprotein gene markers (Sing & Boerwinkle, 1987). In psychiatry, a marker in the D₂ dopamine receptor has been reported in several studies to be associated with alcoholism (Cloninger, 1991). That is, the frequency of this allele appears to be greater in severe alcoholics than in controls, although failures to replicate have been reported.

A major advantage of allelic association analysis is that it can use samples of unrelated individuals, whereas linkage requires pedigrees of related individuals. In addition, allelic association is just as applicable to

quantitative traits as to disorders. Most importantly, by increasing the sample size of relatively easy-to-obtain unrelated subjects, association analysis can be made sufficiently powerful to detect small genetic effects.

A problem is that there are so many DNA markers. The allelic association approach is like a myopic search for a few needles in a haystack. In contrast to linkage which can detect a major gene far away from a marker, allelic associations can only be detected when a marker is very near a gene that affects the trait. For behavioral traits influenced by many genes as well as nongenetic factors, a near-sighted strategy such as association may be needed to see fine details of the landscape near a marker even though it has to sacrifice the ability to see distant mountains. This is not really a sacrifice because there are no mountains to be seen. Nonetheless, there are so many markers that randomly drawing straws from the haystack is unlikely to pay off. The odds can be stacked in our favor by beginning the search using markers in or near genes of neurological relevance. The odds can also be improved by using large samples and well-measured extreme groups to increase the power to detect small effects. The goal is to identify some, certainly not all, genes that contribute to the ubiquitous genetic variance found for behavioral traits.

Allelic Association and High Ability

We are using this allelic association approach in an attempt to identify QTL associated with high cognitive ability. DNA markers are employed that are in or near genes with possible neurological relevance such as the many neuroreceptor genes and genes involved in the regulation of these genes. From the WRTP sample of more than 500 children, we selected three groups of Caucasian children: 24 children with the highest IQ scores, 21 with average IQ scores, and 18 with the lowest IQ scores. The average IQ scores of the three groups are 130, 104, and 80, respectively.

We have obtained blood from these children and established permanent cell lines by transforming the lymphocytes with Epstein-Barr virus. Permanent cell lines provide unlimited amounts of DNA for marker analyses as well as a permanent resource for future DNA analyses of these samples. We have compared allelic frequencies for these groups for more than 20 DNA markers, including dopamine receptor 1 and 3, monoamine oxidase B, myelin associated protein, neurofilament protein, and fragile X repeat length. Although interesting preliminary results are beginning to emerge, we have agreed not to publish these results until we have replicated them in an independent sample. Our replication sample includes children with even higher IQ scores (mean IQ of 142), as well as children with even lower IQ scores (mean IQ of 74).

Nearly all molecular genetic research focuses on disorders, looking for DNA markers linked or associated with disruptions of normal development. We are

especially interested in identifying "increasing" alleles that contribute to high ability. For this reason, the pattern of results we are particularly interested in finding is one in which the allelic frequency is similar for the low-IQ and middle-IQ groups but different for the high-IQ group.

Conclusion

More is known about the origins of individual differences in general cognitive ability than any other behavioral dimension, although we are still closer to the beginning than to the end of the behavioral genetics story (Plomin & Neiderhiser, 1991). It is clear that genetics plays a major role in the story, and our DF analysis indicates that high ability is also strongly heritable. The convergence of evidence for the importance of genetic influence suggests that the current neglect of genetics in research on giftedness and talent needs to end.

Molecular genetics provides powerful tools that can be used to identify DNA differences among individuals without relying on familial resemblance. In addition to providing indisputable evidence of genetic influence, it will revolutionize genetic research by providing a measured genotype for investigating multivariate and longitudinal genetic issues, the links between the normal and abnormal, and interactions and correlations between genotype and environment. In a broader perspective, it will help to integrate genetic research in the increasingly fractionated biological and behavioral sciences at the universal level of DNA. The much-used phrase *paradigm shift* seems no exaggeration for advances of this magnitude. As is the case with most important advances, it will raise new ethical issues as well (Wright, 1990).

Acknowledgements—Preparation of this chapter and some of the quantitative genetic research it describes were supported in part by grants from the National Institute of Aging (AG-04563), National Institute of Child Health and Human Development (HD-10333 and HD-18426), National Institute of Mental Health (MH-43373, MH-43899), National Science Foundation (BNS-91-08744), and the John D. and Catherine T. MacArthur Foundation. Our current molecular genetics research is supported by grants from the National Institute on Alcohol Abuse and Alcoholism (AA-08125), National Institute of Child Health and Human Development (HD-27694), and National Institute on Drug Abuse (DA-07171). The QTL association study of high ability described in the last section is a collaborative project with M. Chorney, D. K. Detterman, G. E. McClearn, P. McGuffin, and M. Owen.

Brain Research Related To Giftedness

H. J. EYSENCK AND P. T. BARRETT

Institute of Psychiatry, University of London, U.K.

Introduction

The term "gifted" is essentially undefined; it is used mainly in three quite different ways (Muehle, 1969; Knoche, 1977; Helbig, 1988). In the first place, it is used as synonymous with "intelligent"; high IQ is the measure used to define giftedness (Rost, 1993). This definition began with Terman et al. (1925), Meili (1951), and Hofstaetter (1957); Rost (1993) gives a long list of authors who have adopted it. There are many clear advantages favoring this use of the term. Giftedness, however interpreted, nearly always involves high IQ, even if this is not considered to be the only ingredient. It is relatively easy to measure; there are many good IQ tests, as well as tests of special cognitive abilities (verbal, numerical, visuo-spatial, etc.). Underlying the IQ, there are good theoretical and experimental foundations. Finally, most studies of giftedness, particularly in the area here surveyed, have in fact correlated brain research findings with IQ. For all these reasons, most of the work here discussed has used IQ as the preferred measure of giftedness.

A second definition of "giftedness" relates to the concept of "creativity" (Glover, Ronning & Reynolds, 1989; Eysenck, 1993). Creativity is a dispositional trait, not highly correlated with intelligence, and measured usually by tests of *divergent*, rather than *convergent* type tests, unusual word associations, preference for complex as opposed to simple art forms, etc. Unfortunately the term is used in two different ways. It may be used as a *trait*, defined as implying originality in cognitive output, or it may be used to define socially valuable *achievement*. Trait creativity does not correlate highly with achievement creativity, for the simple reason that achievement creativity implies and needs a great deal more than trait creativity. Thus in order to create an original work of art, or a novel theory in science, high intelligence, great persistence, social support, high motivation, and much else is needed, in addition to trait creativity (Eysenck, 1993). Einstein, Mozart, Shakespeare or Titian could not have shown their creativity in an African kraal, an Eskimo igloo, or an Indian wigwam!

A final definition of "giftedness" is in terms of highly specific talents. Musical ability often shows itself at astonishingly young ages (Mozart!), and appears to

be quite unique, particularly at the executive level; when we talk about composers we find that the truly great also have very high IQs (Cox, 1926). Drawing and painting appears to be a similarly unique ability, but again when we approach the genius class there is a strong admixture of intelligence. It would be extremely interesting to measure brain activities in highly musically or artistically gifted children, but this has not been done, and consequently we are compelled to use IQ as our main criterion of giftedness. This is matter, not of choice, but of necessity; using any other definition of giftedness would leave this chapter very short indeed! It would also leave us with very little psychological theory or empirical knowledge. Hence our concentration on brain research related to intellectual giftedness.

Cognitive factors are obviously important as far as "giftedness" is concerned, but there is also much evidence that creativity is highly correlated with personality (Eysenck, 1993). Here too there is considerable evidence of differential brain activity (Eysenck, 1990). Much of the discussion of the relationship between creativity/genius on the one hand and personality on the other has been concerned with the pathological side of personality (Prentky, 1980; Lange-Eichbaum, 1950). We will return to this point on a later page.

Other factors, like motivation, are of course also of supreme importance for creative achievement, but for giftedness as a trait, i.e. a dispositional variable, they are probably less important. Many gifted children fail to show any creative achievement when they grow up; their giftedness fails to be translated into real-life contribution to art or science. This difference between disposition and achievement is central to any discussion of giftedness; we may be gifted, but hide our talent under a bushel!

Given that giftedness, however defined, is a *psychological* concept, why would we look for its causation or correlates in the cortex? The main reason, of course, is that there is a strong genetic determination to all the variables associated with giftedness (Vernon, 1989). The most obvious relation is with IQ; there is no question that IQ is strongly determined by additive genetic variance (V_A), to the extent of roughly 70%. Between-family environmental variance adds another 20%, and within-family environmental variance 10% (Eysenck, 1979). There are many different sources of evidence for

this conclusion: studies of monozygotic twins brought up in separation; comparisons of monozygotic and dizygotic twins; children adopted at birth; regression to the mean; inbreeding and its opposite, heterosis—these are just a few of the methods used to measure the heritability of intelligence and put together a model of the genetic architecture involved.

Intelligence, in addition to a general ability factor (Spearman's *g*) contains also a number of specific ability factors, and it is important to discover whether these, too, are heavily determined by genetic factors. Nichols (1965), Petrill and Detterman (1991), and specifically Cardon et al. (1992) have answered the question in the affirmative. Cardon et al., in technically by far the most adequate study, looked at verbal, spatial, perceptual speed and memory factors independent of *g*, and found strong evidence for genetic determination. This is important as it serves to *direct* a child's interest and motivation in accordance with his special gifts; general giftedness is supplemented by special gifts determining the child's major likelihood of successful adaptation.

In a similar way there is ample evidence to show that personality, too, is strongly determined by genetic factors (Eaves, Eysenck, & Martin, 1989; Loehlin & Nichols, 1976). Here twin and adoption studies again play the most important role, and demonstrate quite clearly that at least half the phenotypic variance in the great majority of personality traits is contributed by genetic factors, although *epistasis* plays a role in addition to V_A . Practically all the environmental variance is within-family, with little if any evidence for between-family variance playing a part, contrary to common belief.

When we turn to such conceptions as creativity, genius and special artistic talent, we have to confess that we have little in the way of experimental research that could be compared with the large body of empirical material that exists in relation to IQ (Vernon, 1989). It is sometimes suggested that the fact that giftedness seems to run in families may support a genetic interpretation, but such a suggestion is clearly mistaken. Familial concordance can be produced equally easily by environmental as by genetic means; by itself it argues for neither explanation. Quite the opposite is in fact true; the fact that many a genius is born in an utterly undistinguished family (Gauss, Newton, Berlioz) makes environmental influences an unlikely candidate, and leaves genetics as the only explanation. Of the two dozen most famous mathematicians in the history of the world, all but two were born into families not containing any mathematicians (Eysenck, 1993); where but from a random segregation of genes could they have received their talent?

The main point here is that if DNA plays a large part in intelligence, and probably in creativity and special abilities, then surely we must postulate some intermediary links of a psychophysiological or hormonal kind between DNA and behavior. DNA cannot *directly* influence behavior; it can only do so via such intermediaries as

those postulated above. Hence the need to search for these intermediaries which will presumably emerge as biological correlates of creative and "gifted" behavior. This, at least, is the way research workers in this field have integrated these areas, and we will follow along the same path.

Experimental Methods in Brain Research

Before we examine the research evidence relating brain physiology and function to giftedness and intelligence, it is perhaps useful to describe some of the measurement techniques and terminology that are associated with this area.

The Electroencephalogram (EEG)

The EEG is a record of the electrical activity of the brain, conventionally recorded using metal electrodes placed in contact with the surface of the scalp. The electrical activity represents the mass action of neurons at both the cortical and subcortical levels of the brain. Effectively, the EEG is measuring voltage changes over time. Due to the density of the skull, interstitial fluids, and membrane thickness, the EEG signals are heavily attenuated and subsequently of the order of amplitude of tens of microvolts. Brain electrical activity is continuous and can be analyzed, using the mathematical methods of spectral decomposition and analysis, to show which particular frequencies are present at any point in time within the continuous trace. Conventionally, there are four major frequency bands of interest:

Delta: frequencies below 4 Hz. Delta wave activity is of high amplitude but low frequency. It is associated with unconsciousness whether induced by physical trauma, tumor, anesthesia, seizure, or sleep.

Theta: frequencies between 4 and 7.5 Hz. Theta activity is mostly seen in adults during drowsiness and sleep. More generally it is associated with maturational processes in young children. There is some evidence that theta activity is associated with emotional response as in feelings of frustration or pleasure. However, this evidence is ambiguous.

Alpha: frequencies between 8–13 Hz. Alpha activity is most commonly observed when an individual is fully awake, relaxed both physically and mentally, and in an environment relatively free of stimuli. These frequencies are seen predominantly over the occipital area of the scalp, with the eyes closed. Alpha wave activity is very sensitive to changes in mood and information processing workload.

Beta: frequencies above 13 Hz to about 40 Hz. Beta activity is associated with desynchronization or break-up of the alpha rhythm, due to novel stimulation, visual perception, or increased cognitive information processing activity. Generally, beta waveforms are observed in the frontal and central regions of the brain.

The ongoing EEG waveform can be analyzed in terms of single events or regions of interest (spikes, alpha spindling, paroxysmal discharges, artefacts), or by using power spectrum analysis, examined with regard to the frequencies being generated over a particular period of time. Topographic EEG is the name given to the methodology that graphically represents this frequency activity recorded over time, across up to 64 electrodes placed on the scalp. This spatial distribution of electrical power at each frequency, computed at each electrode position, can be plotted in the form of contour lines, color densities, or grey-scaled bitmaps. The power at each frequency for areas of the scalp between electrodes can be estimated by interpolation methods.

A comprehensive overview of the area can be found in Niedermeyer and Lopes da Silva (1982), Maurer (1989), Fisch (1990), and Binnie and McGillivray (1992).

Averaged Evoked Potentials

While the analysis of ongoing EEG has provided much information with regard to clinical syndromes and symptomology and has provided some insight into the relation between brain activity and behavior, it is limited in terms of the period of analysis of the data. Generally, ongoing EEG is assessed over a period of seconds or minutes and parameters computed from the data reflect this gross level of activity. However, when the brain is presented say with a tone or light flash or any stimulus of brief, transient duration (milliseconds), it is the instantaneous electrical response of the brain that is primarily of interest, not the long-term ongoing, background EEG. A problem that arises here though is that the instantaneous brain response is in most cases extremely difficult to detect from the general background “clutter” of ongoing brain activity. To use an analogy from the engineering world, the signal (the brain response) is masked by the noise (the background EEG activity). There are two ways of approaching the solution of this problem. The first involves developing signal processing methods that are sufficiently sensitive to detect the signal within the noise, the second approach uses the principle of averaging to enhance the signal. The first approach, known as single trial evoked potential analysis, is only just beginning to show promise (as discussed later). The second approach, that of averaging waveforms, has been the conventional method of analysis to date. If we repeatedly present a stimulus to an individual and record the instantaneous brain response to each stimulus (storing say half a second's worth of activity immediately following stimulus presentation), and add these stored traces to one another, slowly the evoked response is seen to emerge from the gradually reducing background activity. Essentially, each recorded trace contains a waveform that consists of a response and background activity over the duration of the response. If the background activity has no relation to the stimulus, it can be viewed as random “noise”. If we add several

traces together, the noise will tend to sum to zero (as with statistical “noise”), while the signal will tend to become larger relative to the reduction in noise. This is because the signal is a relatively constant feature of each trace, in effect non-random. Hence, when summing the voltage values which contain the signal, the features of the signal are enhanced. Depending upon the strength of the signal in response to a single stimulus, as few as 5 or as many as 1000 or more stimulus trials may be required to enhance the evoked potential. For most experiments looking for cortical evoked potentials, somewhere between 50 and 100 trials are normally presented. Prior to the advent of computers, signal averaging was done visually, using a storage oscilloscope that displayed each trace superimposed over previous traces. Since the early 1960s, however, a computer has been used to sample the voltage values from an EEG electrode after a stimulus has been presented, store the values as an array, then add to it the next sequence of trace values for each stimulus presentation. The final values in the array, divided by the number of stimulus presentations, represent the averaged evoked potential (AEP).

Figure 1 shows a typical AEP recorded using an auditory tone stimulus of 30 milliseconds (msec) duration and averaged over 100 stimulus presentations. As can be seen from this figure, the main features of interest appear to be evident at about 20 msec or so into the response, with the response appearing to diminish after about 400 msec. From the calculations made in producing this trace, and from the trace itself, several parameters can be extracted that describe trace variability, peak latencies, trace and peak integrated amplitude, and the spectral power at each frequency that is evident within the trace. In addition, by varying the stimulus or information processing required to be used by an individual during the presentation of a stimulus, it is possible to observe “paradigm specific” signal features. For example, the P300 latency parameter is computed from an AEP, being measured as the time from stimulus onset/offset to the maximum amplitude

FIGURE 1. An averaged evoked brain potential to 100 auditory tone stimuli.

observed around 300 msec. There is in fact a definite positive voltage peak at around 300 msec that is a function of the specific experiment paradigm that introduces some level of uncertainty concerning a feature of the stimulus. Further information about evoked potential methodology can be found in Regan (1989) and Brunia, Mulder, and Verbaten (1991).

The Measurement of Cerebral Hemisphere Lateralization

If ongoing EEG or AEPs have been recorded from at least two sites on the scalp, one electrode over each brain hemisphere, then assessment of hemispheric differences can be examined using a variety of computed parameters. These parameters can be based on power at specific frequencies between the hemisphere sites, latency and amplitude differences, and the synchronicity of activity between the sites. A review of the computational aspects of lateralization analysis is presented by Sprott and Bryden (1983).

Brain Imaging (rCBF, SPECT, PET, CAT, MRS, MRI)

Since the late 1970s and early 1980s, methods of graphically imaging brain structure and activity have become possible. While X-ray techniques have been available for many years, these have generally required high power irradiation of body tissues that carry a risk of physical injury due to the radiation effects. In addition, the spatial resolution of the X-ray image was not particularly good when used as an imaging procedure for soft tissue structures like the brain. One approach to solving this problem is to examine regional cerebral blood flow (rCBF) within the brain, using some form of volume measurement as an estimate of brain activity. If an individual is administered a low radiation level, short half-life, radioactive isotope that is absorbed by the blood but does not cross the blood-brain barrier, it is possible using gamma scintillation cameras to inferentially compute the cerebral regional blood flow from the isotope "washout" activity. Crude spatial localization of blood flow and volume can thus be "imaged" in this manner. Alternatively, it is possible to use an isotope that does cross the blood-brain barrier and is "trapped" in cells for up to about 6-7 hours. Single Photon Emission Computed Tomography (SPECT) is used in conjunction with this particular technique as only a single photon is produced in each radioactive collision (positrons colliding with electrons). Rotating gamma cameras around the head of a subject detect photon activity and thus permit computation of the probable source of that activity. Although it is possible to use SPECT for reconstruction of regional tissue structures, it remains problematic to compute blood flow values.

A related approach to modeling the dynamics of brain activity is the Positron Emission Tomography (PET) methodology. In this technique, a low-level radioactive isotope is "tagged" onto a substance such as glucose, which is then injected intravenously into an individual. Since neural activity requires glucose to be metabolized for energy purposes, it is possible to detect areas within the brain that have metabolized glucose by using the isotope positron collision activity within the area of metabolic activity. The primary difference between SPECT and PET is that the radioactive substances used for PET collisions produce two photons per collision. These photons always have opposite directions of travel. From this directional information, source reconstruction is possible and subsequently the entire set of information is displayed as a graphical image. A 3D image is built up from the repeated analysis of data in terms of planar "slices" of the skull. So, in addition to having the ability to image the structural aspects of the brain, the dynamics may also be investigated by mapping the metabolic activity via isotope positron interaction.

The first structural 3D modeling technique for morphological imaging of the brain *in toto* used low power X-rays coupled with enhanced signal processing algorithms. The Computed Axial Tomography (CAT) scan projected X-rays in tightly defined planes, building up the 3D image from the computed particle interactions within each focused plane. Although the spatial resolution was still not high, it was, however, the first time a 3D realization of brain morphology had ever been produced *in vivo* within a living human subject. Since this pioneering work, X-ray power required to produce images has decreased while image resolution has increased via signal processing algorithms. In addition, a new method of imaging has recently been introduced, based upon the effect of an intense magnetic field upon the spin alignment of certain unpaired protons and nuclei within brain tissue. With the introduction of an externally applied strong magnetic field, the unpaired nucleons align their spins either parallel or antiparallel to the axis of the field. The two spin orientations have slightly different energies, with the separation between these energy levels proportional to the magnitude of the magnetic field. In addition, there is some movement around the spin angle by each specific type of nucleon that has been likened to a form of resonance within the magnetic field. These resonance frequencies are unique to each particular type of nucleon, allowing identification and spatial mapping of the presence of chemical substances by the use of such frequencies. This technique of Nuclear Magnetic Resonance (NMR) is also known as Magnetic Resonance Spectroscopy (MRS) and more generally as Magnetic Resonance Imaging (MRI) when applied to the detection of water protons (hydrogen nuclei) only. Both MRS and MRI are truly non-invasive imaging techniques in that they require no inhalation or ingestion of radioactive substances as with rCBF, SPECT, or PET, or bombardment with X-rays as with CAT scanning. In addition the spatial

resolution of MRI and MRS is far superior to that provided by the other techniques. Two recent reviews by Dager and Steen (1992) and Prichard (1992) outline the methodology and provide some initial evidence of its utility in brain research. A paper by Adams et al. (1992) also provides an insight into the comparative clinical utility of the various imaging methodologies discussed above.

Cerebral Hemisphere Lateralization

During the past 20 years a technological revolution has taken place within the fields of functional brain research, neuropsychology, and cognitive psychophysiology. This advance in technology has permitted measurement of brain structure, function, and activity that has had a significant impact on knowledge about the involvement of the brain in behavior. Strangely, this revolution appears to have been largely ignored within the area of giftedness. In addition, the standard of research implemented in this particular area is so low in quality as to render most of the reported results and conclusions unsound. The main focus of this chapter will be the exposition of the primary methodologies (and results following from their use) that are now available to researchers examining brain structure and function. Initially, we have examined the most relevant research results that have been generated from the psychophysiological investigation of gifted children.

One area that has persistently attracted research has been that concerned with the lateralization of cerebral hemisphere information processing and the concomitant notion of cerebral dominance. Since the work of Sperry (1964) and Gazzaniga (1967) reporting the behavioral effects of severing the two cerebral hemispheres, much experimental effort has been expended in attempting to demonstrate that right hemisphere processing is concerned with spatial, gestalt, "creative" functions, and left hemisphere processing with sequential, analytical, verbal information processing functions. With regard to the application of this lateralization construct to giftedness, the hypotheses put forward generally involve the notion of right cerebral dominance being associated with high levels of creativity, artistic and esthetic appreciation, and high levels of skill in games involving rapid assimilation and use of spatial information (tennis, pool, snooker, chess). Thus, gifted children are viewed as having some form of enhanced right hemisphere processing capability, whether such enhancement is via greater processing "power", "speed", or interhemispheric information exchange.

For example, Olson (1977) used a visual field task to investigate whether gifted children, who demonstrated Piagetian formal operational thought, used their right visual field to process verbal and spatial information (in the form of questions printed on sheets of paper, presented at the midline of a subject's field of view).

Olson concluded that the gifted children predominantly processed verbal questions using their right visual field, and spatial questions with their left visual field. Although this result was not especially novel, the use of a sample of children who were classified as Piagetian concrete operational level demonstrated that these children primarily used their right visual field for all printed items, both verbal and spatial. Hence, Olson inferred that early acquisition of Piagetian formal operational thought is related to giftedness and is associated with early hemispheric lateralization of information processing. Unfortunately, Olson did not report how many children took part in the study, their age or sex or handedness, the definition of the classification of "giftedness", how the Piagetian stages were measured in the children, and how the visual field usage measurements were made (except via videotape by several uninformed observers). The result from this study is therefore of dubious accuracy and validity.

Another related approach to determining hemispheric lateralization functions within the gifted child is that concerned with conjugate saccadic eye movements. These movements are used as an index of brain hemispheric processing. The reasoning (and assumptions) behind the use of these movements is as follows: if a subject is asked to visually fixate on an experimenter while being asked a question that involves introspection, the subject's eyes will move to the left or the right while such introspection is taking place. The lateral shift is sufficiently consistent to allow for classification of a subject as either a right or left mover. Evidence from several studies using this technique have indicated that left lateral movement is associated with spatial items, indicative of right hemispheric processing. Right lateral movement is associated with verbal items (Bakan, 1969; Harnad, 1972; Hines & Martindale, 1974; Rekdal, 1979; McCallum & Glynn, 1979; Doerr, 1980). The more creatively gifted, the more the predominance of left lateral eye movements and inferred right hemisphere activity. Leaving aside the assumption that lateral eye movement saccades actually reflect contralateral brain hemisphere processing, it is interesting to note Gur's (1975) observations on conjugate saccadic behavior. In a series of studies using this methodology, Gur noted that saccadic behavior may be more related to the position of the experimenter than to the assumed hemispheric processing content of an item. When solving spatial items, he found that when the experimenter was sitting behind a subject, eye movement was predominantly to the left (indicating right hemisphere processing). However, when the experimenter faced the subject, lateral eye movement was predominantly in one direction only, regardless of item content. Gur concluded that when an experimenter faces a subject, saccadic behavior is a function of a subject's characteristic mode of response. When the experimenter is seated behind a subject, the saccadic response is more a function of the type of item presented. Apart from Gur's observations, the other problem with this line of research is that

brain hemispheric involvement is inferred rather than measured directly.

More recently, Charlton, Bakan, and Moretti (1989) reviewed the current literature on eye movement and hemispheric processing literature. They concluded that the link between eye movement laterality and brain hemisphere processing is no longer an assumption but that converging lines of evidence from experiments using EEG, nuclear imaging, and cerebral blood flow provide support for such a proposition. Charlton and Bakan (1990), using 80 right-handed university students, also demonstrated that subjects who are classified as "left movers" tend to produce more random runs in a sequence of binary choices than "right movers" (the subjects were required to imagine that they were flipping a coin 300 times and note whether a head or tail occurred). The strength of the relationship between laterality and the number of runs in the sequence was -0.23 (using a differential laterality quotient), indicating greater right hemisphere involvement in the production of random runs. The correlation is significant at $P=0.0401$ two tail, but only explains 5% of the variation between laterality and number of runs. The results from this experiment, as with most others reviewed by Charlton *et al.* (1989) and from more current studies, indicate that the global assertions concerning conjugate lateral eye movement as a measure of hemispheric specificity are not strongly supported at all. For example, studies by Yagi (1987), Neubauer, Schuler, and Pfurtscheller (1988), Farah, Weisberg, Monheit, and Peronnet (1989), Dunn, Bartscher, Turaniczo, and Gram (1989) and Raine (1991) all yield results that tend to suggest that hemispheric lateralization within subjects is not a strong phenomenon. What dominance effects there are tend to be transient and related more to the task conditions rather than any enduring bias (Raine, 1991). Further to this point is the review by Gevins (1983) of the studies purporting to demonstrate hemispheric lateralization using spontaneous EEG and evoked brain potentials. Noting the criticisms of this research made earlier by Donchin, Kutas, and McCarthy (1977), Gevins systematically reviewed each of 17 major studies in this area. Each study was found to contain gross methodological and statistical flaws such that any results found were either ambiguous or invalid. Gevins' own work in this area (Gevins *et al.*, 1981; Gevins, Schaffer, Doyle, Cutillo, Tannehill, & Bressler, 1983; Gevins, 1989; Gevins & Illes, 1991) has shown that the simplistic assertions concerning cerebral hemisphere lateralization, cerebral dominance, and the division of processing within discrete brain hemispheres are not supported by detailed experimental work that examines the dynamics of spatial EEG and evoked brain potentials. His work and that of his co-workers has demonstrated that localization functions are transient and complex. This was demonstrated quite clearly in the Gevins *et al.* (1983) study on the lateralization of brain potentials during a visuomotor task. More recently, Efron (1990) critically reviewed the field, with equally negative results.

On another research front, Ertl and his colleagues (Chalke & Ertl, 1965; Ertl & Schafer, 1969; Ertl, 1971) demonstrated that averaged evoked potentials (AEPs) recorded from the brain response to visual flash stimuli were related to IQ test scores. Specifically, the latencies of the peak components within the AEP trace correlated negatively with IQ between about -0.30 and -0.50 . Ertl interpreted this correlation as indicating that high IQ subjects have "neurally efficient" brains. Ertl further extended this proposition by proposing that the most valued measure of neural efficiency was the average frequency of the non-alpha wave activity. He subsequently introduced the Brain Wave Analyzer, a device for automating collection of EEG and computation of seven parameters concerned with assessing neural efficiency. Two of these parameters involved estimation of brain hemispheric activity, a symmetry parameter assessing hemispheric synchronization of activity over several frequencies, and a dominance parameter assessing the ratio of frequencies generated in the left hemisphere as contrasted with the right hemisphere. Two studies by Fischer, Hunt, and Randhawa (1978, 1982), and a study by Trout, Packwood, and Wilson (1976) demonstrated that the only parameter marginally related to IQ was the symmetry parameter, assessing the synchronization of activity between the two hemispheres, albeit only at two electrode locations over the parietal area of the scalp. Greater symmetry was associated with higher performance on the cognitive tests.

Finally, returning to the emphasis of hemispheric dominance, some early empirical studies found that there was a small but apparently reliable deficit for left-handed subjects on test of spatial ability (Levy, 1969; Miller, 1971; Nebes, 1971). The proposed hemispheric explanation for this effect is that the bilateral development of the language abilities thought to characterize left-handed individuals encroach upon the neural space allotted for development of the spatial abilities in the right-handed, leading to a decrement in spatial ability. However, a recent review of later studies in this area by Natsopoulos, Kiosseoglou, and Xeromeritou (1992) has indicated that this explanation is not supported by the evidence. Rather, the opposite appears to be the case. Of relevance here is the work of Geschwind and his colleagues (Geschwind & Behan, 1982; Geschwind & Galaburda, 1984, 1987). He has argued that prenatal exposure to high levels of the predominantly male hormone testosterone may influence underlying brain organization by enhancing the development of the right hemisphere relative to that of the left. Benbow and Stanley (1980, 1983) and Benbow (1986, 1988), in an examination of the physiological characteristics of the intellectually gifted and mathematically precocious, found that there was a greater number of males than females in the gifted groups of children who formed the sample for the Study of Mathematically Precocious Youth. In addition, it was also found that there was a higher number of left-handed children in the groups than would be expected by chance and that giftedness

was positively related to visual myopia and incidence of allergies. The large-scale analysis of the project Talent data (Flanagan, Dailey, Shaycroft, Gorham, Orr, & Goldberg, 1962) reported by Lubinski and Humphreys (1990, 1992) replicated the findings of Benbow concerning the relationships between myopia and the frequency ratio of males to females in the gifted groups. However, the evidence on allergy problems was not replicated.

O'Boyle and Benbow (1990) and O'Boyle, Alexander, and Benbow (1991) further examined the role of the right hemisphere in cognitive processing using dichotic listening for syllables and chimeric faces (Levy, Heller, Banich, & Burton, 1983a, b) in right-handed children. The results from these experiments indicated that gifted children (defined as being in the top 2% of the Scholastic Aptitude Test) tended to demonstrate more high frequency EEG in the left hemisphere while in a resting "baseline" condition and greater desynchronization of alpha frequency in the right hemisphere while solving the chimeric face problem. Notably, when processing verbal information, no differences were observed between the gifted children and a control group of average ability children. One problem with the O'Boyle et al. (1991) study that specifically used the EEG to determine hemispheric activity was that there were only six children in the gifted group and eight in the control group. As Gevins (1983) has previously indicated, results based upon such low numbers of subjects lack both statistical power and credibility.

The areas of investigation reported above are those that seem to best define the approaches adopted by researchers involved with the physiological concepts of giftedness. Although there have been some other studies that have appeared from time to time in the literature—for example, the work on sleep patterns in gifted children—reported in Pivik, Bylsma, Busby, and Sawyer (1982) and Busby and Pivik (1983), and some work reported by Lubar, Gross, Shively, and Mann (1990) on the differences between gifted, normal, and learning disabled children in AEP laterality—few significant results have emerged from the work. Rather, the complexity of the phenomena under examination has invariably swamped the data, especially when most of the experiments have involved groups of gifted children of less than 10 subjects. The observational, semi-actuarial, work of Benbow, Lubinski, and Humphreys reported above does provide insight into the patterning of attributes associated with giftedness (defined primarily by high scores on a wide range of psychometric ability tests), but cannot allow computational inference as to causality or underlying physiological associations (Eysenck, 1988). Given a more restricted definition of giftedness is considered, based upon psychometric IQ test scores (Levine, 1985; Leung, Robson, & Lim, 1992), one avenue of research in this area is to examine the biological basis of IQ test scores. The data from Lubinski and Humphreys on mathematical precocity in children support the fact that these children all scored well

above average on IQ test composites. Thus, although psychometric IQ may not be a necessary condition for defining giftedness, it does nevertheless appear to be one of the most important attributes in giftedness per se. In addition, the use of psychometric IQ scores assumes that the abilities under examination are measured on a continuum. That is, the concept of giftedness is defined solely on the basis of elevated psychometric test scores, not on other behavioral traits or characteristics of an individual. The importance of considering this avenue of research is that instead of having to focus on discrete groups of individuals classed as gifted, normal, or learning disabled, the entire measurement range of the IQ scores under examination can be used. This has benefits for statistical measurement properties of the data, as well as enabling analytical inferences to be drawn about the categorical nature or otherwise of the definition of giftedness. In addition, sampling problems are eased due to the loosening of restrictions placed upon membership of any sample. To obtain a representative sample of gifted children that might satisfy test power constraints for a reasonable effect size generally involves sampling at least 40 or 50 such children, by sex (it is also debatable whether the statistical inference properties of normal distribution theory are applicable when subsampling from the tail of a distribution). In addition, working with restricted groups such as these can produce unexpected statistical problems as discussed by Vernon (1990) and Lynn (1990a) concerning the relationship between spatial and verbal abilities in restricted IQ range samples.

One area which has produced some very significant results is that examining brain/hemispheric size differences and their relation to psychometric ability test scores. Unlike the more conventional studies using cranial capacity and head circumference (Jerison, 1973; Broman, Nichols, Shaughnessy, & Kennedy, 1987; Lynn, 1989, 1990b; Osborne, 1992) that suggest a positive correlation of around 0.3 between these physiological parameters and IQ, two recent studies have reported relationships between direct brain volume measures and IQ. Yeo, Turkheimer, Raz, and Bigler (1987) used computerized axial tomography (CAT) scans of 41 individuals in order to compute brain hemispheric volume. Their results indicated that total brain or total hemispheric volumes were not related to IQ test scores. However, a simple measure of hemispheric asymmetry (left-right hemisphere size) correlated 0.57 with an IQ difference score computed by subtracting WAIS performance IQ score from the verbal IQ score. This correlation indicates that the larger the verbal IQ in relation to performance IQ, the greater the size of the left brain hemisphere to the right hemisphere. Although the correlation between brain asymmetry and the IQ difference score was larger for the male than for the female subjects, the two coefficients were statistically equal in size. Willerman, Schultz, Rutledge, and Bigler (1991), using magnetic resonance imaging (MRI) to assess brain size in 40 college students, found that brain

size did correlate with psychometric IQ scores at around 0.35, after corrections for body size and a deflationary correction for the extreme measurement range of IQ in their sample. Hemispheric asymmetries were computed in a similar fashion to the Yeo et al. (1987) method, yielding a significantly different pattern of correlations. These asymmetry correlations (reported in Willerman, Schultz, Rutledge, & Bigler (1992)) demonstrated that for males, hemispheric asymmetry correlated 0.44 with the verbal minus performance IQ difference score, replicating the Yeo et al. finding. However, for the female subjects, this correlation was -0.55 , indicating a larger right hemisphere being associated with verbal performance. In fact, for the female group, it was found that the size of the left hemisphere better predicted nonverbal performance than verbal performance, a finding reversed within the males. Ankney (1992) in a re-examination of brain mass data initially collected from autopsy records by Ho, Roessman, Straumfjord, and Monroe (1980a, b) also demonstrated that brains from males are about 100 g heavier than female brains, correcting for body height and body surface area. These data are interpreted by Ankney in the framework of a general assumption that specific abilities, at which males and females excel, are related to specific areas or quantities of brain mass. This assumption is given some credence in the review of work in this area by Kimura and Hampson (1992).

Information Processing: The Brain

Nuclear imaging of brain structure, briefly mentioned above, has also produced some preliminary results that suggest this methodology has a major part to play in the eventual understanding of brain-behavior relationships. Some initial work in cerebral regional blood flow (reviewed in Wood, 1983) indicated that task specificity could be observed in blood flow increases in particular areas of the brain, specifically verbal tasks being associated with increased left hemisphere flow and spatial tasks being associated with increased right hemisphere activation. However, as Wood points out, this work cannot be said to strongly support such clear laterality effects; rather it is of a suggestive nature only. A recent study reported by Leli et al. (1982) using 11 normal right-handed male subjects indicated that a right-left sensorimotor discrimination task produced significant increases in blood flow in both hemispheres, with left hemisphere blood flow increases being negatively related to WAIS performance IQ (administered on a separate occasion). The problem with this study, as with most others using nuclear imaging, is that the small numbers of subjects used do not allow any statistical inferences to be drawn with a reasonable level of confidence. So, while studies such as these might be indicative of a possible relationship, they cannot indicate what its size might be. For example, a 99% confidence interval on a correlation of 0.75, using 11 subjects, ranges from 0.06 to 0.95.

Haier (1990) has suggested that the primary way forward for intelligence research is principally through radioactive isotope PET and structural, non-radioactive, MRI proton-based imaging techniques. The basis for such a statement comes from his own and others' work on cortical glucose metabolic rate in individuals who also complete psychometric or behavioral tests. The "activation" form of experiment is one where the radioactive substance is given immediately prior to a subject completing a cognitive or behavioral task. The radioactive isotope tagged-glucose is subsequently metabolized by the specific areas of the brain that are involved in the task, then imaged via the PET methodology. The "passive" form of experiment is where cognitive or behavioral measures are completed external to the imaging process. Glucose metabolic uptake is effected during resting conditions where an individual is isolated from sound and light while the isotope doped glucose is administered and ultimately imaged. The cerebral spatial uptake of glucose is then correlated with the external variable test scores. De Leon et al. (1983) compared 15 young normal subjects with 22 elderly normal subjects and 24 Alzheimer patients on WAIS IQ and other tests of cognitive function in a passive format experiment. Correlations of up to 0.6 were found between glucose metabolic rate and IQ, higher cortical activity being associated with a higher metabolic rate. These correlations were computed over a combined normal elderly and Alzheimer patient group, with no significant difference between the elderly and young normal groups. Chase et al. (1984) in a similar study essentially replicated these results. However, this form of passive experiment has generally failed to generate consistent brain-behavior relationships (Duara et al., 1984; Haxby et al., 1986; Boivin et al., 1992). In contrast, the activation study of Haier et al. (1988), using eight subjects who completed Raven's Advanced Progressive Matrices during the glucose uptake period, indicated that higher cortical glucose metabolic rate was related to lower performance on the matrices. This result was confirmed by Parks et al. (1988) using a test of verbal fluency, and Berent et al. (1988) who showed negative correlations between WAIS memory scores and glucose metabolism rate. These activation studies indicate that high IQ subjects appear to solve problems more "efficiently" than do low IQ subjects, requiring less energy to maintain performance at a higher level of accuracy. Haier et al. (1992a) tested this hypothesis in an experiment that examined learning of a spatial game task within a group of eight normal subjects. It was hypothesized that learning should produce a decrement in cerebral glucose uptake. The subjects were initially injected with the glucose and PET scanned while playing the game for the first time, they then practiced the game constantly over a 2-month period and were then scanned again while playing the game. The results indicated significant widespread reductions in glucose uptake across several regions of the brain. Haier et al. (1992b) extended the analysis to examine whether higher

IQ subjects had greater reductions in glucose uptake than lower IQ subjects. The pattern of correlations between Raven's Advanced Progressive Matrices, WAIS IQ scores, and metabolic reduction coefficients indicated significant negative relationships, thus confirming the hypothesis. However, with such small sample sizes, these results can only be taken as preliminary indications of effect size. A correlation of about 0.7 observed over eight subjects is significant at $P = 0.053$ with a 99% confidence region between -0.28 and 0.97 . Taking all the activation studies reported above, there are now indications of a consistent negative relationship between glucose uptake rate and cognitive abilities, even if the probable size of such a relationship cannot yet be estimated. As Matarazzo (1992) has indicated, this is only the beginning of this particular approach to examining brain-behavior relationships. A further technical advance in this area is the advent of Magnetic Resonance Spectroscopy (MRS) applied to *in vivo* brain tissue. This technique was originally used for *in vitro* characterization of chemical samples. In fact the development of MRI was based upon adapting existing MRS technology to the detection of hydrogen nuclei in water molecules within tissue structures. However, the main problem with current MRI imaging is that it is suited to detection of relatively large protons only, mainly water-based. MRS, on the other hand, is capable of detecting a variety of nuclei such as those based upon phosphorus, carbon, and hydrogen.

Ongoing Brain Activity

The ongoing electrical activity of the brain is an obvious source of data for the psychophysiological recording of events possibly related to IQ, but a careful survey by Lindsley (1961) showed quite early on that there is no clear-cut relation in normal adults, although in early childhood (when slower gamma and delta waves give way to faster and prevalent alpha) and in brain-injured persons (Ostow, 1954) some relationships are found. Recently, Gasser and co-workers (Gasser, Mocks, Leonard, Bacher, & Verleger, 1983; Gasser, Von Lucadou-Muller, Verleger, & Bacher, 1983; Gasser, Bacher, & Steinberg, 1985) have reported correlations between spectral power and IQ, averaging about 0.5 in children. All EEG parameters were standardized for age as were the tests of intelligence (the WISC verbal subtest and the Columbia Mental Maturity Scale). A group of mentally retarded children ($N=25$) also used in the 1983 Gasser, Mocks, et al. study were shown to generate higher EEG \times IQ correlations (averaging about 0.6) than the normal children group ($N=31$). Gasser et al. (1985) demonstrated that the test-retest reliability for absolute and relative spectral power within the six power bands was mostly in the range of 0.60–0.75.

Giannirapani (1985) has recently published a monograph detailing extensive investigations into the localization of EEG spectral power and mental abilities as assessed by the WISC and WAIS IQ tests. EEG was

acquired under eight conditions ranging from white noise, music, complex visual patterns, to solving arithmetic problems. Sixteen monopolar electrode placements were used encompassing prefrontal to occipital placements. The main results from the analyses indicated that performance on the various subtests of the WISC and WAIS was significantly related to EEG power at specific frequencies within specific brain areas.

Thatcher, McAlaster, Lester, Horst, and Cantor (1983) and Gasser, Jennen-Steinmetz, and Verleger (1987) examined the spectral coherence of the EEG from various scalp regions of children. Coherence was defined as the similarity estimate of power generated at a particular frequency across two signal channels over a fixed duration. The function varies between $+1$ and -1 , and can be interpreted (and manipulated) much in the same way as a product moment correlation. A coherence value of $+1$ would indicate that both signals (say from two regions of the brain) have the same power at a particular frequency within a particular duration. The Gasser et al. study reported results from the same children as those used in their previous studies. Thatcher et al.'s sample consisted of 191 children aged between 5 and 16 years; they partialled out age and sex before examining the coherence measures. Overall, both studies showed that higher coherence values were associated with lower IQ. That is, the higher the IQ, the more differentiated the brain activity between scalp regions. This result is similar to that reported above by Fischer et al. (1978, 1982) using Ertl's brain wave analyzer. Fischer et al.'s results marginally indicated that the greater the hemispheric synchrony, the higher the IQ of a subject. Within Gasser et al.'s mentally retarded group of children, the coherence values were appreciably higher than observed in the normal control group of children, indicating greater synchrony of activity. These two studies were seen as an important indicator that one index of biological intelligence may simply be the amount of brain used by an individual in any problem solving task. In the EEG area, *use* is being inferred from the disruption of semi-stable background frequency generation across various scalp locations. From the PET activation studies reported above, the inference from the EEG coherence parameter results appears ambiguous, mainly because it is unknown precisely how to map cerebral glucose metabolic rate to EEG frequency and power. Also, cognitive task conditions and sample composition within the two areas of study are completely different. The EEG studies involved children at rest, the PET studies used adults actively engaged in a cognitive task.

Averaged Evoked Potentials

From the late 1960s onwards, a systematic body of evidence has been produced indicating several relationships between parameters computed from specific features of averaged evoked potentials (AEPs) and IQ test scores. As indicated above, Ertl was the first investigator to show that short visual AEP component peak latencies

were found to correlate with high IQ. This work was replicated and extended further by Ertl and Schafer (1969), Ertl (1971, 1973), Bennett (1968), Shucard and Horn (1972), Hendrickson (reported in Eysenck, 1973, p. 429), Weinberg (1969), and Gucker (1973). The average correlation found across these various studies was about -0.30 . However, several investigators were unable to obtain replication of these results (Rhodes, Dustman, & Beck, 1969; Dustman & Beck, 1972; Dustman, Schenkenberg, & Beck, 1975; Davis, 1971; Rust, 1975), generally finding zero or slightly positive correlations between latencies and IQ. Engel and Henderson's (1973) study of 119 children led them to conclude that no relationship existed between visual evoked response latencies and IQ. This was a significant study in that their methodology was good and the subject numbers large. Eysenck and Barrett (1985) discuss more fully this issue and some reasons for the non-replication of Ertl's initial results. One important issue here was the selection of subject groups. Ertl tended to use polarized IQ groups (high vs low IQ) rather than a normal range, a point made especially by Dustman et al. (1975) who concluded that the small latency-IQ relationship could only be demonstrated using extreme subject groups.

In addition to the analysis of the AEPs in terms of component latencies, Ertl (1971, 1973), Osaka and Osaka (1980), and Shucard and Callaway (1973) also computed their power spectra. From these analyses they concluded that the amplitude of the maximum spectral frequency did not correlate significantly with IQ. However, Flinn, Kirsch, and Flinn (1977) in a similar analysis found that low IQ subjects had larger low frequency (< 12 Hz) amplitudes than high IQ subjects. In addition, high IQ subjects were found to have significantly larger high frequency (> 30 Hz) components than low IQ subjects. The correlation between IQ and amplitude within the lower frequency power bands was about -0.37 . For the higher frequency bands it averaged about 0.36 .

Recently, Hendrickson and Hendrickson (1980), Blinkhorn and Hendrickson (1982), and Hendrickson and Hendrickson (1982) have provided new evidence on the correlation of IQ with AEP parameters. Based upon a novel model of synaptic structure, function, and nerve transmission, the Hendricksons derived two measures that could be extracted from an AEP. A complexity measure (otherwise known as the *string* measure) was assessed by computing the contour perimeter of the AEP waveform; the larger this value, the higher an individual's IQ. The second measure, the *variance*, was computed by taking the average variability of each sample point on an AEP over a number of epochs. The greater the variance, the lower an individual's IQ. The empirical evidence regarding the complexity/variance of the AEP is drawn from two studies. The first, reported by Blinkhorn and Hendrickson (1982), correlated the complexity (string) measure from auditory AEPs with performance on Raven's Advanced Progressive Matrices (APM) and a variety of verbal ability tests. Various

correlations between the string measure (computed from AEPs generated over 90, 64 and 32 epochs) and the APM yielded a mid-range correlation of approximately 0.45 . The verbal test scores did not correlate significantly with the string measure. However, because the range of the scores on the APM was restricted, Blinkhorn and Hendrickson corrected this value for a full range of IQ. The correlation was thus boosted to a maximum of 0.84 . In the second study (Hendrickson & Hendrickson, 1982) a random sample of 219 mixed sex, secondary school children was used, with measured IQ using the WAIS test. The correlations between the WAIS performance total and the string and variance measures were 0.53 and -0.53 respectively. The correlations between the WAIS verbal total and the string and variance measures were 0.68 , and -0.69 respectively. Several replications of these pioneering results have been attempted by various workers with some success. Two reviews of the area by Deary and Caryl (1992), and Barrett and Eysenck (1992) provide the details of these studies.

A second approach to examining the AEP \times IQ relationship has focused on the effects of information processing workload on AEPs (Schafer, 1979; Schafer, Amochaev, & Russell, 1981). These studies have all demonstrated a cognitive modulation of EEG activity, that is, unexpected stimuli tend to produce higher amplitude AEPs than do expected stimuli. Schafer has extended the scope of this empirical phenomenon by hypothesizing that high IQ individuals would commit less neural effort to processing expected stimuli than would low IQ individuals; this difference in effort (neural adaptability) being observed in reduced amplitude AEPs from high IQ subjects. Schafer and Marcus (1973) and Schafer (1982, 1984, 1985) reported correlations averaging about 0.63 between the level of neural adaptability and IQ scores. That is, the greater the amplitude disparity between AEPs computed from epochs generated by expected and unexpected series of auditory stimuli, the higher the individual's IQ score. When corrected for attenuation of range within the IQ test scores, the average correlation was about 0.78 . It is of interest to note that Callaway (1975) was unable to obtain a significant correlation using a similar methodology. A detailed review of the theories underlying both the Hendrickson and Schafer paradigms and the experimental evidence noted above is provided in Eysenck and Barrett (1985).

Finally, there is the work by Zhang, Caryl, and Deary (1989a, b) on the relationship between visual AEP components, inspection time, and IQ. Inspection time (IT) may be defined as the minimum display time required by an individual to accurately discriminate a difference between two stimuli. The prototypical task emerged from a psychophysical theory developed by Vickers, Nettlebeck, and Willson (1972). Nettlebeck (1987) and Kranzler and Jensen (1989) have reviewed a large body of evidence demonstrating that IT correlates with IQ on average between -0.4 and -0.5 . Within the Zhang et al. experiments, IT stimuli were presented

on a LED display; the task required discrimination of the relative length of pairs of illuminated lines (one twice the length of the other) which were followed by a backward mask. Using an adaptive algorithm, an individual's IT was assessed to 85% accuracy; then another 100 trials were presented at this level. EPs were recorded from a single central vertex electrode. From the analyses undertaken by Zhang et al., a new AEP component was generated, called the *P200*, parameter. This is defined by computing the mean voltage for an AEP, and noting the intersection of this mean value by the upward slope of the waveform from the *N140-150* trough, the time is counted until the *P200* peak is reached by the waveform. Across two groups of 16 subjects, this parameter correlated from 0.43 to 0.58 with their IT values. From another series of experiments reported in Zhang et al. (1989b), the *P200*, parameter and AH5 IQ correlated -0.34 across 35 subjects and between *P200*, and IT, 0.65 across 37 subjects. As part of this second series of experiments, Zhang et al. also included a condition of simple (SRT) and discriminative reaction time (DRT). *P300* component amplitude and latency was assessed for each individual and correlated with SRT and DRT values and IQ. None of the correlations between RT and *P300* measures was significant. In addition, no *P300* measures correlated with IQ. This is in contrast to a recent paper by McGarry-Roberts, Stelmack, and Campbell (1992) who recorded *P300* potentials during the performance of six simple computer administered cognitive tasks. Using the MAB IQ test scores from the 30 subjects who took part, they found that *P300* latencies increased with increasing task difficulty and that two canonical variates (for *P300* latencies and MAB IQ) correlated inversely with each other ($-0.36P < 0.05$). O'Donnell, Friedman, Swearer, and Drachman (1992) also replicated this negative correlation between the *P300* AEP component and a factor score based upon three WAIS subtests of Information, Similarities, and Picture Completion. This correlation was -0.44 within 41 subjects. The results from both the *P200*, and *P300* AEP paradigms indicate that the latencies of these parameters are consistently negatively related to IQ test scores. Since there is a large body of evidence confirming the relationship between *P300* and cognitive information processing workload, it can be concluded that the shorter latencies found within higher IQ subjects may reflect neural efficiency or higher speeds of processing, a conclusion that may partially support Haier's speculations above, based upon his work using PET imaging.

One possible problem with the AEP work reported above (and in fact all AEP work) is that the AEP represents the average of a set of waveforms recorded in response to a stimulus. It is assumed that each waveform represents a consistent brain response to a stimulus, with only slight error or "jitter" around each sample point. In fact this is the basis for the Hendrickson string and variance measures given above. However, this assumption may not be valid for all evoked potential

traces, neither may it be desirable if an investigator is looking for transient responses to stimuli that cannot be replicated or repeated in any meaningful fashion, but which are significant to an area of study. For example, consider using video film "events" to look at emotional responses to transient stimuli within a video sequence, or the use of a rare probe stimulus to ascertain attentional processes while a subject is engaged in alternative cognitive processing. Effectively, the stimulus and brain response may be considered as a unique pairing, with any attempt at averaging rendered impossible by the nature of the stimulus itself. In these cases, a single trial evoked potential is required to be extracted from the ongoing background EEG. This has proven almost impossible with current techniques of signal processing and waveform analysis (Cerutti, Baselli, Liberati, & Avesi, 1987; Basar, 1988). However, a recent advance in waveform analysis has opened up a new avenue of research into extremely fast transient waveforms. The method is known as wavelet analysis, first proposed by Grossman and Morlet (1984). Without going into technical details, the wavelet transform surpasses current Fourier decomposition of signals such that an evoked potential can be separated from background EEG with very high resolution of both frequency and time, simultaneously. That is, as a signal occurs, the instantaneous frequencies that have produced the signal can be computed moment by moment, with a time resolution far exceeding that of classical Fourier analysis. At present, this methodology is still being investigated and computational algorithms examined (Mallat, 1989; Crowe, Gibson, Woolfson, & Somekh, 1992; Bartnik, Blinowska, & Durka, 1992). However, the significance of this methodology is that it will allow much finer temporal resolution of discrete evoked potentials within the brain. In addition, the ability to estimate the instantaneous frequency "mix" of signals will also provide information as to the likely sources of generation of the waveforms. As the spatial resolution of the nuclear imaging methodologies increases, so does the temporal and spatial resolution (via magnetoencephalography (see Regan, 1989)) of the electrical imaging techniques.

The Psychophysiology of Personality

The literature on biological determinants of personality has been surveyed by Eysenck (1990), Gale and Eysenck (1992), and Zuckerman (1991). Here we shall be concerned only with those personality dimensions which are closely related to the creative aspects of giftedness, i.e. personality traits which enable certain aspects of giftedness such as originality to appear. There is considerable evidence that *introversion* is frequently found associated with artistic and scientific success (e.g. Goetz & Goetz, 1979a, b; Roe, 1951; Eysenck, 1993). Artists and scientists are differentiated in terms of *neuroticism-stability*, with scientists tending towards

the stable end, artists towards the neurotic. Of course these are only trends, and not everyone who is artistically gifted is neurotic, nor are all scientists stable. However, overall there appears to be a fairly definite tendency in this direction.

The evidence suggests fairly strongly that underlying the extraversion-introversion dimension are physiological differences in *cortical arousal*, which in turn is modulated by the ascending reticular activating system (Eysenck, 1967). Extraverts respond poorly to incoming stimuli, and require strong stimulation to achieve an acceptable level of arousal; hence their high sociability, variety-seeking, changeable behavior. Introverts over-respond to incoming stimuli, and respond best to low levels of stimulation; hence their aversion to social occasions, sensation-seeking and risk-taking. There is a large body of literature linking psychophysiological measures (EEG, EDR, CNV, etc.) with extraversion, with results which have usually supported the theory (Eysenck & Eysenck, 1985).

As regards neuroticism-stability, it seems clear that this is related to the limbic system and the autonomic system, with excessive reactivity related to neurosis, particularly in the sympathetic part of the autonomic system. The problems in verifying this general theory have been discussed in detail elsewhere (Eysenck, 1990), but overall the theory is probably along the right lines. Artists, who "recollect emotion in tranquillity", would have little to recollect unless their emotions were particularly strongly and easily engaged; this may account for their high degree of neuroticism. Scientists should not be swayed by emotion but by reason; this may be the reason why they are more likely to be stable and unemotional.

However, more directly related to creativity is the third major dimension of personality, namely *psychoticism* (Eysenck & Eysenck, 1976). This is conceived of as a dispositional trait variable, predisposing people to respond to severe stress with functional psychotic disorders; people high on this trait are not psychotic, but share with psychotics some of the characteristics which are frequently found in schizophrenics and manic-depressives. The discovery of this personality dimension helps to explain the paradox that has always attended the finding of considerable psychopathology in so many geniuses, coupled with the equally insistent finding that fully developed psychosis is hostile to the production of original works of science or art (Eysenck, 1993).

Most relevant here is the tendency towards "overinclusive thinking" on the part of psychotics. This resembles the greater associative spreading of ideas of creative people; they tend to have associative gradients which are flat and extensive, rather than steep and restricted. On the word association test, for instance, psychotics and creative people both tend to give associations to stimulus words that are remote and unusual. There are of course also marked differences between normal high *P* scorers and psychotics; the former retain the ability to look critically at the products of their fertile brains, and

reject far-fetched and nonsensical associations, while the latter are unable to do so.

The literature on the biological causes and correlates of schizophrenia, manic-depressive illness, and psychoticism is also immense, and cannot be discussed here; readers interested in following up this particular aspect of giftedness are invited to read Zuckerman's (1991) textbook, as well as Eysenck's (1993) attempt to formulate a theory of creativity on this basis. Our purpose in writing this brief section has been mainly to draw attention to an area of giftedness that is usually neglected, but which is likely to repay extended study.

Summary and Conclusions

It will be obvious that the very complex set of results and theories here reported cannot easily be summarized. In attempting to do so we will of course have to omit many qualifications that are needed to avoid the unjustified appearance.

(1) "Giftedness" is a fuzzy concept that can be defined in three major ways: (1) as synonymous with *general intelligence*; (2) as synonymous with *creativity*; (3) as synonymous with special (artistic or scientific) ability.

(2) Most work on the biology of giftedness has been done in respect of intelligence, and hence most of this article is devoted to that topic.

(3) Giftedness is also related to *personality*, and brief mention at least has been made of some of the work done in that area.

(4) Intelligence, personality and special abilities are all strongly determined by genetic factors, and as DNA cannot directly influence behavior, there must exist biological intermediaries (psychophysiological, hormonal) which correlate with giftedness.

(5) Lateralization of cerebral hemisphere functioning, and general cerebral dominance, have often been suggested as being closely related to giftedness. While the evidence does not rule out such a possibility, support is meager, and the theory has not been stated in an acceptable form.

(6) Resting EEG recordings and evoked potentials have been found to correlate quite highly with intelligence, but anomalies are still too frequent to give us a convenient and acceptable measure of giftedness, although the time may not be far off when such a measure becomes feasible.

(7) Information processing investigations using nuclear imaging, positron emission tomography and magnetic resonance spectroscopy all hold out great promise of precise location and measurement of mental activity and individual differences, but here too it is too early to be certain of replicability.

(8) Much of the work reported in all these fields is of inferior quality, done on too small and poorly selected samples, and poorly carried out and reported. No such studies should be carried out and reported unless the number of subjects was at least 50, groups clearly

defined along measurable continua, and procedures and statistical analyses outlined in detail.

(9) Personality correlates of giftedness in the biological field have a good theoretical basis, and have received considerable empirical support. They form an important aspect of giftedness, particularly in the sense of creativity, and have a good theoretical basis in psychophysiology.

(10) The whole area is in a state of growth, and promises to give us many answers to causal questions raised by the problems associated with giftedness. The technical problems are considerable, but not insurmountable, and it seems likely that the next few years will see a marked increase and improvement in the number and quality of papers devoted to this topic.

Thinking Processes: Being and Becoming Gifted

B. M. SHORE

McGill University, Montreal, Quebec, Canada

L. S. KANEVSKY

Simon Fraser University, Burnaby, British Columbia, Canada

Introduction

In this chapter we explore thinking processes as an important component of a contemporary conception of giftedness and its development. We address four issues related to thinking processes and giftedness: First, some of the principal ways in which the thinking processes of gifted persons differ from those of other people, with a focus on recent and ongoing research into cognitive processes; second, and very speculatively, evidence to link the intellectual performance of very young children to the higher level thinking observed in older children and in adults; third, and briefly, the nature and success of programs intended to train people to think in these ways and thereby to enhance their intellectual abilities; and fourth, some concluding thoughts about broader educational implications.

One of the first challenges facing a researcher interested in gifted children is to define giftedness in terms that can be operationalized in the investigations that follow. Studies have ranged widely in the definitions and their operationalization. We would like to suggest that rather than being a liability, this diversity may be an asset to the body of literature addressing the role of cognition in giftedness. This chapter will introduce the reader to findings of studies based on differing definitions and explore consistencies and inconsistencies that contribute to our evolving understanding of high ability.

In any attempt such as this, we are necessarily constrained by the persistent problem of defining giftedness. In adults, the cognitive literature has adopted the term “expert” (Ericsson & Smith, 1991), but there is no more agreement about the meaning of “expertise” than “giftedness”. We have chosen to work with three operationally defined groups, and to live with the problems resulting from their inequivalence and the possibility that outstanding performance on one of the criteria at a particular stage in one’s life is correlated with similar standing on either of the other criteria later at other times. These three groups are of children with high IQs, children who do very well in school, and adult experts.

To understand differences in thinking processes, we must examine children or adults who are exceptional in contrast to others in some recognized way. It is necessary to identify target processes that distinguish types of high performance, and to discover the correlates, predictors and consequences of these processes, with reference to the original variable on which the different groups were identified, and also with other variables. It is very important to take into account that this line of research is intended to produce alternative definitions of giftedness, not merely to embellish existing definitions.

With the very young, this research begins with children who might be described as developmentally advanced in their intellectual functioning. This includes advanced vocabulary, logical reasoning ability, ciphering, and verbal comprehension, among other qualities. It does not much concern us to attempt to define in advance whether we are talking about a “top” group of 1%, 5%, or 50%. Measures of IQ or similar tests directly address such issues, and are widely used in this type of research.

With school-age children and adolescents, some of the research on thinking processes continue to compare children who differ widely in IQ, and some consider scholastic performance. The continued emphasis on IQ reflects its ubiquity in identification procedures within formal “gifted programs” (Alvino, McDonnell, & Richert, 1981; Yarborough & Johnson, 1983)—we do not endorse this, but we merely observe it. The inclusion of children who do extremely well in school should, under ideal circumstances, take into account the nature of the school experience. High grades in a course of study exemplified by rote repetition of the texts or teachers’ statements does not define the same kind of intellectual (including creative) performance as high success in an enquiry-based program in which students are investigators in the subject matter (cf. Bruner, 1960). Once again, the underlying thinking processes being equated with giftedness may be very different. On the other hand, if common thinking processes are found among gifted persons defined by a variety of definitions,

then this would be especially interesting, and we are proposing in this chapter that such an understanding of high ability is beginning to evolve.

One of the ways the cognitive literature directly addresses high performance in adults is in the form of the discussion of expertise. While there is as much variation and imprecision in the definitions of expertise (Anderson, 1982; Ericsson & Smith, 1991) as there is about giftedness (cf. Maker, 1982; Renzulli, 1986; Sternberg & Davidson, 1986), essentially experts are people with advanced training, competence, and experience in a field. The cognitive literature compares experts in some context with nonexperts typically labeled as novices. The latter are usually adolescents or young adults about to enter a period of training to develop expertise (e.g., medical studies, tournament chess competition, computer programming, electronic or other diagnosis, etc.).

From this perspective we arrived at our three somewhat different working definitions of groups in whom thinking processes are to be studied: children with high IQ (or similar) scores, children who do very well in school, and adults recognized in their domains of activity as experts. As unsatisfactory as this situation may be to a doctrinaire theoretician or psychometrician, we propose that these definitions are educationally very useful. We do not purport that they cover all types of giftedness or any of their components. Education as a nearly universal activity of great social importance cannot wait for theoretically perfect circumstances to gain important understandings of how children and adults think, and how these might ultimately be connected. Working with key concepts based upon cognitive psychology, we and other researchers are discovering that there is much to be learned from the coordinated study of these three groups.

Thinking Processes and Giftedness

Theoretical Context

Three theoretical threads can be traced in current research on thinking processes in the gifted. The first is essentially developmental and is well represented by the works of Bloom (1985), Feldman (1986), Horowitz and O'Brien (1985), and the forthcoming volumes edited by Horowitz and Friedman (in press, a, b). There is a developmental controversy about high ability in school children: Is their superior performance merely precocity (Robinson, 1977; Rogers, 1986; Scruggs & Cohn, 1983), or does it reflect fundamental differences in thinking processes? Each view has direct implications: Accelerate gifted students through existing curriculum in response to precocity, or adapt curriculum (including teaching methods) to take account of differences in thinking processes. Both perspectives have been argued at one time or another, though the movement in this controversy has been increasingly toward understanding

differences in thinking processes (Borkowski & Peck, 1986; Carr & Borkowski, 1987; Keating, 1975; Scruggs, Mastropieri, Monson, & Jorgensen, 1985; Shore, 1982; Sternberg, 1985; Webb, 1974). A quantitative alternative to the precocity argument is that gifted individuals are endowed with more of something that distinguishes them, such as denser dendritic structure of brain cells, myelination, memory capacity, etc. The two are not incompatible, since one addresses function and the other structure. Of course giftedness may emerge as the result of both quantitative and qualitative differences rather than one or the other. Berliner (1986) has bridged these two positions with the interesting suggestion that sustained precocity eventually becomes differences in kind, not merely amount. This hypothesis remains to be tested in the context of cognitive research.

A second important theoretical framework has been offered by Sternberg (1984, 1985). His Triarchic Theory of Intelligence has three main types of information-processing abilities: (a) metacomponents, for planning, monitoring and evaluating thinking, (b) performance components, used to execute tasks, and (c) knowledge-acquisition components, related to achievement. Davidson and Sternberg (1984) presented a subtheory of giftedness in which coping with novelty and automatization of complex tasks are important. Metacomponents were suggested in Flavell's (1976) earlier speculation about the nature of metacognition. With regard to performance components, we had been attracted to the importance of flexibility in problem-solving strategies as a complement to metacognition (Shore, 1982). Starting in the early 1980s, Sternberg and his co-workers began the development of extremely useful theory that permitted links to be made between cognitive processes and giftedness. Our major contribution has been to generate a large and still growing bank of evidence in support of some of the links perceived by both research groups. This theory and evidence link psychometric understanding of abilities and a cognitive approach based on a dynamic understanding of the processes.

The dynamic nature of the processes we are addressing raises the third important theoretical thread which has been emphasized in our work. It is an extension of Vygotsky's (1978, 1986) theory of the development of higher intellectual processes to the study of giftedness. Investigations of the IQ-related and individual differences in what and how children learn has provided evidence that the quantitative-qualitative controversy might better be conceptualized as a rich interaction (Kanevsky, 1990, in press). The combined contributions of the differences may result in spiralling developmental advantage for able learners over their peers. They acquire more knowledge more efficiently, and so on, throughout their lives.

Principal Contributions of Our Studies

In this overview of our contributions (and those of our students) to this topic, we focus on the evolution of our

studies from replications or extensions of classic laboratory tasks through to studies of classroom learning. This development is partly but not entirely historical. While more of the earlier studies employed laboratory tasks that may be regarded as having less “ecological validity”, understanding cognitive processes has required that we vary the designs of our studies across these settings at different times. We have also distinguished between studies that have been published and others which are in progress or recently completed. We have not yet determined if our data point entirely and directly support theories such as Sternberg’s and Vygotsky’s. There is certainly a great deal of congruence, and the opportunity to theorize about our findings will come soon; a few speculations will be offered later.

We began with studies employing familiar *laboratory tasks* on which individual differences warranted further study. Our results and those obtained by graduate students working with us showed that:

- on a variation of Piaget’s conical mountain task in which we used a toy farm scene, gifted preschoolers were less likely to make egocentric errors in perspective taking and were better able to take another’s perspective even when the two views partially overlapped (Tarshis & Shore, 1991);

- on a series of puzzles and construction tasks, mothers interacted with more able preschoolers in ways which favored the children’s development of metacognitive techniques for monitoring their problem solving (Moss, 1986, 1990);

- on the portable rod-and-frame task in which a bar is to be aligned vertically while framed by a box without additional cues, verbally able teenagers used verbal abilities rather than spatial skills as the task appears to demand (Shore, Hymovitch, & Lajoie, 1982; Shore & Carey, 1984);

- on a highly spatial computer game in which successive operations in a machine shop are emulated in order to produce products from blocks, in addition to being more successful at the task, more able young teenagers also recommended improvements to the game that would have increased the challenge and complexity of the task (Bowen, Shore, & Cartwright, 1992);

- in research on impulsivity (fast, inaccurate performance) and reflectivity (slow, accurate), fast and accurate students are usually a minority and are not discussed; we found that children from an unselected group who were fast and accurate on the measures bore many similarities to students we might describe as gifted (based on IQ) and, further, that accuracy over speed was their distinguishing characteristic (Lajoie & Shore, 1986, 1987);

- high IQ children switched strategies on water–jar combination problems when alternative solutions were valid but not required; metacognition appeared to be higher with more able and accurate students when they were faster, corroborating Lajoie and Shore’s advice that it was not necessary for able students to slow down to enhance certain kinds of performance; solution speed

decreased on a key trial where an alternative solution was possible but not necessary, suggesting that it may have been considered (Shore & Dover, 1987; Dover & Shore, 1991).

- young high IQ children acquired and generalized a strategy for solving two versions of the Tower of Hanoi puzzle more efficiently than their average IQ peers; in addition, more of the high IQ children spontaneously expressed their recognition of the similarities in the tasks and their preference for achieving a solution without the tutors’ aid when they were struggling (Kanevsky, 1990; Kanevsky & Rapagna, 1990).

Work yet to be reported (done with L. Lazar) has shown that:

- on a computerized pattern-recognition task which enabled separate timing of the planning and execution stages, more able subjects devoted a relatively greater proportion of their overall time to the planning stage, and executed the final solution much more rapidly.

The main problem with the above tasks was low “ecological validity”. How much of real life is spent solving computer puzzles or doing laboratory style tasks? In addition, prior knowledge is of uncertain importance and it was difficult to examine creative processes.

We then introduced *confirmatory studies* in which the tasks were test materials from school curricula in mathematics and physics, wherein key research has been done on expertise. Our results to date have shown that:

- high performing secondary school physics students exhibited superior metacognitive knowledge and drew more extensively upon their prior knowledge in the subject than students doing less well in the same classes, and the patterns of responses for these better performing students more closely resembled those of experts than average-performing students also included in the study (Coleman & Shore, 1991).

Studies yet to be reported have shown that:

- more able secondary mathematics students will, when unsuccessful in mathematics problems, switch to a second legitimate solution strategy with apparent automaticity, whereas less able students revert, if they change at all, to trial-and-error (a study with C. Kaizer);

- the course of action for such flexibility may be determined very early in the solution process, for example, at the point of categorizing the problem; a study (with S. Pelletier) has shown that high performing secondary mathematics students and graduate students in mathematics spontaneously group and subgroup more problems together than average performing students, evidence that they perceive similarities across problems that are regarded as distinct by others;

- on a computer game based upon determining the pattern in number-series problems, able students more often test explicit hypotheses as part of their solution strategies (a study with M. Godrie).

We are also trying to reach beyond “real” tasks in laboratory settings to the study of *learning over time*

in classrooms or other settings. This work, recently completed or in progress, has found that:

—faced with the task of giving meaning to unfamiliar or erroneous terms embedded in a text, gifted learning-disabled students' performance and understanding of their own functioning resembled those of gifted children more than learning-disabled children—gifted learning-disabled students are metacognitively strong (see Hannah, 1989, for a preliminary report);

—more able senior high school physics students have more elaborate and inter-related knowledge structures into which new learning is integrated, and specific training in cognitive mapping (such as used by Donald, 1987; Kozma & Roekel, 1986) enhances this process across ability levels (a study with L. Austin).

Possible Theoretical Directions

Ascribing meaning in context, hypothesizing links among complex concepts, proposing enhancements to complex games, and the other processes we have examined involve a degree of creative or productive thinking. Getzels and Csikszentmihalyi (1976) pointed out that creative contributions depend on question asking and problem finding. This may be a useful theoretical perspective to take with these studies. Xenos-Whiston (1989) studied the teachers at our summer laboratory school for gifted students over eight years, and has shown that these exemplary teachers of the gifted are distinguished as a group by being contributors to knowledge (e.g., publishing, artistic production, program development, materials design) and in expecting similar efforts from their students. This supports attention to knowledge production as a curricular element. It is also consistent with Bruner's (1960) admonition not to teach the conclusions of a field, but, instead, the processes by which an expert learns. It also echoes Kamii's (1985, 1989) observations of young children's mathematics learning, in which the discovery and invention of the subject is crucial, and peer teaching is the catalyst for learning.

In contrast, the acquisition of basic information is of relatively limited interest in this research, given the populations we are studying—gifted students and experts. It is important not to overemphasize parallels with classic studies in which the target learning is nonsense syllables, paired words, or simple factual knowledge. Nonetheless, Scruggs and Mastropieri (1984) have shown that differences in learning strategies occur between gifted and other secondary school students even with associative learning or the acquisition of factual information.

We have not yet decided what might be the best theoretical context to bring all these elements together. There is certainly great consistency with contemporary cognitive science, but this literature has paid insufficient attention to individual differences. There is

also considerable support in our work for important elements of Sternberg's (1985) "triarchic" theory of intelligence and its componential subtheory (1981). He (1986) has also offered a conception of giftedness consistent with his theory. Some cognitive theories begin with the thinking processes of experts. They attend to these processes because the outstanding performance of experts is drawn to their attention in some manner. Correspondingly, intelligence theories need to describe and explain outstanding rather than merely commonplace accomplishments and functioning. Some cognitive theories have focused more on the development of cognitive abilities than on the products, for example those of Piaget and Vygotsky.

In addition, theories of intelligence have not been sufficiently integrated with theories of creativity to incorporate what appears to us to be an important element in any suitable theory, namely, knowledge production. Guilford (1967, 1972, 1975) had such an insight, but his work on the "Structure of Intellect" and that of his successors (most notably Meeker, 1969) does not deal adequately with the complexity and breadth of some of the tasks on which we have observed important differences, nor with the time frames on which this performance occurs.

Finally, Vygotsky's theory holds promise for gauging the similarities and differences in the thinking of high and average ability individuals; however, it is a relative newcomer to investigations involving gifted and creative individuals. At this time, its ability to contribute to this discussion is hindered primarily by the limited selection of tasks appropriate for implementation in the contemporary variations of his dynamic assessment methodology.

We expect that a theory which can account for the kinds of performance we are discussing will have to link all these elements: creativity or knowledge production, learning, individual differences, and the nature of expertise. Familiar examples are found in higher education: the occupational imperative for scholars to have original ideas, and the curricular goal for students to ask original questions and attempt to answer them. Research and development enterprises also place great value on knowledge production. Bruner (1960) pointed out the relevance of such efforts at all levels of education. Our goal is to examine learning processes and experiences—including educational experiences—that underlie becoming a knowledge producer.

This builds upon the work completed and that underway as follows:

—research on the thinking processes in relation to the education of gifted children, which suggests that knowledge-production goals are especially appropriate for gifted and creative children (Haensly & Roberts, 1983; Renzulli & Reis, 1985), perhaps for all children in different ways (Bruner, 1960);

—our examination of the relation between professors' research methods and teaching methods, which shows

that few undergraduates engage in knowledge production (Shore, Pinker, & Bates, 1990);

—our research and others' demonstrating that in many ways the learning processes of gifted students resemble those of experts in a field different to those of other students—and one of the distinguishing characteristics of experts is their involvement in knowledge production.

How Gifted Children Think Differently

In this section we summarize seven of the principal ways in which the thinking processes of gifted children are different from those of others. We draw upon our own research described above but also upon the broader literature. Portions of this summary are also found in Shore (1991), and the complementary literature has also been summarized by Coleman and Shore (1991).

MEMORY AND THE KNOWLEDGE BASE

Capable students and experts know more, but that is not all. They better know what they know; their existing knowledge is highly interconnected and new knowledge is immediately linked in many ways to prior knowledge (Larkin, McDermott, Simon, & Simon, 1980). This was one of the most important of Krutetskii's observations: Capable students,

without comparing the "similar", without special exercises or hints from the teacher, independently generalize mathematical objects, relations, and operations "on the spot" . . . (pp. 262–263).

Kanevsky (1990, in press) found this ability in her dynamic analysis of the learning potential of high IQ children as young as four years old. Three prominent cognitive theorists have made related assertions. Ausubel (1968) suggested that what a learner already knows and how it is organized directly affect further learning and memory. Resnick's (1989) cognitive theory of learning further asserts that learners elaborate what they learn and strive to understand it explicitly for the purpose of connecting new knowledge to old. Greeno (1989) and Resnick have suggested that effective memory absolutely requires such placement in content.

Gifted students and experts also know better how to use what they know. In a broad review of the literature, Alexander and Judy (1988) showed that the extent of specific and strategic knowledge interact to favor academic performance. Sternberg (1981) had theorized that gifted students might use their extensive knowledge bases differently from the non-gifted. Coleman and Shore (1991) found supporting evidence: High and average achievers in an advanced high school physics course, plus two physics graduate students and a physics teacher as experts, were asked to think aloud while solving five physics problems. The responses were tape-recorded, then transcribed and divided into clauses

(noun-verb segments). These segments were coded in several categories. Experts and high performers made significantly more references to prior knowledge that was not given in the problem, and fewer to information given in the problem. Such use of prior knowledge implies more than its existence; one must also know how and when to use it selectively.

SELF-REGULATORY PROCESSES

Experts monitor and guide their own thinking while they work on a task (Bereiter & Scardamalia, 1987; Glaser, 1985; Paris, Lipson, & Wixon, 1983; Scardamalia & Bereiter, 1985). This process is called metacognition (Flavell, 1976). It has been raised in the gifted literature (Meichenbaum, 1980; Wong, 1982; Woodrum, 1979), and is evident in many of Krutetskii's (1976) reported protocols (see especially his Chapter 13). Sheppard (1992) found that high ability 10- to 12-year-olds were more aware of and able to describe the self-regulation of their thinking while they engaged in a challenging activity after drawing a machine intended to function in a manner similar to that of their mind.

In the previously mentioned study on physics problems, Coleman and Shore (1991) also found significantly more correct evaluations of their own thinking processes by experts and high performers (and fewer incorrect statements indicating metacognitive processes).

SPEED OF THINKING PROCESSES

It is commonly thought that bright students are intellectually faster. The more items one answers correctly on timed tests, such as most IQ tests, the higher one's score. The same is true for most school examinations. Overall solution times on problems are, indeed, shorter for experts, but the expert-novice literature points out that experts take longer pauses while retrieving relevant information to solve a problem (Larkin, 1979), and that they rapidly develop rapid, automatic skill (automaticity) in basic operations (Perfetti & Lesgold, 1979). Davidson and Sternberg (1984) proposed that more intelligent persons spend more time on higher-order planning in problem solving.

Several of our studies illuminate this point. Dover and Shore (1991) used Luchins's (1942, 1951) water-jar combination task with gifted and average 11-year-old pupils—we shall describe the study in more detail below. One of the results was that slower performance accompanied flexibility and metacognition in average subjects, but rapid performance accompanied greater metacognitive knowledge and flexibility in gifted subjects. Lajoie and Shore (1986) showed that accuracy was a more important predictor than speed of overall performance on an IQ test. A further study, as yet unreported (with Lazar), used a computer pattern-recognition task in which the planning and execution stages could be separately timed. Relatively more time

was spent by more able students on planning, but much less on reporting the solution.

PROBLEM REPRESENTATION AND CATEGORIZATION

Experts represent and categorize problems differently from novices (Chi, Glaser, & Rees, 1982; Neigemann & Parr, 1986; Sternberg, 1981; Sternberg & Powell, 1983). Krutetskii (1976, see his chapter 12) clearly identified a period of "information gathering" as an important stage, and showed that able students more readily determine the nature of missing data, their representation of a problem extends beyond the information given, and they better exclude irrelevant information. Scruggs, Mastropieri, Monson, and Jorgensen (1985) reviewed similar processes in the gifted literature.

Kanevsky's (1990) average and high IQ four- to eight-year-olds differed in their spontaneous recognition of the similarity of features of the two versions of the Tower of Hanoi puzzle that they were given as acquisition and generalization tasks. As one would expect, the high ability children more often commented on the commonalities in the rules, apparatus, and strategy. It was suggested that this was due to differences in their understanding or internal representation of the problem that made these commonalities more apparent to them. As a result of this, the group differences in the generalization of the solution strategy is also believed to be partially attributable to differences in the children's problem representations. The high IQ children were also quicker to develop a clear understanding of the task. This was apparent in a distinct drop in their need for assistance two to three trials before their average ability peers. Most high ability children mastered the solution strategy in the two trials after achieving an understanding of the task while the average ability children required from three to eight.

Another study, nearing completion with graduate student S. Pelletier, used adaptations of several of Krutetskii's problems with high and average performing mathematics secondary students. Students were asked to group them into similar types (based on Chi, Glaser, & Rees, 1982). No mention was made of solving the problems. High performing students, like a sample of mathematics graduate students, used fewer levels of categorization, seeing greater common elements among more problems. Such differences during initial categorization of the tasks support the notion of differences in problem representation.

PROCEDURAL KNOWLEDGE

The cognitive literature distinguishes between declarative and procedural knowledge (Dillon, 1986). Declarative knowledge roughly consists of "what" one knows, and procedural knowledge with how to do things or to use one's knowledge. Experts employ

highly elaborated procedures or strategies, sometimes rapidly developed (Glaser, 1985; Heller & Reif, 1984). Krutetskii (1976) described this vividly:

The trials made by mathematically inept students always bore the character of blind, unmotivated manipulations, chaotic and unsystematic attempts to find a solution (more accurately, they were attempts at guessing, at coming across a solution at random).

Capable pupils, however, were marked by an organized system of searching, subordinated to a definite program or plan. The trials of the capable pupils were always purposeful, systematized attempts, directed toward verifying the assumptions they had made. In making a trial, capable pupils usually realized why it was being made, what was expected, and what was to come next (p. 292).

In another study yet to be reported, with C. Kaizer, conducted with grade eight students, we observed students whose intellectual strengths were either more verbal or visual while they solved mathematical word problems from Krutetskii. When they had difficulty solving a problem, the more able switched to another appropriate strategy. The less able engaged in trial-and-error or guessing. Our study in progress (with M. Godrie) also appears to be confirming the testing of assumptions or hypotheses, as reported by Krutetskii.

FLEXIBILITY

Flexibility has many meanings, of which the common feature appears to be the ability to see alternative representations or adopt alternative strategies, especially when it is necessary to make a change for success on a task. Flexibility has been a central concept in some conceptualizations of creativity (Cohen, 1989; Goswami, 1990), in Davidson and Sternberg's (1986) view of the role of insight and adaptation to novelty (also see Davidson, 1986), and in several influential views of special or remedial education (e.g., Feuerstein, Rand, & Rynders, 1988). Krutetskii (see pp. 282-283) also emphasized that flexibility is one of the most important qualities of outstanding performance in mathematics, and it is frequently referred to in general Russian views of abilities. Vygotsky's methodology for the dynamic assessment of learning potential challenges a learner to acquire and to transfer a strategy. Knowledge that can be flexibly applied is of greater interest than inert knowledge. We have to be careful not to say that the less able are incapable of being flexible, since their flexibility may be constrained by their more limited knowledge.

Shore and Carey (1983) selected two groups of teenagers, one high on a verbal subtest of an IQ test (vocabulary), and a second group that was higher on a spatial subtest (block design). All were presented with a spatial task, the rod-and-frame apparatus in which one is asked to recognize the verticality of a rotatable rod against a background which can also be turned so as to distract the viewer. The high-spatial students were

"lost for words" to explain their own generally accurate performance. The high-verbal group talked much more while doing the task, using verbally expressed imagery to guide their equally accurate solutions. The high-verbal group appeared to reinterpret the task to suit their strengths. Getzels and Csikszentmihalyi (1976) found that one of the observable qualities of art students who a decade later became successful artists was that they carefully examined a still-life object from many perspectives and reinterpreted the problem; others leapt right into a direct representation.

Dover and Shore's (1991) water-jar study used nine tasks. The first two were practice. Numbers 3 to 6 required three jars. Numbers 7 and 8 could be solved with two or three jars. Number 9 could only be solved with two jars. We found that able students more often successfully broke the "set" at number 9 when they had to switch from using three jars to two, they made fewer errors on all trials (half made none at all), and they were faster on further test trials (numbers 3 to 6) where alternative solutions did not exist, but significant speed differences disappeared on trials 7 and 8 where either two or three jars could be used. Able children replied more often without prompting, and were more aware of how the "set" influenced their thinking strategies; however, they were not more likely to spontaneously offer the alternative solution strategy (using only two jars instead of three) when it was available but not necessary (numbers 7 and 8). This nicely illustrates the importance of examining the process of students' thinking across a task, not just their visible performance or a tally of right and wrong.

PREFERENCE FOR COMPLEXITY

Some time before the prominence of cognitive theory as we now know it, creativity researcher Barron (1958) documented how successful creative adults in such professions as architecture and art had greater preference for complexity in drawings and shapes than did an unselected sample. They were also much more tolerant of ambiguity and did not insist upon the tidy resolution of a problem. Today, we might well label his target group as "experts". Two recent studies have linked this preference for complexity to giftedness. Garofalo (in press) has shown that superior secondary mathematics students, whom he describes as meaning-oriented rather than solution-oriented, preferred more complex and demanding problems. Bowen, Shore, and Cartwright (1992) also found that gifted students suggested changes to a computer game that would increase its complexity and challenge.

Experts, gifted and creative people seem to thrive in environments which are rich and active, in which they do not know all the answers, indeed, where right answers to questions are not the principal intellectual commodity. This may well apply to all learners, though their achievements may vary even under such conditions.

When tasks were not found to be sufficiently complex, young, high IQ children attempting to master a Tower of Hanoi solution strategy would introduce some complexity of their own. They would elaborate the story context of the task or make suggestions of ways to make the task more difficult even before the strategy had been acquired.

Of course there is some overlap among these seven ways in which the thinking processes of gifted learners have been observed to differ from those of other people. Flexibility, for example, depends on procedural knowledge, the nature of the knowledge base and problem representation. These differences provide pedagogical clues which may benefit bright children and also help to improve the learning performance of other students. Some of these implications might also make for more interesting lessons and more interesting independent projects. These are hypotheses which could and should be tested in classrooms.

Development of Thinking Processes

Investigations of the lifespan development of thinking processes of gifted individuals do not exist. The research literature is interspersed with comparative studies of thinking, learning, and problem-solving skills, but none is longitudinal in nature. In this section we shall attempt to link our work with young children to other work that describes early evidence for the thinking processes addressed throughout this chapter. This will highlight areas that have potential to explain differences found in the thinking of gifted and non-gifted adults. It must be noted that these are highly speculative and desperately in need of further study.

Field observations made during the Harvard Project (White, 1983), a longitudinal study of two-and-a-half-year-olds, uncovered a number of similarities and differences between talented and average children. No "appreciable differences" were found in sensory skills, perceptual-motor abilities, general motor control, or popularity. The more talented children were, however, able to attract and hold the attention of adults more effectively. They used adults more effectively as resources, made more self-evaluative comments, had "an unusually well-developed capacity to sense discrepancies or differences" (p. 14), dealt well with abstractions, were less egocentric and thus better in perspective-taking activities. They were able to plan and complete more complex tasks and use resources more effectively in doing so. The picture of the differences that emerges appears to be consistent with the research reported earlier in this chapter regarding flexibility, monitoring, and a preference for complexity.

Other advances in our understanding of young children's learning have been facilitated by implementations of modified versions of Vygotsky's (1978) dynamic assessment methodology. One advantage of these procedures when working with young children is that

they require the investigator to interact with the child throughout the acquisition and generalization of an intellectual skill, rather than observing passively. Thus we have gained insight into the progressive internalization of social interaction which Vygotsky believed played a critical role in development.

Patterns of early social interaction between high ability preschoolers and their mothers appear to be one of the influences that promote the development of superior thinking abilities (Moss, 1990). In her investigation of dyadic problem solving of non-gifted and gifted preschoolers with their mothers, Moss found a greater proportion of gifted children's and their mothers' comments were metacognitive in nature than that of their average ability peers. These included comments related to checking results, predicting consequences, monitoring and reality testing in nature. The children were perceived to be internalizing the patterns of questioning and problem solving modeled by their mothers. Based on her findings, Moss suggests that direct modeling of metacognitive activities in parent-child play activities offer "scaffolding" experiences that will facilitate the acquisition of a repertoire of higher level thinking skills that can play a key role in classroom competence when a child reaches school age.

Age-related differences in children's learning were also found in Kanevsky's (Kanevsky, 1990; Kanevsky & Rapagna, 1991) study of generalization using the Tower of Hanoi. In addition to applying their learning more flexibly and learning more independently, the seven- and eight-year-old high IQ children seldom repeated a mistake and were more likely to comment spontaneously on the similarity in the strategy used on the various versions of the puzzle than the four- and five-year-old high IQ children. The increased level of their problem-solving skill was also reflected in the decline in the number of planning comments made with increasing age. The latter can be explained within Vygotsky's theory as evidence of the internalization of what was once experienced in social interaction. Planning for this activity had become "inner speech". There was also evidence of an increasing level of intrinsic motivation for learning (Kanevsky, in press). The high ability children, more than their average peers, enjoyed increasing control over the solution. As age increases, so does their collection of learning-to-control-learning skills. Thus, their learning becomes more efficient and their knowledge increases.

To speculate that this trend might continue throughout life has an intuitive appeal when one considers the superior scores able learners earn on achievement tests, intelligence tests, problem-solving assignments, and so on. Expert learners are expert thinkers when faced with a novel task. This potential to learn is a life-long advantage which offers accumulating benefits. However, this is only speculation. Current research on learning requires the consideration of influences beyond the cognitive when attempting to explain differences in what and how children learn. These include interest, volition (Corno, 1989), self-efficacy (Schunk, 1989),

achievement motivation (Ames, 1992; Elliott & Dweck, 1988), the nature of the interaction (if any) with the investigator or teacher (Zimmerman, 1989), and so on. Therefore, future investigations of the thinking processes of gifted individuals should also acknowledge the roles played by these variables.

Training Thinking Processes

All education is ultimately concerned with thinking skills of one type or another, but we shall limit our discussion of this topic to three issues, and in each of them we shall focus on the kinds of cognitive processes we have discussed: for example, metacognition, flexibility, and planning of responses. We shall not address such approaches as the Meekers' development of Structure of Intellect (SOI) materials (Meeker & Meeker, 1986), or de Bono's (1982) Cognitive Research Trust (CoRT) program. Though these and others have some following in gifted education, neither has been related to the kinds of thinking processes we have described in this chapter.

The three topics we shall address are thinking skills training in general, in special education, and with regard to exceptionally competent performance. We caution that this chapter presents our reflection on a topic for which there is not enough hard evidence to be certain, and it is therefore again highly speculative. Our goal is to provoke reflection on these issues, not to settle them.

Thinking Skills Training in General

The literature on this is small but growing. There is also great divergence of models and types of thinking skills that are presented. Specific training approaches particularly address metacognition (Carns & Carns, 1991; Pesut, 1990), including the use of self-questioning techniques to enhance metacognition (Haller, Child, & Walberg, 1988), and control of transfer (Jelsma, VanMerrinboer, & Bijlstra, 1990), and generally take the form of direct training practice in the skills involved. We earlier mentioned our ongoing research (with L. Austin) that is demonstrating that cognitive mapping (Kozma & Van Roekel, 1986) can be used to enhance the webbing of concepts and high level learning in the classroom. The literature is characterized by optimism that these strategies can be taught and learned, accompanied by suggestions about how to do it (Anderson, 1982; Lochhead & Clement, 1979; Nickerson, Perkins, & Smith, 1985; Peat, Mulcahy, & Darko-Yeboah, 1989; Pressley & Associates, 1990; Segal, Chipman, & Glaser, 1985), but very few studies have addressed the transfer of these skills from the training programs to arms-length classroom learning (Feldman, 1990) or to performance outside the classroom (several unanswered research questions are offered by Chipman, Segal, & Glaser, 1985). There is not universal agreement that these

programs work, including observations of the limitations of the evidence available (Sweller, 1990).

It is our impression that the processes and their applications are too general and still too vaguely defined for broad applications to lead to useful specific results. If we accept Piaget's thesis that children must construct their own realities to learn well, expressed in educational terms by Bruner (1960) and Kamii (1985, 1989), then we cannot expect children to learn general thinking strategies out of context and to then apply them to specific learning. There cannot be a process without context or content, a lesson still not learned even by many gifted programs. Every mathematics student learns that operations are performed on something, and what the something is can considerably affect the process.

Teaching metacognition, strategy flexibility, knowledge webbing, or other cognitive skills, needs to be what the cognitive literature calls situated, in context. Perhaps this is not necessarily the case with adults whose knowledge base is already large and more abstract. One of the problems in the cognitive literature from which these ideas have come is that it is a literature of adult (expert) performance, yet the majority of applications have been with children. This is a risky extrapolation, but definitely worthy of study.

Thinking Skills, Special Education and Reading

The greatest amount of research on metacognitive and other thinking training has been in special education and in remedial reading instruction. As we have just suggested, this is an example of extremely broad generalization from concepts recognized in expert adult performance to underperforming children. This daring application has met with considerable but not universal success.

Metacognitive skills, especially monitoring (Chan & Cole, 1986; Palincsar & Brown, 1984), can considerably improve children's performance. Thinking-skills programs have been extensively used among learning-disabled students (Larson & Gerber, 1987; Orlando & Bartel, 1989) and in the improvement of reading (Duffy & Roehler, 1987; Duffy et al., 1987; Palincsar, Brown, & Martin, 1987; Paris, Jacobs, & Cross, 1987; Stevens, Madden, Slavin, & Farnisch, 1987). The weight of evidence to date is that cognitively based thinking strategies, especially self-questioning and metacognition, do enhance substandard performance, especially in young adolescents (Haller, Child, & Walberg, 1988), and sometimes dramatically (Feuerstein, Rand, & Rynders, 1988).

Nonetheless there remain cautions in the design and implementation of such programs (Abikoff, 1991; Bettencourt, 1987; DeStefano & Gordon, 1986). The most difficult problem is to be able to generalize from successful applications. How individualized are the interventions, and to what extent is their success related

to the general skills being taught or to the nature of the program? There is the risk of an implicit contradiction in a domain of educational activity characterized by individual educational plans (IEPs) and the successful application of highly generalizable teaching strategies. We need to know what the critical ingredients are in each successful case. We especially need to know the limits of such interventions. Case studies have indicated that amazing progress is possible in individual cases, but what can be reasonably expected in large numbers? Do cognitive training programs overcome intellectual deficiencies, do they provide a path around them, or to some extent a combination of the two? Are the newly acquired skills used in the same ways as they are by initially more competent learners and by adult experts? Are they as effectively transferred? Are there individual differences in their applicability?

Thinking Skills and Giftedness

A number of recommended programs for gifted children, especially in North America, include explicit thinking-skills training. Among the most common approaches in gifted programs are SOI (Meeker, 1969; and subsequent materials), Future Problem Solving (Crabbe, 1982), Odyssey of the Mind (Micklus, 1985), numerous applications of Creative Problem Solving (Parnes, 1962), and CoRT (de Bono, 1982; Maier, 1982). We found only one reference to cognitive processes such as we have addressed, in a program for disadvantaged gifted children (Shlomo & Reichenberg, 1990), and others to art education for gifted students (Kay, in press). Kay's work in particular suggests that cognitive skills can be acquired in context with excellent outcomes. Replication in a number of other areas is, however, much needed. An excellent model for assessing the impact of such training in both gifted and general education is provided by Starko's (1988) evaluation of the outcomes of students' involvement in programs designed according to principles recommended by Renzulli (cf. Renzulli & Reis, 1985). She demonstrated positive effects not merely in the training activities, but also in attitudes toward school, insight into personal strengths and weaknesses, career goals, and research skills.

Slightly contrary results were obtained in a study in which the intervention was more constrained than in Starko's observation of the implementation of Renzulli's Type III activities. Average and high ability 10- to 12-year-olds were found to be differentially sensitive to a five-day metacognitive awareness program. On the first day, Sheppard (1992) found the high ability students were more able to create a metaphorical machine that worked as their minds did while they were also engaged in a challenging activity (in this case a hard mathematics problem). Their descriptions of the machine's operation included more steps than those of their average ability peers. By the fourth day, the high

ability students had tired of the machine metaphor and began to invent fictional machines or ignore the machine constraint on their product completely (it seemed as though they changed the task from Type II to Type III). The average ability students were still growing in their ability to find machines and explain the similarities between the machine's operation and their mind's on the fifth day. A more thorough investigation of the effect of awareness training on the outcomes of metacognitive strategy instruction is planned. At this point, it can be said that high ability students are more metacognitively aware before training and, as in other skill domains, they become bored with routine practice.

One of the speculative issues that has attracted our attention is the place of gifted students in the development of adults who later become experts. We have suggested elsewhere (Shore, in press) that experts may be selected for training from the ranks of highly motivated young people who already have acquired a large part of the knowledge and skills that enables them to be recognized by recognized experts as likely to be able to be trained to be like themselves. These people are called novices in the cognitive literature, and the research we have cited suggests that gifted students greatly resemble these novices (not to be confused with total beginners). Shulman (1986), in his discussion of teaching, wrote: "Our central question concerns the transition from expert student to novice teacher" (p. 8). This relativistic use of the term "expert" may be appropriate, since being a student is an occupation that some people definitely master. However, at the point of choice of occupation or application of the rudiments of expertise already acquired, the learner is definitely a novice. We suggest that this developmental issue may be one of the most interesting to pursue in terms of cognitive skills and gifted students, and that it might provide a very useful link between the gifted and cognitive literatures.

Overall Assessment of Training Programs

Some very interesting models have been developed, but they have so far little direct application to programs for highly able students. A lot of work remains to be done in validating the training of cognitive skills among less able students, but the work shows great promise. It is not possible to state clearly at this time that anybody can learn to think like a gifted child or like an adult expert, and that may never come to pass, but an entirely reasonable goal is to enhance the thinking skills of a large number of people to any reasonable degree as a result of studying successful thinking in children and adults. This is clearly an attainable goal. The next task is to present the successes with sufficient precision to be able to better understand the limitations and opportunities of this approach, and thereby to more effectively plan future applications. This has been done in some areas of special

education and remedial reading, but not yet in general education.

Part of the problem is that the applications have so far been from successful adult or expert thinking to developing solutions for children with difficulties. One of the great opportunities for links between gifted and general education is to redefine some of these processes in developmental terms, and specifically in terms of the childhood antecedents of expertise. The specification of developmental trajectories for cognitive and metacognitive skills must be pursued before this can be achieved. Are there qualitative differences in the nature of the skills that develop? Do they simply differ in the rate of development? Are other factors at work as expertise develops? These are goals that we shall pursue and look forward to exploring with others, and we begin with the following (and concluding) discussion.

Educational Implications

An important component of educational success is teachers' awareness of how children learn and think. Carpenter, Fennema, Peterson, Chiang, and Loef (1989) showed that a simple week-long workshop intervention which helped teachers understand how children learned mathematics led to noticeable changes in their classroom performance and in their students' learning. If we are going to be able to define appropriate differentiated pedagogy for bright students, then educational researchers and practitioners need to understand if and how these pupils think differently from others. If they merely think more quickly, then we need only teach more quickly. If they merely make fewer errors, then we can shorten the practice and skip some of the review. Precocity and accuracy do not necessarily imply any qualitative difference fundamental to an understanding of intellectual giftedness any more or less than differences in the nature of children's problem representation and the flexibility of their thinking.

In accord with the theoretical directions which we speculated might be taken by this line of research, we are drawn back to an educational implication which we propose may be of over-riding importance, and which may, in somewhat different but equally important ways, apply across ability levels. This is that bright children need, especially need, to be introduced to learning from the point of view of an enquirer, an explorer, a question asker. Bright learners should experience the kind of thinking that leads to new discovery, at every opportunity. There is also little doubt that all children can benefit from such a mindset. They might not benefit to the same degree or in all the same ways, but discovering these differences is one of the challenges of this research.

Discovering the nature of outstanding ability and factors influencing its development should, in general, have benefits for all children.

From this perspective, the challenge in the selection and training of teachers is to ensure that they are

independent learners, have experienced and experience making a contribution to knowledge in any valued field of human endeavor, be it artistic or cultural, social, academic, or professional. Shulman (1986, p. 14) explored the nature of teachers' professional knowledge and turned Shaw's rather insulting phrase "He who can, does. He who cannot, teaches" into "Those who can, do. Those who understand, teach". The offending phrase appears only in an appendix to *Man and Superman* (Shaw, 1946/1903, p. 253) in a somewhat tongue-in-cheek handbook for a revolutionary or anarchist. Education is not the only enterprise to suffer his fifteen pages of biting wit.

Studies of highly gifted or high performing individuals (Bloom, 1985; Feldman, 1986) have repeatedly shown "that extraordinary achievement requires recognition, encouragement, and years of hard work" (Gruber & Richard, 1990, p. 148). Parents, teachers, mentors, coaches—they go by many names—are central to this process.

Teachers need to respond to children's interests as primary curriculum guides. There are also some very specific things, derived from the research we have described, that should be validated as important practices, for example:

- (1) Help students to make broad connections in memory.
- (2) Use knowledge widely in new situations.
- (3) Use different learning modes, not always verbal.
- (4) Invent new solutions to problems.
- (5) Value elegant solutions, not just right answers.
- (6) Emphasize planning of response strategies.
- (7) Relate new learning to old.
- (8) Assessing patterns, relations, missing and redundant information.
- (9) Downplay (but do not ignore) low-level functions.
- (10) Reinforce and model metacognitive strategies.
- (11) Provide diverse tasks that require the application of new learning in different contexts and media in order to promote generalization.
- (12) Nurture an awareness of self-regulatory activity.

When learning new material it is possible to summarize the main points and to consider how this new learning is related to previous learning in the same and different subjects, and to general experience. The links, direct or fuzzy, become as important as the points. When students are working on a project or task, they can be asked and ask themselves to assess how their work is proceeding, whether it appears to be leading them to their desired outcome, and whether they wish to reconsider part of the plan they are pursuing (if they have not such a plan, this exercise might help). Students can try to divide their work on tasks into information-gathering and execution stages. They can concentrate on evaluating the quality of their harvest in the first stage before launching into the latter. They can judge if they reached out adequately into the extremes of linked knowledge in order to make the best of their current activity. Are there other suitable strategies, or how would someone with

other expertise approach this? When they encounter a difficulty, what adjustments to plans may be useful? Do they sense themselves guessing inappropriately? Can they anticipate what might be the difficult points in a task before beginning it, and be prepared with alternative approaches? Can they benefit from working collaboratively?

Our view has been expressed elsewhere in the literature on general education, and it is interesting how closely it parallels advice available in the gifted literature (cf. Rogers, 1983):

Indeed, the urgent need to teach thinking skills at all levels of education continues, but we should not rely upon special courses and texts to do the job. Instead, every teacher should create an atmosphere where students are encouraged to read deeply, to question, to engage in divergent thinking, to look for relationships among ideas, and to grapple with real-life issues (Carr, 1988, p. 73).

With these recommendations in mind, the need for a better understanding of the developmental trajectory of cognitive and metacognitive skills becomes critical. Learners will need developmentally appropriate assessments of their performance and feedback in order to optimize their progress.

Might these approaches be well matched to processes that are spontaneously demonstrated by very capable learners? How much would their learning and attitudes toward school improve if this were done? Could other students benefit as well from such elaboration of their curriculum?

These questions have not been answered by research on practices in gifted education (cf. Shore, Cornell, Robinson, & Ward, 1991), and laboratory-style research is not likely to provide full answers. Such research can be done in classrooms with the active collaboration and even leadership of teachers who are interested in the education of capable students. In classrooms, the interactive contributions of cognitive, metacognitive, motivational, emotional, and environmental variables to learning can be considered in concert rather than in isolation. Thus, an integrated understanding of the influences they play in overall development can be constructed. To study them individually is no longer satisfactory.

The research summarized in this chapter has offered evidence of both precocious development and qualitative differences in the content and processes of the thinking of gifted or expert individuals and their less able or experienced peers. It may also be appropriate to resume studies of aptitude-treatment interactions to investigate the differences in the outcomes of gifted and other students who have been provided the same curriculum and instruction.

We have been concerned for a long time that gifted education has been progressively cutting itself off from the mainstream of education by expressing the learners'

uniqueness in terms of qualities that appeared to be in conflict with the goals and methods of general education (Shore, Rejskind, & Kanevsky, in press). Attention has been focused on the need for rapid pacing and other acceleration, extended and advanced subject matter. Little attention has been paid to the adjustments that need to be made in methods of learning and teaching to take account of thinking differences, nor to what we can learn from the successes of able students to improve the learning of other students as well. Research on thinking processes may offer the possibility of a benefit to general education through meeting the needs of able students. This may be politically as well as pedagogically important.

Acknowledgements

The research at McGill University reported in this paper was supported by the "FCAR" program of the Ministère de l'éducation du Québec and the Social Sciences Research Council of Canada. We are grateful to PhD student Pui-Wan Cheng in the Department of Educational Psychology at the University of Alberta for sharing with us her bibliography on metacognitive instruction and to MA student Cheryl Corber-Wiltzer in the Department of Educational Psychology and Counselling at McGill University for her assistance in locating additional references on the teaching of thinking skills.

The section of this chapter enumerating examples of thinking processes in gifted children is based in part upon a presentation in Moscow, in June 1991, to the Institute of General and Educational Psychology of the Academy of Pedagogical Sciences. Portions of an abridged version of that talk (Shore, 1991) are included in this chapter with the permission of the journal.

Longitudinal Studies of Giftedness: Investigating the Fulfillment of Promise

RENA F. SUBOTNIK

Hunter College, City University of New York, New York, U.S.A.

KAREN D. ARNOLD

Boston College, Chestnut Hill, Massachusetts, U.S.A.

Introduction

The purposes of education for the gifted parallel the objectives of longitudinal research. Educators seek to identify individuals whose early achievements relate to accomplishments later in life. School systems provide special programs and opportunities for the gifted in order to affect the realization of promise. And researchers and practitioners attempt to understand the ways in which the characteristics of gifted individuals interact with naturally occurring and intentional environments that shape continued behavior and achievement.

The study of individuals over time allows for both descriptive and explanatory findings about gifted individuals (Nesselroade & Baltes, 1979). Like cross-sectional studies which examine samples of different ages or ability levels on the same dependent variables at the same point in time, longitudinal investigations illuminate group and individual differences in gifted populations. Longitudinal methods go beyond cross-sectional research, however, in investigating the processes of change (Schaie, 1983). Specifically, longitudinal designs accomplish the following purposes:

- to describe and to provide causal explanations for intra-individual change;
- to describe and to provide causal explanations for inter-individual differences in intra-individual change;
- to describe the interactions of developmental variables.

Definition of Longitudinal Research

In essence, longitudinal research can be defined as repeated measurement methodology (Nesselroade & Baltes, 1979) in which data are collected from the same individuals on the same or comparable variables

for two or more distinct time periods (Menard, 1991). Multiple observations of the same individuals over time permits analyses of changes and developmental differences within and among individuals. This basic definition distinguishes longitudinal research from cross-sectional and retrospective studies, even though these latter designs are often used as indirect measures of change.

Cross-sectional studies, or the measurement of individuals at one point in time, are often used to impute intervention outcomes. Simultaneous measurement of individuals of different ages is often used as a proxy for developmental change; however, cross-sectional studies can directly measure only inter-individual differences. Retrospective studies, in which eminent individuals reflect on past experiences, also fail to provide a true causal view of developmental outcomes. In retrospective research, intra-individual change patterns are distorted by hindsight. Retrospective designs cannot provide contemporaneous reports of significant stages in life experiences nor record subjects' perspectives on events as they occur. Further, control groups are generally unobtainable due to the difficulty of matching subjects of retrospective studies on childhood or adolescent characteristics.

Beyond the basic requirement of repeated measures, longitudinal study designs vary widely, leading some scholars to consider longitudinal designs as a family of methods (Nesselroade & Baltes, 1979). Standard rules do not exist for study duration, for the number of data collection points (or waves) in a longitudinal inquiry, or for the amount of time between waves. The common educational research practice of one semester or academic year pre/post test studies with two or three data points is not generally considered to be longitudinal. Instead, longitudinal studies report on information collected from subjects over months and years. A recent inventory of European longitudinal

research contains only studies with at least three data points, spanning at least three years, and focusing on individual development (Schneider & Edelman, 1990). Straight retrospective studies were excluded.

Within the longitudinal study paradigm, researchers use a variety of designs and data collection methods, including qualitative interview and ethnographic approaches, survey research, quasi-experiments, and single-subject designs. In addition, the content and theoretical context of a given study determine its design. Longitudinal methodology is especially useful for the study of human development, exploring the growth and change that takes place within an individual over time, and for noting similarities between that individual and others in his or her cohort. Of particular interest in the field of gifted education are the following three strands: how budding talent is transformed into extraordinary performance, how gifted children's development compares to that of average children or dissimilarly gifted children, and determining the effectiveness of programs designed especially for children identified as gifted.

Examples of Longitudinal Research Questions and Procedures

Example #1: Talent Development

What characteristics and educational experiences produce exceptional teachers of gifted students? To study such a question, variables cited in the literature on teacher characteristics must first be identified. Second, interviews with teachers known to be outstanding based on reports of students participating in local gifted programs should be conducted. Did these teachers receive special training? Did they start teaching early in their adult lives, or did they bring to teaching their experiences from another profession or trade? Were their parents or grandparents teachers? What are their opinions about the label "gifted"? Collecting such base-line data on a cohort operates in much the same way as conducting cross-sectional research.

Supported by the literature and interviews, some hypotheses could be generated and refined concerning the necessary characteristics and progressive experiences that lead to excellent instruction for gifted students. Educators returning to university for advanced degrees who have superior recommendations as teachers could be identified as a study cohort. Data could be collected from observations, interviews, questionnaires, and attitude surveys. Each year, follow-up information could be collected on philosophy of teaching, perceptions of giftedness, the application of personal interests to curriculum design, attendance at staff development and conferences related to gifted education, enrollment in post-masters program, teaching assignments, and so forth. Over the years, patterns of characteristics and experiences within the cohort would become increasingly salient and useful for analysis. After 10 years, some

very valuable qualitative and quantitative data would be available for policy making and teacher training. The study would be strengthened if, in the fifth year, another cohort was established to control for the political and social milieu of the study period. Control groups for each cohort would be made up of less highly recommended educators. Yearly outcomes from each cohort and corresponding control groups would be assessed. Which teachers evolve from novice to master over the course of the years? What progression characterizes the development of master teachers? What base-line variables serve as predictors of outstanding instruction? What educational opportunities, as opposed to naturally occurring interventions, seemed most useful? What obstacles hindered the fulfillment of exceptional promise?

Example #2: Cognitive Development and Program Evaluation

A community might create a special program for gifted children with exceptional spatial reasoning ability because it values talents that relate to movement, three-dimensional design (engineering, architecture, or sculpture), and mathematics. A spatial reasoning instrument would be chosen and testers trained to administer it. A cohort of primary age children would be identified and invited to participate in this educational program. Unlike the first example provided above, subjects would be identified based on an abstract test removed from the actual skill itself. Over the course of their elementary school years, various measures of academic, creative, moral, aesthetic, and verbal ability could be collected from the identified group, from a random sample of children in the regular program, and from a high verbal group in a different gifted program. A longitudinal study would allow investigators to observe how strong spatial skills interact with academic requirements at various stages of the children's elementary school experience. The test's reliability and predictive validity could be explored and developmental differences among groups of children could be compared over multiple points in time. The age at which a screen for spatial abilities would be most likely to catch both late bloomers and precociously talented children could be investigated to find the most propitious time for test administration. Finally, we can ask: Does early identification of spatial reasoning skills with concurrent provision of special services predict the fulfillment of talent in movement, design, or mathematics?

Review of Longitudinal Research Using Gifted Populations

Central to the identification and nurturing of giftedness is a longitudinal question: What early manifestations of ability are trustworthy indicators of culturally desirable adult accomplishments? Seminal longitudinal research

addressing the relationship of early exceptional performance and later accomplishment was conducted by Terman in order to test the validity of the Stanford Binet intelligence test as an instrument that could identify childhood genius and predict adult productivity (Burks et al., 1930; Oden, 1968; Terman, 1925; Terman & Oden, 1947, 1959). Terman began his study in the 1920s with over 1500 California school children who scored in the top 1% in IQ. His major interests were to disprove popular beliefs of the time including the "early ripe, early rot" phenomenon, in which precocious children's gifts would decline into entropy before maturing to adulthood. A second popular supposition held that an individual's gift was inevitably accompanied by a companion negative quality. In other words, a brilliant child would certainly be weak in social or physical domains. In order to dispel these popular myths, Terman collected a wide assortment of data on physical, emotional, academic, and social variables. He contacted his subjects at several key points in their lives to test his theories that children identified as gifted by the Stanford Binet would indeed grow up to be highly successful and productive adults. When his midlife reports revealed distinctive patterns of success for most but not all of his subjects, he was able to make cross-sectional comparisons that referenced specific childhood and adolescent characteristics that augured well or poorly for his high IQ subjects.

Vaillant (1977) directed the latter phase of a 30-year follow-up of male Harvard undergraduates who had attended the university in the 1940s. Subjects had been selected on the basis of academic brilliance and emotional stability. In adulthood, the greatest and, for Vaillant, the most interesting group differences appeared in the area of coping mechanisms. Information on how members of the study cohort dealt with inevitable life difficulties allowed the researchers to develop a schema for correlating categories of coping mechanisms with life satisfaction, health, and career attainments. This long-range view of the Harvard men provided a rich set of variables to explain some of the profound differences that separated gifted undergraduates from one another in later years.

In order to explore personality development of gifted men as predicted by standardized and projective tests, Murray (1938, 1955) conducted a 23-year study of male, upper-middle class, Harvard undergraduates. Murray focused on variables such as memory, social interaction, and responses to stress. The elegant design utilized five cohorts to replicate each component of the project. There have been no further waves of this study conducted, and to date there have been no further analyses of the data.

Current Research

The latest report from a longitudinal study based on problem finding ability was published in 1990 by Csikszentmihalyi. Getzels and Csikszentmihalyi

(1976) collected data from students at a prestigious art institute in the early 1970s, including intelligence tests, values and attitudes scales, and observations of their subjects at work. Problem finding was defined as the ability to manipulate objects into interesting artistic problems. Those who were categorized as problem finders interacted with more objects and took a longer time to come to closure on the composition of their drawings. At the 7-year data collection point, problem finding emerged as the best predictor of success in the professional world of art. At the 18-year follow-up, problem finding played a smaller predictive role in attaining recognition in the art world. Instead, social skills and other components of practical intelligence, such as networking, took precedence.

Much of the longitudinal research conducted during the past 20 years follows relatively small samples within single cohorts. A tiny fraction are cross-cultural or cross-national. Some of the most ambitious projects are government- or foundation-sponsored studies of general populations in which gifted subpopulations can be investigated. In the United States, for instance, the National Longitudinal Study of the High School Class of 1972 traces a nationally representative sample of adults (Burkheimer et al., 1982; ETS, 1991; Fetters, 1975). Similarly, "High School and Beyond" is tracking American students who completed secondary school in 1980 (ETS, 1991; High School and Beyond, 1985). The Malmo longitudinal study began in 1938 with all 1542 third graders in that Swedish city's public and private schools. The core sample of 754 was last contacted in 1988. Although not designed as an investigation of giftedness, the original purpose of the Malmo study was the exploration of the relationship between home background and IQ (Fagerland, cited in Schneider & Edelman, 1990).

A German longitudinal study of approximately 9000 13th-school-year students was begun in 1973 by the Institute for Test Development and Talent Research. Designed to trace the educational and career paths of the subjects, the sample size has allowed longitudinal analyses of high achievers (top 10% in grade point average and scholastic aptitude tests) in science, mathematics, and business (Trost, 1991). At age 30, the high achievers were more likely to be working harder and longer at more satisfying and well-paid jobs (Trost, 1990). These projects were not designed primarily as investigations of gifted individuals, yet the large sample sizes and the availability of machine-readable data for secondary analyses allow for observations of some gifted subsamples.

Such large-scale studies with nationally or regionally representative samples have the advantage of control groups and generalizability. Looking at the gifted as a subset of a more general sample is less ideal, however, than collecting data on original subject characteristics that test theoretically-driven or multidimensional identification methods. Generally, this research was not designed to answer questions about exceptional individuals, therefore information of interest was missed and significant data were lost to ceiling effects. Also, qualitative information

is normally lacking from large-scale national studies. Finally, even these major research efforts of relatively short duration suffer from the time-of-measurement and history effects of single-cohort longitudinal studies.

Large-Sample Multi-Cohort Studies

A few large-sample, multi-cohort longitudinal studies of gifted populations are currently underway. In Germany, the Munich Longitudinal Studies of Giftedness began in 1985 with a sample that was identified based on a multi-dimensional definition of giftedness (Heller, 1991; Perleth & Heller, 1993). The total sample of 26,000 children and adolescents comprises six cohorts who have been measured on a wide variety of cognitive, personality, and achievement variables at three data collection points. In addition to the use of multiple identification methods and diverse quantitative measures of development, the investigation includes a qualitative interview component. The scale and design of the study have allowed the researchers to control for the effects of age and grade in school and for cohort effects. Time-of-measurement effects remain a problem despite the multiple cohorts. Because of the short spans between cohorts, they all share the common historical experiences of the late 1980s. Early findings, however, point to the importance of retaining multiple methods for early identification of the gifted. Achievement in specific domains has thus far been predicted by domain-specific tests, while personality factors such as motivation have played a mediating role in achievement outcomes. IQ tests alone have proven to be unsatisfactory predictors of the development of particular talents.

A Russian replication of the Munich study begun in 1989 by Matyushkin should add significantly to the knowledge base. A planned replication will also take place in Korea (Perleth & Heller, 1993). Cross-national comparisons of results will offer an authoritative account of the interaction of culture and the development of giftedness. Another study which allows the rare opportunity for cross-national comparisons is a longitudinal investigation of technical creativity in Germany and China. The goals of the study include comparative analyses of a model of technical creativity in two distinct cultural settings, and determination of the contribution of technical creativity in the prediction of scientific talent (Hany, 1993; Hany & Hany, 1988; Heller & Hany, 1989).

Giesen directed an 18-year study of four cohorts first studied in the 11th grade (Giesen, 1981; Gold, 1988; Hummer, 1986). The study, which began in 1972, explores the correlates of academic achievement and satisfaction with schooling, as well as the socialization outcomes of different educational tracks. The sample of approximately 3000 German students was followed through high school and university by means of questionnaires, intelligence tests and knowledge assessments.

Schaie (1983a) has studied life span development and written extensively on longitudinal research methods. The Seattle Longitudinal Study is a 21-year longitudinal investigation of intelligence in adulthood (Schaie, 1983b). The study uses a sophisticated multi-cohort sequential design, in which seven birth cohorts are followed longitudinally over a 14-year period, in order to control for historical and time-of-measurement effects. Schaie's research refutes the widespread belief that mental abilities decline continuously after young adulthood (Schaie & Baltes, 1975; Schaie & Hertzog, 1983).

The largest American longitudinal project focusing on giftedness is a 50-year follow-up of individuals who show early talent in mathematical reasoning (Lubinski and Benbow, 1993). The Study of Mathematically Precocious Youth (SMPY) began in 1972 with a cohort of 13-year olds who scored highly on a mathematics test normally taken by older students as a college entrance examination (Scholastic Aptitude Test of Mathematics: SATM). The SMPY sample of 4000 students currently includes four cohorts who have participated in three or four waves of data collection. Many of the study subjects took part in special educational opportunities ranging from acceleration to programs associated with the project. Findings from the first 20 years of the study show that exceptional scores on the SATM in early adolescence are associated with high academic achievement and the choice of careers in mathematics and science. Large numbers of math-talented young adolescents, particularly women, leave mathematics-related fields, however. (See Benbow, this volume, for a more complete description of gender differences in mathematically talented students.) The SMPY research is a good example of a large-scale longitudinal study which controls for cohort and history effects. Over the half-century of the entire study, the design will also allow control for time-of-measurement effects. The concentration of the SMPY research on a single talent domain and means of identification permits intensive analysis of the development of exceptional mathematical reasoning ability and the predictive validity of one test.

Small-Sample Single-Cohort Studies

Single-cohort studies that follow relatively small samples for years or decades tend to fall into one of three categories: outcome studies of samples identified as gifted in a specific domain, studies of the predictive validity of measures of giftedness, and follow-up studies of the effects of gifted programs. In the past 15 years, longitudinal studies of each type have been conducted with diverse populations, variables, and designs. This diversity, along with the single-cohort designs and small sample sizes, discourages the direct comparison of study results as well as the generalizability of findings from any given study. Despite these cautions, common patterns can be determined from the body of recent longitudinal work. Furthermore, even single-cohort lon-

itudinal designs are well suited for investigations into the development of giftedness, the realization of early potential, and the unique paths of gifted individuals.

Subotnik and Steiner (1993) followed secondary school students who showed exceptional early promise in science. The 96 students in their sample were Westinghouse Science Talent Search winners chosen in a national competition on the basis of outstanding original research. Interview data revealed that the attrition from university science by Westinghouse winners was related to poor choice in selection of an undergraduate institution, which led to a dearth of mentors and to a lack of opportunities for undergraduate research, rather than to poor academic performance or waning interest. The Westinghouse study provides an example of the benefits of a small, intensively studied, group of highly talented individuals.

The Illinois Valedictorian Project utilized a similar qualitative design to study the effects of outstanding secondary school performance on subsequent educational and occupational attainment (Arnold, 1993b). Arnold followed 81 students who graduated in 1981 as one of the top grade earners in midwestern American public or private high schools. Despite superb academic performance in their university studies, female subjects lowered their intellectual self-esteem over the undergraduate years, and the transition from academic to career achievement was particularly complex and problematic for these academically talented females (Arnold, 1993a). In general, early scholastic performance was found to be highly predictive of future educational achievement but less effective as an indicator of career attainment or eminence. Although the Illinois Valedictorian Project is a single-cohort design, U.S. studies on the effects of secondary school performance have begun in other states (Perrone & Dow, 1993).

Kaufman (1981) followed Presidential Scholars who were identified in the 1960s as the top two graduating high school students in each state of the United States. This select group was deeply affected by the events and values of their historical era. As adults, women Presidential Scholars achieved less highly than their male counterparts in educational and occupational spheres.

In an Israeli study, Milgram and Hong (1993) investigated the relationship of adolescent leisure activities to adult accomplishments. Eighteen years after secondary school, 48 of the original 159 subjects were surveyed on their occupational accomplishments. A third of the men and women were employed in fields that matched their adolescent leisure activities and this group had higher adult work attainment than peers whose careers were unrelated to their early interests. Milgram and Hong concluded that creative leisure activities are useful predictors of adult accomplishment.

A German study of the social life of highly gifted students has followed 300 elementary school students and their significant teachers, peers, and family members (Rost, 1993; Wild, 1991). Begun in 1987 with a nationally

representative sample, the Marburg Giftedness Study compares highly gifted children with a control group on a range of psychological measures and on school and leisure activities. Children were identified as gifted in terms of broad intellectual capacity as measured by a composite of three intelligence test scores. Gifted children were found to be at least as well adjusted as non-gifted schoolmates, were more popular with peers, and used more adaptive achievement-oriented cognitive approaches and attributions. Family variables and play behavior were similar across intelligence levels. As compared to testing, Rost found teacher selection, peer designation, and self-nomination ineffective tools for identifying giftedness.

In Norway, researchers at the University of Trondheim have been following 46 students who were first contacted in 1984 at ages 10–11. This study focuses on how gender differences in mathematics and science interact with background characteristics and aspirations of gifted Norwegian students (Undheim & Nordvik, cited in Schneider & Edelstein, 1990).

Monks and associates conducted a study of gifted secondary school students in Holland (Monks, van Bostel, Roelofs, & Sanders, 1986). Subjects were studied on a wide range of ability and psychological variables including such factors as intelligence, creativity, learning style, achievement motivation, and social-emotional characteristics. The Monks study draws from the Triad Model of Giftedness (Renzulli, 1986) in describing outcomes for gifted students.

Freeman (1979) directed the Gulbenkian Project in England, a longitudinal study of the social and emotional development of gifted children. Study subjects were pupils whose parents had identified them as gifted. These 70 students were matched with two control groups, one of equally intelligent classmates who had been nominated by parents, and a second of random ability peers. Freeman found that intelligence and general adjustment were not negatively correlated, but concluded that parent nominations tend to result in less well-balanced children identified as gifted.

American investigators at Harvard Project Zero are tracking the development of musical reasoning in children and the process of musical thinking in conservatory instrumental and voice students (Davidson & Scripp, 1993; Scripp & Davidson, 1993). With their focus on comparing normal with exceptional development, the Project Zero studies of musical reasoning are providing educators with essential information that can be used to provide appropriate curricula and services for musically talented individuals. A study from the Chopin Institute in Poland has traced longitudinally 35 musicians as a subset of a cross-sectional study of 166 professional musicians. The study centers on family background, personality characteristics, career growth, and conditions for talent development at the highest levels in music. Study subjects range in age from 20 to 90 years old (Manturzevska, cited in Schneider & Edelstein, 1990).

Predictive Validity of Tests

The predictive validity of tests relates closely to the identification of giftedness. Terman's interest in intelligence, for example, led him to define giftedness as exceptionally high IQ. This definition, in turn, required valid and reliable instrumentation. Later conceptions of giftedness have stressed domain-specific talents, like mathematical aptitude, or particular cognitive abilities, like creative thinking. Still other theories and school-based programs consider giftedness as a multidimensional construct. Definitions of giftedness relate directly to policy and program efforts. Tests which purport to measure exceptional potential and behavior, therefore, have concrete implications for individual identification and treatment, rendering test validity a central issue in the field.

Terman's studies can be viewed as long-term research on the predictive validity of IQ measures. More recently, Benbow and Stanley's (1986) SMPY studies investigate the Scholastic Aptitude Test in mathematics as a forecaster for educational achievement and career attainment in science and math. The predictive validity of a widely used test of creativity has been the subject of a series of longitudinal studies (Torrance, 1980). A review of these studies by Cramond (1993) concluded that the Torrance Tests of Creative Thinking (TTCT) were better predictors of adult creative achievement than IQ, secondary school grades, and peer nominations. The Munich studies of giftedness found the predictive validity of the TTCT to vary according to the age of the test taker (Perleth & Heller, 1993). Milgram and Milgram (1976) found the TTCT problematic because of its correlation with intelligence, developing the Tel Aviv Creativity Test as an alternative measure of ideational fluency that would not be confounded with intelligence. Milgram and Hong (1993) found that the Tel Aviv Creativity Test, taken by Israeli adolescents, was correlated with adult accomplishment.

The ability of psychometric instruments to predict specific later outcomes varies according to the criterion variable, or type of gifted behavior, under investigation. Tests of creativity, not surprisingly, appear to be better predictors of creative and artistic behaviors than IQ tests. Tests of mathematics reasoning predict math and science achievement, and IQ tests continue to be valid predictors of many academic accomplishments. Few research studies have compared directly the outcomes of different identification methods. A welcome exception is Albert and Runco's longitudinal study of a group of boys identified as gifted on the basis of IQ scores and a second group of boys who showed high ability in mathematics (Albert, 1993; Albert & Runco, 1986). A German group compared the predictive validity of performance versus paper-and-pencil tests, using a sample of 300 kindergarten children. Ninth grade performance, particularly in mathematics, was found to be correlated with teacher ratings, grades, and mathematics achievement tests (Gitter, cited in Schneider & Edelstein, 1990).

A Croatian longitudinal study followed 558 students from their early teenage years in 1970 until 1989 in order to determine the validity of a regional gifted identification model (Korin, cited in Schneider & Edelstein, 1990). Researchers at the Institute for Psychology for the Hungarian Academy of Sciences have been investigating the validity of teacher ratings and a battery of psychological tests in predicting later gifted behavior. The 1033 subjects were first studied at 9 years of age. Notably, this study includes two cohorts (Gefferth, cited in Schneider & Edelstein, 1990).

The German National Scholarship Foundation initiated an elegant multi-stage identification project in 1970 designed to provide financial and academic support to Germany's top potential scholars. The initial pool included all 13th-year students in German schools offering the *Arbitur* certificate. Awards were based on a series of standardized tests, interviews, and recommendations. A follow up conducted after 5 years explored the contributions of the various components of the identification procedure to academic achievement, satisfaction with area of study, and self-esteem (Laagland, 1978; Trost, 1986).

Remaining areas to be investigated include comparisons of test validity for individuals of different ages, cultures, and nations. Given the current practice of identifying highly able children on the basis of a multidimensional definition of giftedness, longitudinal research needs to account for the weight that each dimension contributes to achievement outcomes.

Gifted Program Outcomes

Of paramount interest to educators of the gifted is the effect of special programs and educational interventions on long-term outcomes. The very concept of differentiated education of the gifted is controversial, as is the scope and nature of gifted and talented programs. National and local educational policies, funding levels, and program designs all rely on the belief that gifted students require special opportunities to fulfil their potential. Only longitudinal research designs can establish an empirical link between interventions and outcomes. Extracting the influences of any specific characteristic or life experience on adult accomplishment is a daunting methodological task, however, and few studies of adults begin in the childhood years when most gifted programs occur.

Fortunately, some longitudinal studies of gifted program outcomes have been conducted. Moon and Feldhusen (1993) followed 23 students 6 years after their participation in an elementary school gifted program (PACE). Subjects had spent at least 3 years in a pull-out program based on the Purdue Three-Stage Model (Feldhusen & Kolloff, 1979). The elementary school gifted program appeared to have developed students'

Emerging Themes in Longitudinal Research: A Brief Synthesis

The longitudinal literature on giftedness is a lively and diverse area of research. Studies of talent development, test validity, and program effects have been carried out in varied contexts. The studies described in this chapter, viewed comprehensively, present some unifying themes that are ripe for further exploration. Gender seems to be a universally important variable in patterns of development and change. Across studies, females show lower self-confidence and aspirations, even when matched with males of equivalent talent or test scores. Further, tests tend to predict males' achievement fairly accurately but to underpredict female accomplishments. Inclusion of samples with low socioeconomic status and other underrepresented groups in gifted programs are expected to convey the same pattern of outcomes.

What are some of the variables found to provide the structure and support for talent development and achievement? Early in life, a gifted child benefits from family values that focus on achievement motivation. Later, mentors are essential for providing intellectual stimulation, emotional support, and entry into the professional world.

Personality variables play a central role in defining the extent to which a gift will be developed. Individuals who make opportunities for themselves to be involved intensively with passionate interests, and who aspire to mastery in those areas, hold the keys to future renown or perhaps even eminence.

What the field of gifted education considers to be success is, in fact, a central question driving the direction taken by longitudinal study. Is high level professional competence in areas of national need a reasonable outcome? Is self-actualization an appropriate criterion variable? Or should the focus be on finding and developing world class talent to enrich and extend fields important to global quality of life?

Methods of identification are inextricably tied to our chosen outcomes. Psychometric instruments are used in virtually all screening processes for reasons of efficiency and effectiveness. The studies described in this chapter generally support the continued use of testing with the proviso that instrumentation be appropriate for program goals or talent domains and not be the sole source of information used for decision making. A move to multi-dimensional screening processes is beneficial, but must correspond to domains schools are able to support. Gifted programs designed to meet the needs of children with heterogeneous talents will necessarily have different and perhaps less spectacular outcomes than those catering to talent development in a specific field. In general, the body of longitudinal research confirms the efficacy of differentiated education for the gifted, pointing to the importance of supporting giftedness and talent at home and at school for the benefit of the individual and society.

cognitive skills and enhanced their self-confidence. By late adolescence, many PACE participants and their parents viewed the program as having been a life-changing educational experience. Another study (Delcourt, 1993) traced students 3 years after their participation in a theoretically-driven, secondary school gifted program based on the Renzulli Triad conception of giftedness (Renzulli, 1986). Unlike the structured intellectual activities of the PACE program, however, the Triad students worked independently on creative projects. Delcourt found that adolescent interest and experience in producing high quality products related closely to young adult career goals, activities, and accomplishments (Delcourt, 1993).

Spiegel (cited in Schneider & Edelstein, 1990) studied the cognitive and social development effects of day care on gifted and non-gifted Austrian children between ages 2 and 6. In Britain, researchers investigated the effects of a science curriculum that sought to accelerate the onset of formal operational thinking in 12-14-year-olds (Adey, 1988). A longitudinal study assessed developmental differences in creativity and cognitive measures among Russian children at ages 6-7 and 16-17. Subjects had taken part in a special learning process stressing creativity (Shoumakova, cited in Schneider & Edelstein, 1990). Rudnitski (1993) followed the careers of men and women who participated in a special graduate school program based on Tannenbaum's theory of giftedness (1986). A decade after their participation in the Graduate Education Leadership Project (GLEP), most of the 38 subjects had attained leadership positions in gifted education. The study indicates that an adult program with multi-dimensional identification procedures, special opportunities, and mentoring experiences positively affects the professional outcomes of gifted men and women.

Other longitudinal studies of gifted programs include Fleming and Hollinger's (1993) 10-year study of a late 1970s career program for gifted high school girls. Generalizability of the Project Choice study is restricted by cohort effects, in which historical gender roles interacted strongly with subjects' aspirations and career outcomes. The research is strengthened, however, by the robust sample size, a control group, and the inclusion of diverse school settings and subjects. The Project Choice design permitted the documentation of interactions between program participation, high school setting, and socioeconomic status, and their effects on the career paths of gifted women.

Although these research projects on the outcomes of gifted programs were rigorously conducted and reported, they, like the small-sample, single-cohort studies described above, cannot definitively establish the results of interventions (Trost, 1990). Much larger samples and carefully constructed control groups will be necessary to move beyond the tentative finding that early identification and participation in theoretically-based gifted programs relates to subsequent performance in various talent areas.

Practical and Methodological Advantages and Difficulties of Longitudinal Research

As previously stated, a large body of critical questions in the field of gifted education are best answered by some form of longitudinal inquiry. Demonstrating the effects of a particular program or identification method on achievement is critical, given increasing fiscal accountability and pressing international needs for creative productivity in various fields. In order to rationalize the use of potentially expensive, controversial and politically sensitive selection practices, educators of the gifted must be able to show that admission and service policies are reasonably effective and efficient. Monitoring the progress of individuals with exceptional potential can also highlight obstacles to the fulfillment of promise. This knowledge can then serve as the basis of future educational policy.

In addition to its unique ability to answer questions about gifted development and outcomes, longitudinal research provides special rewards to researchers. Terman experienced ongoing relationships with a number of his study participants. Anyone who employs in-depth interviews as a component of longitudinal study will inevitably establish ties with individual members of their cohort. Watching gangly, self-conscious adolescents evolve into serious graduate students or clever entrepreneurs is an intensely interesting experience. Gifted subjects tend to be particularly intriguing because they have insights into the investigated topics and often make original contributions to the study's theoretical or methodological framework. In the case of the Westinghouse longitudinal research conducted by Subotnik since 1984, one of her study subjects became so fascinated by the project that she offered to assist in the data collection and analysis of the next stage. Her contributions were so valuable that she became co-author of the report (Subotnik & Steiner, 1993).

In the course of tracking and reporting on 1981 Illinois high school valedictorians, Arnold (1993b) has described the various twists and turns that are innate to long-term life histories. She employs the example of academically brilliant "Ellen", who had appeared headed, at two collection points, for a life of female stereotyped domesticity. In between, and currently, Ellen has taken more dramatic plunges into academic pursuits. She is presently a doctoral student in science education. If at any one of the earlier points cross-sectional instead of longitudinal methodology had been used, the picture of Ellen and many of her peers would have been distorted. Longitudinal study allows for a more comprehensive representation of talented adults encountering the vicissitudes of social, physical, and emotional events and changes. Longitudinal studies remind readers that the fulfillment of potential can occur in many different patterns and times over the course of the life span.

Finally, those readers who have struggled with intransigent bureaucracies for access to a sample of children

or adults can appreciate how searching for lost subjects in a longitudinal study can be a small price to pay for continued access to an interesting and endlessly informative subject pool.

The major drawbacks of conducting longitudinal research are the formidable commitment and resources required for comprehensive study designs. Academicians seeking quick publications and grantors desiring prompt results find the time span of repeated measures research problematic. Although the need for studies with multiple cohorts, control groups, and large representative samples is pressing, the financial requirements for such designs can be prohibitive. Costs are high for repeated survey administration, data analysis, postage, interviews, transcriptions, phone expenses, and travel. Major longitudinal studies can require the organization of research institutes with continuing professional and support staffs, budgets, and facilities. Only government agencies and large foundations can contemplate long-term funding of these studies, a commitment made more tenuous by their changing priorities and by cycles of public opinion and policy regarding gifted education.

The logistical difficulties and enormous researcher commitment are as challenging as the financial demands. Keeping track of subjects over the duration of a study is a time-consuming and frustrating task. Reaching geographically mobile subjects, particularly for interviews, is also challenging, as is the task of reducing and interpreting huge amounts of data. In short, the more adequate the design—with multiple cohorts and large samples—the greater the financial, logistical, and researcher demands.

Longitudinal methodology is vulnerable to various threats to validity (Schaie, 1983). Repeated measures can result in bias through practice effects as subjects become familiar with test items or interview questions. Further, long-term participation might contaminate results by affecting the behavior, self-image, or reflectiveness of subjects.

Subject attrition plagues every longitudinal study and threatens the validity of findings. Researchers lose subjects who die, become unreachable after moves, or refuse to continue their participation. The problem is particularly acute with a cohort that exhibits exceptional talent in a specific domain such as sculptors, scientists, or dancers. Such samples tend to be smaller than those composed of younger students studied under the rubric of more generic intellectual, academic, or creative giftedness. The loss of subjects from unique small-sample cohorts can result in dangerously small follow-up sample sizes.

Regardless of sample size, attrition (or subject mortality) is not random (Arzi, 1989). In addition to possible differences between geographically stable and mobile individuals, subjects may leave studies when they are unhappy, not achieving highly, or deviating from what they perceive the study to value. Understanding how nonrespondents might differ systematically from remaining subjects is extremely difficult. Finding a small

group of “leavers” and comparing them to respondents is probably the best way to deal with this problem. Researchers can also analyze the cases of subjects who leave and subsequently rejoin longitudinal studies. In any case, researchers must acknowledge that attrition is non-random and speculate on possible systematic differences between subjects who are lost and those who are retained.

Single-cohort studies suffer additional threats to validity. A cohort, or group of same-age individuals, experiences the same social context within a given time period. These historical, or cohort, effects can confound developmental findings. Changing roles of Western women, for instance, make it difficult to generalize from the experience of the Terman study women or from the Project Choice participants to gifted women in general. Similar to contaminating cohort effects are time-of-measurement effects in which subjects experience specific historical events that interact indelibly with their development. The American Depression, recent political changes in Eastern Europe, and Southeast Asian immigration to the West are examples of specific phenomena that might deeply influence certain cohorts. Finally, single-cohort studies, especially those lacking control groups, cannot disentangle maturation effects or the influence of an educational experience from other life events.

Are these weaknesses sufficient to argue against the use of longitudinal designs? The practical difficulties in mounting a multi-cohort study are well worth overcoming for the ability to illuminate significant steps in the process of change and to establish the consequences of educational interventions. Even single-cohort studies remain valuable as investigations of previously unstudied groups and exceptional individuals with rare talents. Although care is needed in generalizing from single-cohort studies, intensive small-sample research can provide critical insights into the uniqueness of gifted individuals and generate hypotheses for future large-scale studies. Finally, meta-analyses of single-cohort longitudinal studies can build a convergent picture of the development of giftedness.

Needs for Future Research

The greatest proportion of current longitudinal study in gifted education deals with populations of adults or youths. Starting with an adult or late adolescent cohort allows the researcher to circumvent cognitive developmental issues that obscure variables of more interest to the investigator. Also, many who conduct longitudinal research are interested in a specific talent area, and a wider arena for the display of talents exists by the teenage years as compared to earlier years. Further, older adolescents and adults are able, upon questioning, to reflect on their talents and articulate their feelings and thoughts more easily than young children. Finally, outstanding productivity in adulthood is the outcome

of real interest for many longitudinal researchers, and the wait is shorter from adolescence than from early childhood. These are sensible reasons for studying adults and adolescent subjects, and certainly provide rationales that have been taken to heart by most researchers employing longitudinal methods in gifted education.

In terms of service to the field and educational practice, research on adolescents ignores the preponderance of gifted programs at the primary and elementary school levels. Secondary schools are apparently seen as better meeting the needs of academically talented students through homogeneous grouping or tracking. Musically talented students may often participate in instrumental and vocal ensembles. The athletically talented have access to individual and team sports. If secondary school students are exceptionally fortunate, they can work with mentors during their final pre-university years. At the early elementary level, in contrast, educators' energies tend to be focused on protecting children from the primary school curriculum with its emphasis on the acquisition of basic cognitive skills like categorizing and recognizing relationships, skills the intellectually gifted child has, by definition, already mastered.

Many important questions about childhood giftedness have not yet been adequately addressed. How is the development of children identified purely on the basis of potential—who show no demonstrable talent except for school or test-based skills—different from the development of peers? What is the long-range effect of different types of programs on gifted students' academic, social, and creative growth? Project Spectrum is proposing early recognition of a wide variety of talents in young children (Gardner & Hatch, 1989). How will this educational agenda intersect with the talent development research thus far conducted with adolescents and young adults?

Providing collections of longitudinal research for use by scholars and educators is an important step in the expansion of the knowledge base on giftedness. Several volumes of studies in the social sciences have appeared in the last decade (Migdal et al., 1981; Schaie, 1983; Schneider & Edelman, 1990; Verdonik & Sherrord, 1984; Young et al., 1991). Most of these collections focus on North American studies. The European Science Foundation has recently provided funding for an inventory of European longitudinal studies (Schneider & Edelman, 1990), most of which are unavailable in English-language journals. The European Network on Longitudinal Studies on Individual Development (ENLS) was formed in 1985 to collect reports and to provide a dissemination and communications network for scholars. Each of these inventories of longitudinal research includes some studies on giftedness, and access to international data sets would be particularly important in encouraging cross-cultural and cross-national comparison studies.

Repositories of longitudinal data sets, such as the Murray Foundation in Boston, provide researchers with access to data for secondary analyses; many large-sample

longitudinal studies of general populations are appropriate for reanalysis of gifted and non-gifted subsamples. The National Research Center for Gifted Education, recently established in the United States, has listed the need for longitudinal research as a top national priority in the field (Reid, 1991). Subotnik and Arnold (1993) are the editors of the first collection dedicated to longitudinal studies of the gifted. National Institutes and volumes of collected works that focus attention on longitudinal research, compile longitudinal studies, provide data sets for reanalysis, or sponsor visiting scholars, are badly needed, given the expense of repeated data collection and the importance of study findings.

Based on the accumulated literature, what directions can longitudinal research take to contribute most to the field of gifted education? Two paths invite exploration. One direction is to continue to provide the missing pieces that connect adult fulfillment of talent with demonstrated potential in a specific field. Some excellent studies that address how well performance in general academic, mathematics, science, and leisure time activities serve as predictors of outstanding talent have been briefly described above. In order for these studies to become more rigorous, thereby overcoming the design weaknesses delineated in this chapter, more multiple-cohort studies must be conducted that address the contaminating influences of historical context, time-of-measurement effects, and subject attrition. Replication studies may be conducted with new cohorts. Greater emphasis on cross-cultural and cross-national investigations within each talent area could increase profoundly the generalizability of study outcomes. Secondary analyses and meta-analyses of existing data sets are a fruitful and underutilized source of information. Lastly, longitudinal research needs to rely more consistently on strong theoretical foundations.

The second direction for research, and perhaps the most pressing challenge, is to apply the techniques of longitudinal research to educational practice in the primary and middle elementary schools. The largest amount of financial and creative effort in the field is expended on elementary school programs. Investigations of the interactive effects of individual talent with other aspects of human development—cognitive, affective, moral, and aesthetic—should be encouraged and promoted.

The field of gifted education needs answers to questions of paramount academic, ethical, and political importance: Are we identifying and serving the right people? Are we providing appropriate services to the people we identify? What factors in talent development are controllable through education? Progress in answering these questions will rely heavily on more widespread use of longitudinal research methods.

Prodigies and Savants: What They Have to Tell Us About Giftedness and Human Cognition

MARTHA J. MORELOCK AND DAVID HENRY FELDMAN

Tufts University, Medford, Massachusetts, U.S.A.

Introduction

Giftedness is perhaps most intriguing when it is found where it is least expected. This may account for the fascination which child prodigies and idiot savants have long held for human beings. The child prodigy displays astounding adult-like mastery of a demanding domain of endeavor; while the idiot savant manifests islands of extreme capability showcased against a backdrop of overall severely deficient intellect.

Historically, research into prodigy and savant capabilities has been conducted within two separate disciplinary frameworks. Studies of savant talent are rooted in the literature on mental retardation; while those of prodigies are found in the literature on giftedness. Recently, however, developmentalists from both disciplines have suggested that the domain-specificity characteristic of both prodigy and savant talent means that our concepts of intelligence, giftedness, and handicap need to be revised (Feldman, 1980, 1982, 1986; Gardner, 1983; O'Connor, 1989). Research within the last 20 years suggests that the prodigy and the idiot savant phenomena—as different as they may seem to be on the surface—share certain commonalities which are revealing for our understanding of human cognition in general. Equally revealing may be the stark differences which they manifest.

This chapter begins by providing a general overview of the individual histories of research on the prodigy and the savant. Moving to a more narrow focus, it will then combine discussion of the two phenomena by comparing examples of prodigious performance with ones of savant performance in two of the domains where both have been found: music and art. It will conclude with a speculative discussion of possible brain-based commonalities and differences serving as substrates for prodigy and savant capabilities.

The Prodigy

A prodigy is a child who, before the age of 10, performs at the level of an adult professional in some cognitively

demanding field (Feldman, 1986). This precise definition of prodigiousness has only been in existence since 1979 (Feldman, 1979)—in spite of the fact that “prodigy” was used loosely to refer to extraordinary youngsters for many years prior to that. Historically, the term was part of a prophetic tradition signaling impending change (Feldman, 1986). It referred to an entire range of unnatural phenomena extending from the advent of notable uncanny or extraordinary happenings to the existence of humans or animals regarded as “freak”.

Over time, the term began to be used more narrowly to refer to extreme human precocity (Morelock & Feldman, 1991). The “sign” or “portent” aspect of its meaning was dropped, while the essential connotation of “unnatural” or “inexplicable” remained. The term continued, however, to be used indefinitely to refer to a broad range of manifestations of precocity (Barlow, 1952).

With the advent of IQ and its widespread acceptance as the gauge of giftedness, the phenomenon of the prodigy became subsumed under the IQ umbrella (Feldman, 1979). Children who could compose sonatas at the age of 6 were implicitly assumed to be high IQ children with penchants for given fields. Nevertheless, there appeared in the European literature two systematic research studies of child prodigies failing to support the equivalence of prodigious achievement with extraordinarily high IQ (Baumgarten, 1930; Revesz, 1925). In 1980, a third study of prodigious achievement appeared (Feldman, 1980). Published in the American literature, it too brought into question the relationship of IQ (i.e., generalized abstract verbal-conceptual capability) to prodigious achievement in various fields. To date, these three remain the only scientific studies of child prodigies in the world literature.¹ They are discussed below.

A Case Study of A Music Prodigy

Revesz (1925) conducted the first case study of a music prodigy to appear in the world literature: an in-depth study of 7-year-old Hungarian music prodigy Erwin Nyiregyhazi. It utilized a combination of interviews;

observations of Erwin in and out of performing situations; anecdotes from family, teachers, and acquaintances; and formal assessments using the available techniques of the day (e.g., the 1908 Binet–Simon Scale). It continues to be unique in that it is the only study to analyze in detail the musical cognition as well as musicianship skills of a prodigy. For example, Revesz assessed Erwin’s basic acoustic faculties and musical memory, his transposing and sight reading skills, his interpretive skills as a pianist, and the technical quality of his musical compositions. According to Revesz, Erwin’s musical abilities compared favorably with those of other legendary prodigies and great musicians of the day.

Erwin’s talent showed itself from a very early age. By the age of 2, he was correctly reproducing tunes sung to him, and before he turned 4, he had demonstrated perfect pitch by reproducing on the mouth organ any melody sung to him. When he was 4, he began to play the piano and compose melodies. He began taking formal music lessons in his fifth year; and from age 6 to 12, Erwin became a celebrated performer—playing before the British royal family as well as other audiences in Budapest and Vienna.

Revesz used the Binet–Simon scale to assess Erwin’s general intellectual ability. Test results showed that Erwin’s mental age exceeded his chronological age of 7 by 3 years. Thus, by modern reckoning, his IQ measured slightly above 140. Revesz asserted that the test failed to adequately reflect the true extent of Erwin’s brilliance, noting that the child “analyzed his own inner life in the manner of a trained psychologist” and “expressed himself with great caution and in remarkably pregnant phraseology” (Revesz, 1925, p. 42).

Revesz noted that in spite of Erwin’s remarkable musical talents and exhibited brilliance, the prodigy was, in every respect other than his music, a child: “Erwin was a child in the full sense of the word; a clever, gay, friendly, charming boy. . . . He played as children play, was fond of boyish exploits, and enjoyed them very much” (Revesz, 1925, pp. 57–58). This mingling of child and adult in the prodigy proved to be a consistent theme throughout later studies of prodigiousness as well (Baumgarten, 1930; Feldman, 1980, 1986).

Nine Prodigies: Patterns of Ability and Personality

Baumgarten (1930) studied nine child prodigies: two pianists, two violinists, one orchestra conductor, one artist, one geographer, one chess prodigy, and a dancer. She chose to focus specifically on the children as whole personalities rather than emphasizing only their

extraordinary achievements. She also examined their individual patterns of varying abilities. Like Revesz, she wrote of the intriguing mixture of adult and child qualities and the frequent childlike naiveté demonstrated by her subjects. She found that the prodigies appeared ambitious, pragmatic, wary of those who might harm their careers, passionately devoted to their fields, unafraid of public performance, and desirous of using their gifts for the good of their families.

On a battery of standardized intelligence tests, the children’s scores ranged from 120 IQ to at least 160 IQ, when translated into contemporary terms. Their performance was impressive, to be sure, but certainly not as unusual as one would have expected from the degree of extraordinariness of their special talents. Baumgarten’s conclusion was that her subjects’ overall intellectual competence, as reflected in their test results, failed to explain their outstanding performance in particular fields.

In analyzing intra-subject patterns of varying abilities, Baumgarten found some surprising results. For example, violinists and pianists demonstrated poor hand coordination in bending wire, drawing, and folding and cutting—although one girl violinist showed a talent for drawing. At the same time, a 6-year-old boy who showed difficulty in making a circle out of two or three sections or a pentagon from two sections, was nevertheless extraordinarily good at map drawing.

Baumgarten concluded that more than the testing of intellectual abilities was needed to explain prodigious achievement. She suggested that factors of inheritance, temperament, family, education, environment, and culture should also be examined.

The Prodigy from a Cognitive-Developmental Perspective

The third systematic study of child prodigies to be found in the literature (Feldman, 1980, 1986) was inspired by Piagetian cognitive-developmental theory. The study began as a straightforward psychological experiment designed to refute the Piagetian assertion that, universally, children’s cognitive development proceeds in major predictable sequential stages grossly encompassing all of a child’s thinking capacities at any given point in time. It follows from this assertion, that in order to account for a prodigy’s adult-level performance in a specific field, one must assume that the child’s overall cognitive development is generally advanced beyond his or her years. However, four cognitive-developmental measures administered to two 8-year-old chess prodigies

¹Although the literature contains only three systematic scientific studies of child prodigies, a number of biographical or psychohistorical accounts of the lives of prodigies have been published. See, for example, Kathleen Montour’s “William James Sidis: The broken twig” (Montour, 1977), Norbert Wiener’s 1953

autobiography, *Ex-Prodigy: My Childhood and Youth* (Wiener, 1953); Amy Wallace’s 1986 book (also about William James Sidis) *The Prodigy* (Wallace, 1986); and Fred Waitzkin’s 1984 book, *Searching for Bobby Fischer: The World of Chess, Observed by the Father of a Child Prodigy* (Waitzkin, 1984).

and a 10-year-old musician–composer showed all three children performing age-appropriately in logic, role-taking, spatial reasoning, and moral judgment—thus challenging the traditional Piagetian conceptualization (Bensusan, 1976).¹ These findings, like those of Revesz and Baumgarten, suggested that giftedness is *domain-specific*, rather than solely the expression of a generalized and pervasive intellectual endowment.

With the addition of three more prodigies—a young mathematician, a writer, and an “omnibus prodigy” showing prodigious achievement in a number of areas, but who eventually began to focus on music composition and performance²—the study evolved into an open-ended effort to observe, understand, and explain the prodigy phenomenon. Extending beyond a decade, association with the six prodigies and their families resulted in a theoretical framework, the co-incidence theory, which seeks to explain not only prodigious development, but also all human achievement. Below is a brief overview of the theory.

Co-incidence

Co-incidence, briefly defined, is “the melding of the many sets of forces that interact in the development and expression of human potential” (Feldman, 1986, p. 11). Within the co-incidence framework, the developmental process itself—rather than the individual person—is placed at the center of the theoretical structure. The ultimate goal of the theory is to explain how the process works across the full range of situations in human development. The forces of co-incidence, briefly presented, consist of the following (Feldman, 1991).

BIOLOGICAL QUALITIES

Biological qualities include both genetic and nongenetic features forming a foundational substrate for the development of differential talents or general intellectual capacity.

INDIVIDUAL PSYCHOLOGICAL QUALITIES

These might include executive and planning functions such as those featured in the work of Robert Sternberg (1988), or multiple intelligences, such as those proposed

by Howard Gardner (1983); as well as personal and emotional qualities such as unusual sensitivities (Piechowski, 1991) serving to heighten an individual’s response to selective sensory or intellectual experiences.

PROXIMAL CONTEXT

The proximal context includes the immediate surround of the developing child, including such factors as hygiene, nutrition, caretaker practice, and educational interventions.

INTERMEDIATE CONTEXT

This includes family structure (e.g., number of children, birth order, and family traditions which might serve to orient a child toward a particular domain—a family history of interest in mathematics or music, for example). Also included in the intermediate context would be other immediately relevant institutions such as established health care resources.

DOMAIN AND THE SURROUNDING FIELD

This dimension—a central feature of the co-incidence theory—focuses on the development of domains of knowledge (e.g., art or music) and associated shifts in culturally afforded opportunities for vocational or avocational activities connected with those domains (e.g., artist, art historian, musician, composer, music store proprietor). Considerations include the constraints and demands of association with a particular field, its current and emerging forms, techniques and technologies for expression and exploration of those forms, how the field is organized and talent recognized, recruited, and developed, and where supportive resources are obtained. Additionally of interest are those institutions determining the social standing of various fields and allowing or preventing expression of talent within domains.

DISTINCT CONTEXT

The distant context includes social and historical factors encouraging, prohibiting, or shaping the expression of individual potential. Of interest, for example, would

¹The four measures given were: (1) Inhelder and Piaget’s (Inhelder & Piaget, 1958) five chemicals task, a test of level of acquisition of various concrete and formal logical operations; (2) a role-taking task devised by John Flavell (Flavell, 1968) and his associates at the University of Minnesota, the aim of which is to test social-cognitive development by assessing the level of ability to take another’s point of view; (3) a map-drawing exercise, an adaptation of Piaget and Inhelder’s (Piaget & Inhelder, 1948) layout diagram task (Snyder, Feldman, & La Rossa, 1976), which gives a general estimate of the level of the coordination of spatial-logical

reasoning; and (4) a psychometric measure of level of moral judgment and reasoning prepared by James Rest (Rest, 1974) based on Kohlberg’s stages of moral development.

²At the age of 3 1/2, when Adam, the omnibus prodigy, first entered the study, he was reported to read, write, speak several languages, study mathematics, and compose for the guitar. He was, as well, a child of extraordinarily high IQ, with an IQ measuring beyond the assessment capabilities of current instrumentation. He was consequently designated an “Extraordinarily High IQ/Omnibus Prodigy” (Morelock & Feldman, 1991).

be political movements, religious institutions, war, or economic growth and decline (Simonton, 1984).

Co-incidence and the Child Prodigy

Co-incidence may be thought of as a type of equation into which may be “plugged” more or less the varieties of forces listed above. The synergistic result will be a specific form of expression of human potential—the child prodigy, for example. Of course, the developmental reality is that none of the component forces remain static. All of them, including the developing child, are in a constant state of flux. Orchestrating the interaction of these multiple fluid forces so that there is continuous positive movement toward the fruition of human potential is the challenge presented by the theory of co-incidence.

The child prodigy phenomenon is the result of a fortuitous concordance of the forces of co-incidence leading to the maximization of human potential. Essentially, in most of the cases of prodigiousness contained in the literature, a child of extraordinary native ability is born into a family recognizing, valuing, and fostering that ability when the child’s introduction to the culturally available domain reveals its presence. The child is generally exposed to master teachers who instruct the prodigy in a way most likely to engage the interest and sustain the commitment of the child. Invariably, as well, the child demonstrates a combination of inner-directedness and passionate commitment to the field of achievement.

Prodigious achievement only occurs in domains accessible to children. As a general rule, domains which spawn child prodigies require little prerequisite knowledge and can be both meaningful and attractive to children. In addition, the domain’s media and techniques are adaptable to children (e.g., a child-sized violin must be available for a 6-year-old prodigy violinist). The largest proportion of child prodigies to date have been in chess and music performance. There have been, however, occasional writing prodigies (Feldman, 1986; Radford, 1990), child prodigy visual artists (Goldsmith & Feldman, 1989; Pariser, 1987) and, infrequently, a child prodigy in mathematics (Bühler, 1981).

As was mentioned previously, the idiot savant has its own research history. Following, some highlights of that literature are considered.

The Idiot Savant

There is a much larger base of research on the savant than on the prodigy. This is not surprising, inasmuch as the severe general impairments characteristic of savant functioning have historically resulted in savants being institutionalized, treated, and made the targets of medical intervention.

The term “idiot savant” was originally coined by Dr J. Langdon Down of London (Down, 1887) to refer

to severely mentally handicapped persons displaying advanced levels of learning in narrowly circumscribed areas. In Down’s time, *idiot* referred to individuals operating at the lowest level of retarded functioning based on an evaluation of speech and language capabilities (Scheerenberger, 1983).

With the development of IQ tests, idiocy became translated as encompassing the lowest portion of the IQ scale—extending over an IQ range of 0 to 20 (Craft, 1979). In reality, however, the IQs of all known tested idiot savants have been above 20—and usually fall in the range of 40 to 70 (Treffert, 1989). Somewhat more appropriate, but still a misnomer, is the second part of the term, “savant”—a straightforward adaptation from the French word meaning “to know” or “man of learning”.

Because of the failure of “idiot savant” to capture the essence of the savant phenomena and because of the pejorative connotations of the first part of the term, a number of alternatives have been suggested (Charness, Clifton, & MacDonald, 1988; Rimland & Hill, 1984; Treffert, 1989). Most recently, Treffert (1989), based on a thorough review of the research literature appearing over the last century, proposed a more precise classification terminology and suggested a theoretical explanatory framework. He also proposed an alternative term for the condition: *savant syndrome*—or, if one wishes simplify, just *savant*.

Savant Syndrome Defined

Savant syndrome is defined by Treffert as follows:

Savant syndrome is an exceedingly rare condition in which persons with serious mental handicaps, either from developmental disability (mental retardation) or major mental illness (early infantile autism or schizophrenia), have spectacular islands of ability or brilliance which stand in stark, markedly incongruous contrast to the handicap. In some, savant skills are remarkable simply in contrast to the handicap (talented savants or savant I). In others, with a much rarer form of the condition, the ability or brilliance is not only spectacular in contrast to the handicap, but would be spectacular even if viewed in a normal person (prodigious savants or savant II) (Treffert, 1989).

Treffert notes that savant syndrome can be either congenital or acquired by a normal person after injury or disease of the central nervous system. The skills can appear—and disappear—inexplicably and without warning (Selfe, 1977; Treffert, 1989).

Like prodigies, savants occur only within a limited number of areas. Documented savant skills include: calendar calculating (e.g., the ability to quickly calculate the answers to such questions as “On what day of the week will April 29 of the year 2245 A.D. fall?”); music (chiefly limited to the piano); lightning calculating (the

ability to do extraordinarily rapid mathematical calculations); art (painting, drawing, or sculpting); mechanical ability; prodigious memory (mnemonism); or, on rare occasion, unusual sensory discrimination (smell or touch) or extrasensory perception. Treffert (1989) notes that prodigious savants have occurred chiefly within the areas of music, mathematics (lightening and calendar calculating), and memory.

Incidence of Savants

The literature reveals two major populations from which savants emerge: (1) those who can be diagnosed as autistic,¹ and (2) those who are diagnosed as mentally handicapped, but not autistic. Rimland (1978) estimates the percentage of idiot savants in the autistic population as 9.8%; while the prevalence of savants in the mentally handicapped population has been estimated to be significantly less—0.06% (Hill, 1977). O'Connor (1989) notes, however, that as the incidence of autism itself is only 0.04% of births, autistic individuals are far less numerous in the general population than are mentally handicapped people. Consequently, in absolute terms, idiot savants appear to emerge from each source in approximately equal numbers. Savant skills occur six times as often in males as in females (Hill, 1977).

According to Treffert (1989), who is the first researcher to differentiate between *talented* and *prodigious* savants, there have been only about 100 known prodigious savants in the world literature—12 to 15 of whom are still alive.

Features of Savant Functioning

Research reveals a number of features common to the functioning of all savants.

CAPACITY FOR ABSTRACTION

Scheerer, Rothmann, and Goldstein (1945) first documented the "impairment of abstract attitude" typical of savant functioning. By this, they meant that savants are

characteristically unable to transcend immediate sense impressions, consider a situation from a conceptual point of view, and react accordingly. The researchers noted that, generally, savants display minimal abstract reasoning ability combined with almost exclusive reliance on concrete patterns of expression and thought. A savant on whom they conducted a case study, for example, memorized and sang operas in several languages, yet had no comprehension of the abstract conceptual and symbolic meaning of words.

More recent research suggests that the question of abstract reasoning in savants is more complex than originally thought. Studies show that savants have an immediate—seemingly intuitive—access to the underlying structural rules and regularities of their particular domain, be it music (Miller, 1989; Treffert, 1989), mathematical calculation (Hermelin & O'Connor, 1986a; O'Connor & Hermelin, 1984), or art (O'Connor & Hermelin, 1987a). It also seems that the rules intuitively "known" by savants are the same as those applied by practitioners of normal or high reasoning ability who are skilled in the same area. It appears, therefore, that although most savants lack the ability to use verbal abstractions to conceptualize about either their internal thought processes or the particulars of daily life, all can abstract to a degree—at least in circumscribed and domain-specific areas (O'Connor, 1989).

This form of circumscribed, domain-specific abstract functioning is intriguing and worthy of further study. It should be noted that it appears to be qualitatively different from the more pervasive and rational abstract reasoning originally discussed by Scheerer, Rothmann, and Goldstein. More research designed to tease out similarities and differences would be helpful.

METACOGNITION

Scheerer et al. (1945) also noted the general incapacity of savants for reflecting upon their internal thinking processes—what today would be called "metacognition". When asked to account for how they can do whatever it is that they do, savants frequently respond with something strictly irrelevant. One calendar calculator, when asked how he managed his remarkably fast responses to

¹We may yet discover that although there are strong resemblances in the way domain-specific abilities in autistic and non-autistic savants are expressed, the underlying patterns of brain functioning as well as the phenomenological realities of the two types of savants are different. For more specifics about autistic savants, the reader is referred to Rimland, 1978 and 1988. For research findings about "normally intelligent" or "high functioning" autistic children—many of whom, like the savant, show particular islands of unusual ability—see Schopler & Mesibov, 1992.

Advocates of "facilitated communication," a recent and still highly controversial innovation in the field, claim that through its use, some individuals previously presumed to be among the lowest intellectually functioning persons labeled

autistic were able to carry on high-level conversations, discuss abstract thoughts and feelings, and even tell jokes. To date, there are no documented cases of its use with autistic savants, although the idea is certainly an intriguing one. For more on facilitated communication, see Biklen (1990).

Several books have appeared in recent years recounting the emergence of children from autism (Barron & Barron, 1992; Grandin & Scariano, 1986; Stehli, 1991). The biographical accounts include fascinating glimpses into the children's inner experiences while imprisoned in their autistic worlds. Unfortunately, as of this time, we know of no incidences where an autistic savant has similarly recovered.

date questions, said "I make all sorts of mathematical calculations, don't I?" In fact, he was usually unable to add or subtract without pencil and paper (O'Connor, 1989).

SAVANT MEMORY

All savants are notable for their extraordinary memories (Treffert, 1989). Indeed, the mnemonist savant's sole talent consists of his or her impressive memory for miscellaneous or mundane happenings (e.g., some savants have been known to remember the weather conditions for each day of most of their lives). In other savants, it is the norm for extraordinary memory to be narrowly limited to their domains of achievement.

AFFECT

A frequently noted aspect of the savant is a restricted range of emotion generally appearing as flattened affect (Treffert, 1989). The performance of musical savants, for example, frequently manifests this deficit by coming across as shallow, imitative expressiveness lacking subtlety or innuendo.

A review of the literature reveals that music is seemingly the only domain where there is some controversy about the "flattened affect" observation (Howe, 1989; Miller, 1989; Treffert, 1989). There have been cases of musical savants demonstrating emotional connection with the music they were performing (Miller, 1989; Viscott, 1970). In one such case (Viscott, 1970), the savant possessed more expanded verbal abilities than is commonly the case in manifestations of savant talent. This seems to have allowed for a conceptually interpretive response to the music.

An additional consideration in the case of musical savants is the fact that emotional response to music may be, to some extent, the direct result of the physiological changes which it evokes (Winner, 1982). Music not only affects pulse, respiration, blood pressure, and the electrical resistance of the skin, but also delays the onset of fatigue (Mursell, 1937). These same types of changes occur during emotional experience. The question is raised whether the emotional response seen in musical savants may, therefore, be more a straightforward reflection of specific physiological effect than is the case with musicians more conceptually and interpretively involved with the music.

CREATIVITY

Research suggests that savants are incapable of being creative in the sense of producing totally original work. Treffert (1989) concludes, for example, that while a musical savant might imitate, improvise, or embellish based on pre-established constraining musical rules, he or she is generally incapable of composing.

There is indication, however, that musical savants with more highly developed language capacities may

be more likely to be able to compose music. Miller (1989) noted that when he began to study one adult musical savant, L.L., the savant's communicative language skills were minimal—limited to monosyllabic or echolalic responses to conversational attempts. L.L.'s music attempts during this period were skillful and expressive, but remained confined to renditions of songs and melodies of others, with very little inclination to improvise or compose. During the last several months of Miller's observations of L.L., the savant's language changed dramatically. He began to make requests, comments, and to respond in a much more sophisticated fashion to questions. Intriguingly, at the last session in which Miller saw L.L., the savant announced and played an original composition. This curious concordance of the development of expanded language skills and the onset of musical creativity has led Miller to speculate that music and language are not mutually exclusive.

The above sections provided a general overview of what is known about prodigies and savants. The following ones examine more closely some of what is known about their comparative functioning in two of the domains in which both have been found: Music and art.

Music

Music is the domain in which the largest number of both prodigies and savants are found. It is also the only domain in which there has actually been some detailed, though limited, systematic research regarding commonalities and differences between the performance of a prodigy and that of a savant (Miller, 1989). It is, therefore, worthwhile to consider the following.

A Case Study of A Musical Savant

Miller (1989) conducted a detailed case study of Eddie, a musical savant pianist, who was 5 years old at the time of first contact. In obtaining information about Eddie's development from the child's mother, Miller was unable to find out precisely when Eddie became interested in music. During one interview, the mother reported this as being before his first birthday, while at another time, she said it was at about 2 years of age. The occasion was marked by Eddie's having received a toy piano which quickly became his favorite toy. Eddie was also exposed to a musical instrument at church, where he was given the chance to pick out melodies on the piano in the room where his mother attended services. Thus, Eddie's exposure to music was casual and untutored. At the time Miller first saw the 5-year-old savant, the child had received no formal music lessons and there was no piano in the home. In addition, there was no history of a special musical talent in the family, and none of the other members of the family played an instrument.

Miller's study was a longitudinal one spanning a 4-year period during which Eddie, at the age of 6, began

taking formal music lessons. This allowed Miller, who was instrumental in securing Eddie's music teacher, to observe the savant's progress during the period of the formal lessons as well as to devise a number of research tasks geared toward testing Eddie's natural acoustical and musical skills.

The researcher gained a more complete picture of Eddie's musical abilities by exploring the literature on other historically documented musical savants and by selecting three groups of diverse musically talented living subjects with whom to compare Eddie's abilities. In addition—and of particular use to us here—Miller made a final studied comparison between Eddie's musical skills and those of the musical prodigy Erwin Nyiregyhazi, as had been documented by Revesz (1925). Below, we present a synopsis of Miller's impressions and research findings.

Researcher Meets Savant: First Impressions

Miller describes his first encounter with Eddie as unexpected and dramatic. All of the children at the day program for the multiply handicapped which Eddie was attending were legally blind, none had more than rudimentary language, and most were physically handicapped. Massive delays in social, emotional, and cognitive development were the norm. The school curriculum centered mainly around teaching basic daily living skills such as self-feeding and dressing. Consequently, Miller notes that he was skeptical when a teacher remarked that one of the new children at the school played the piano surprisingly well.

Upon first seeing Eddie, Miller reports that his skepticism increased. He describes the 5-year-old as "a very fragile child, bony thin and small for his age. His motor delay was apparent in his hesitant, splay-footed walking. He seemed to lack the fine muscle control needed for something as demanding as a piano" (Miller, 1989, pp. 1–2). Eddie's speech was almost exclusively echolalic, or a virtual repetition of what he heard, except for a few conversational clichés such as "How are you?", "I'm fine", and "Good-bye".

Nevertheless, when Eddie's teacher mentioned the word "piano", the child's face was transformed by a smile of excitement and he purposefully turned to the room containing the piano, needing no prompting to exhibit his talent. At the piano, Eddie's hands found the keys easily and he started to play some melodious chords, "his head tilted back, staring through his thick glasses at the ceiling with an intent expression on his face" (Miller, 1989, p. 2).

Eddie's first recital for Miller consisted of a rendition of the Christmas carol, "Silent Night". Miller describes the melody as well articulated, with an appropriate tempo, and a nice rolling broken chord figure in the bass. "Eddie's hands, which had difficulty holding a pencil, were clearly at home on the keyboard" (Miller, 1989, p. 2).

On Miller's second visit, he came prepared to test the range of Eddie's musical sensitivity. Realizing that technical facility across all major and minor keys on the piano is generally achieved only with considerable instruction and practice, Miller questioned how well Eddie could follow a simple melody through a series of transpositions on the keyboard. Was the child's facility limited to a few common keys, or would the particular key of the piece prove irrelevant?

Miller quickly discovered that Eddie responded happily to efforts to enlist his participation in a musical "game" in which Eddie would repeat a simple melody exactly as it had initially been played by the researcher. Miller played the simple melody line of "Twinkle Twinkle Little Star"—a melody familiar to Eddie—without harmonic accompaniment. First played in the key of C, Miller then repeated the melodic line in G, then in A[#], F[#], and back to C. To increase the challenge, each example was presented in a different pitch range from the immediately preceding one, either an octave higher or lower. Eddie's playing reflected the transposition to a new key with no hesitation. The child seemed equally at ease with any key signature, at least when playing simple melodies. The final trial, during which Miller returned to the original key of C, revealed something new, however. Upon hearing "Twinkle Twinkle" again in the key of C, Eddie's response changed. No longer content to play the simple melody, he instead added several left-hand chords. He also transformed the piece to a minor key with several unexpected modulations in the harmonic structure, using minor thirds rather than the major thirds of the original. Eddie was generating a new version of the piece.

Through this little experiment, Miller discovered that Eddie's talent was not limited to a few well-practiced patterns of movement on the keyboard. The boy had an impressive sensitivity to the tonal structure of a melody line, and he could follow that melody wherever it appeared in the pitch range represented by a piano keyboard. In addition, he was capable of improvisation—he could take a melodic line and produce renditions that were consistent with the conventions of musical composition.

Miller points out that such skill dramatically contrasts with musical abilities of average 5-year-olds. Normally, a 5-year-old could be expected to have, at best, a slim grasp of interval relationships in even a simple melody (Bartlett & Dowling, 1980); and their spontaneous songs often wander from one tonal center to another, with little sense of an overall tonal structure (Hargreaves, 1986). Thus, not only did Eddie demonstrate a much better grasp of the structure of music than one would expect from a normal 5-year-old, but his understanding was manifested naturally and concretely in his playing. Miller comments: "The piano seemed an extension of Eddie's body, and his fingers effortlessly explored its range of sounds as soon as he came in contact with its keyboard" (Miller, 1989, p. 3).

Eddie's extraordinary musical ability led Miller to wonder what it was, exactly, that Eddie knew about music. Of what was this incredible musical intelligence—so disparate with the rest of Eddie's abilities—comprised? The results of his case study revealed some answers to these questions. Below we outline some of Miller's major findings. As they are reported, we will discuss their possible implications for our understanding of music prodigies, as well.

Miller's Findings

ABSOLUTE PITCH: DEFINITION AND INCIDENCE

Absolute pitch is generally defined as "the ability to name the note of any tone heard without either seeing it played or the benefit of a reference note" (Miller, 1989, p. 15). *Extended absolute pitch* means that the ability extends over the whole musical scale and is independent of the instrument used. Miller's search into the savant literature alerted him to the presence of *extended absolute pitch* in all well-documented cases of musical savants. A 100% incidence within the population of well-documented idiot savants seems even more extraordinary when one considers that within the general population, the incidence is estimated to be less than one-hundredth of 1% (Bachem, 1955).

For Eddie, absolute pitch was a skill separate from knowledge of the verbal names of the notes: he was able to match tones to their equivalent piano notes before he had ever been taught the note names. Miller deduced that this same independence of the faculty of absolute pitch from the capacity to verbally identify notes would apply for other savants, as well, since their generally restricted language abilities make verbal association mechanisms an unlikely means of learning. It is interesting, however, that once Eddie learned the names of the notes, he delighted in pointing out the "names" of sounds. A passing police car's siren was F and G; while the bell in an elevator was identified as A#.

EXPLORING ABSOLUTE PITCH FURTHER

Miller tested Eddie and his comparison subjects on the identification of single tones as well as chord groupings. He reports that only the subjects who, like Eddie, possessed secure absolute pitch gave quick, accurate and confident judgments across the tasks presented—even when the chords contained dissonant notes.

Other subjects were able to use "relative pitch" in identifying the presented notes. In other words, after a reference tone was sounded, they were able to recognize a second tone as identical, lower or higher, and perhaps estimate a proportionate distance by which the two presented notes differed. Even so, individuals with relative pitch tended to identify notes more slowly, characteristically considering a number of options before settling on a "guess".

As Miller's absolute pitch subjects varied considerably in age, musical training, and level of general intelligence, the researcher concluded that the consistency of their results against this variability in background argued for absolute pitch as a distinctive skill with important consequences for music perception.

ABSOLUTE PITCH AND "MUSICAL SYNTAX"

Miller proposes that absolute pitch and the intuitive link which it represents between chroma (note name) and tonal frequency suggests the faculty may provide a foundation for the development of higher order structures and a basis for higher order pattern extraction. The beginning musician must learn to map or represent musical notes in a reliable way before he can construct higher order groupings in music. The savant, according to Miller, has a ready means of doing so by virtue of the "internal standard" which he possesses for each note of the chromatic scale, i.e., the faculty of absolute pitch.

Miller suggests that the concept of parallel distributed processing (PDP) (Rumelhart & McClelland, 1986) may prove helpful in explaining how a higher order musical structure or pattern emerges. PDP models characterize information processing as involving the activation of specific groups of units corresponding to aspects of information present in the stimulus array. In music performance, it might work like this: The presence of chroma information (e.g., hearing the note "C") activates several candidate key signatures—keys in which the note "C" naturally occurs, such as C, G, or F Major. At the same time, it inhibits orientation towards other keys in which "C" does not appear—such as D Major. This restricted range of key signatures affects subsequent patterns of activation at the chroma level. Chroma values consistent with the suggested key are augmented; whereas, those inconsistent with the key are inhibited. Thus, by its fundamental frequency, a note not only specifies central categories (chroma), but it also suggests another series of relations among sounds in terms of candidate keys for the musical piece in question. The "inevitability" of various frequency–chroma–scale links represents a pathway by which a young musician with a particularly good sense of chroma identification could start establishing a more complex system for extracting patterns in music—a hierarchical representation of the stimulus structure of music.

Eddie's musical performance, as well as that of other savants, does indeed reflect regularities and consistencies related to the structural rules embedded in musical composition. There is little evidence, however, that musical or other types of savants consciously apply a structured set of rules to their material of interest (Hermelin & O'Connor, 1986a; Howe & Smith, 1988; Miller, 1989). And the speed of savant response would seem to preclude the notion of some interposition of a complex formal rule structure. Miller concludes that, like the child whose language expression and comprehension reflects the rules of syntax, so does

the musical savant's performance show "musical syntax" rule use. In neither case is conscious knowledge of the system of rules necessary.

ABSOLUTE PITCH AND THE PRODIGY

Unfortunately, no one has completed a review of historically documented music prodigies to determine just what percentage has shown absolute pitch. (Certainly, given Miller's statistics with regard to the incidence of absolute pitch in the savant, it seems that such a study should be done.) Nevertheless, accounts of various prodigies' extraordinary faculties of absolute pitch do appear every now and then. . .

Revesz's prodigy, Erwin Nyiregyhazi manifested absolute pitch. Revesz noted the speed and confidence with which the prodigy identified the component notes of complex chords:

Erwin's verdicts were given immediately without reflection and with perfect confidence. One characteristic of the boy's performance was that during these experiments he always smiled in a superior manner, the tasks put before him being so easy to him that he did not take them seriously (Revesz, 1925, p. 75).

An article appearing in the *New York Times Magazine* (Winn, 1979, December 23) included a fascinating account by pianist Lorin Hollander of how his father first discovered that Hollander was a prodigy. . .

When I was 3½, I went with my father to a rehearsal and heard them play a Haydn quartet. I was profoundly moved by the music. When I came home, I wanted somehow to put down what I had heard. I found some drawing paper and began to draw spirals. My father asked me what I was doing, and I began to sing him back the piece, which I remembered perfectly, and told him that I was trying to write it down. My father said, "No, you silly boy, we already have a way of writing music", and he brought out the score to show me. I fell into the music; that's the only way to describe it. Within four minutes I knew the notes, the clefs, everything. A car horn sounded outside and, just for fun, my father asked me what note it was. I immediately answered, "F sharp". He took a spoon and clinked a glass. "B flat". I told him. Then he and my mother realized they had a prodigy on their hands and they started to run around to people to find out what to do" (Winn, 1979, December 23, p. 37).

Then, of course, there is Mozart. Marshall (1991) comments of the legendary child prodigy and musician/composer that his phenomenal musical memory, perhaps the most formidable in history, went far beyond absolute pitch. It included the ability to hear and remember entire compositions—motets, concertos, even operas—to such an extent that he could subsequently write them down. A letter from Mozart's father, Leopold, to his wife from Rome in April, 1770, attests

to the extraordinary abilities of the then 14-year-old Mozart:

You have often heard of the famous Miserere in Rome, which is so greatly prized that the performers in the chapel are forbidden on pain of excommunication to take away a single part of it, to copy it or to give it to anyone. *But we have it already.* Wolfgang has written it down and we would have sent it to Salzburg in this letter, if it were not necessary for us to be there to perform it. But the manner of its performance contributes more to its effect than the composition itself. So we shall bring it home with us. Moreover, as it is one of the secrets of Rome, we do not wish to let it fall into other hands, *so that we shall not incur the censure of the Church now or later* (Marshall, 1991, p. 5).

It may well be that absolute pitch operates in prodigies as Miller suggests it does in savants—to provide a foundation for the structure and higher level abstraction of patterns in music. It seems feasible that Mozart's extensive and precise musical memory allowed for a directly intuited abstraction of complex patterns which could then be set down on paper.

Given Mozart's extraordinary acoustical memory, could we expect him to recall equally well some extended set of random notes or sounds? While there is no data specifically on Mozart addressing this question, there are some additional findings of interest from Miller's case study. . .

MEMORY IN MUSICAL SAVANTS

Miller (1989) presented a series of chord, melody, and rhythm tasks to Eddie and his comparison subjects to assess short-term memory capacities. The findings suggested that savants did extremely well when the task required retention of harmonic information. When tasks involved tonal material presented sequentially, or "melody like" information, they also did quite well, though their performance was not quite so exceptional.

According to Miller's findings, savant musical memory was enhanced by increased structure or organization in the material to be remembered. Generally, the more the stimulus array was composed of "just notes" (e.g., unconventional chords, random tones, or irregular intervals), the less remarkable savant performance was. Miller concludes that savant performance resembles the selective memory found among those with expert knowledge in a domain. He points out that just as expert chess players remember chessboard configurations more easily when they are well-structured and meaningful (Chase & Simon, 1973), "so the savant's memory excels most when the more meaningful or structured aspects of music are present. In each case, it seems most parsimonious to assume that the excellence of immediate memory reflects a complex and well-structured representation of the domain in long-term memory" (Miller, 1989, p. 112). Tasks requiring reproduction

of portions of intact compositions suggested that this response to musical structure extended to a sensitivity to the implicit rules governing music composition in Western culture. For example, notes consistent with the underlying scale of a piece were more likely to be reproduced accurately.

MEMORY IN THE MUSIC PRODIGY

Revesz (Revesz, 1925) also assessed the memory of his young prodigy, establishing that Erwin easily memorized melodious pieces with simple harmony and had no difficulty remembering a large number of operatic arias, having learned them in a very short time. Revesz noted that as a rule, however, only the melodies without the harmonies were reproduced without error. This is interestingly in contrast to Eddie's superior performance in reproducing the harmonic dimensions of music as opposed to the melodic. In considering Revesz's findings, however, Miller (1989) states that in view of Erwin's proven ability to render complex chords with great precision, this conclusion about more extended musical excerpts may reflect an attentional bias or preference (Eddie loved operatic arias) rather than a particular performance limitation.

Erwin, like Eddie, found unconventional musical excerpts more of a challenge. Revesz notes: "In the case of musical pieces of a strange character, such as melodies with complicated accompaniment and peculiar harmonies, his memory did not prove itself equal to the task" (Revesz, 1925, p. 90). Whether this would have proven to be the case as well with Mozart, one cannot tell for sure. But one might speculate that even Mozart's phenomenal musical memory may have been facilitated by the presence of conventional structure in whatever material he was memorizing at the moment.

SIGHT READING SKILLS

Unlike Eddie, Erwin's extraordinary talent included a prodigious acquisition of sight reading capabilities. By the age of 6, Erwin already preferred optical exposure to the music rather than just hearing it; and he obviously benefited from seeing the written score while attempting to master a musical piece. Interestingly, while "reading" a new score without benefit of hearing the music, Erwin would hum the melody to himself while moving his fingers as if he were playing the theme on the piano, thereby fixing the theme in his memory by motor means. Revesz noted that the child appeared to be trying to imprint the treble on his memory by singing, and the lower parts by the action of playing.

LANGUAGE IN THE SAVANT

Only two characteristics are possessed by *all* musical savants. The first is extended absolute pitch. The second is some significant degree of language disability (Miller, 1989). The language deficit appearing in musical savants

has a specific form. Generally, savants show considerable facility in the phonetic (sounds of speech) and syntactic (rules for combining words into phrases and sentences) aspects of language, while manifesting severe deficits in semantics (the acquisition of words and the meanings associated with them) and pragmatics (using language to express one's intentions and for getting things done in the world). Echolalic speech, such as that manifested by Eddie, appears in the great majority of cases.

Miller argues that echolalia implies that the savant has considerable sensitivity to his or her surrounding language as a system of sounds. Additionally, there is some knowledge as to how these sounds are combined to produce extended sequences. What is missing is manifested awareness of the communicative function of language and its role in sharing meanings about environmental events and objects (Sigman & Mundy, 1987). The presence of this specific pattern of partial language ability tells us that development of extraordinary musical abilities in the savant does not require the *absence* of "competing" language. In fact, Miller continues, the most gifted musical savants are *not* mute.

Miller (1989) provides a brief recapitulation of Eddie's language development, noting that at age 5½, his language was monosyllabic and/or echolalic. During the earliest music sessions, Eddie spoke minimally, though by the end of the first month, he would greet the researcher by name. Conversations were generally one-way, with Miller reminding Eddie to listen while a piece was played, informing the savant of the names of the pieces, and responding with verbal approval to Eddie's playing. As time went on, Eddie began to reliably repeat the names of the tunes requested, although often not with the appropriate melody. Miller notes that the first notes of a song were more reliable cues for Eddie than was the song's title. With the advent of formal music lessons, Eddie's language use increased gradually with his learning to name notes and additional tunes. He also began to include comments on the pieces and simple requests or instructions to the teacher during the lessons.

LANGUAGE IN ERWIN, THE PRODIGY

The semantic, pragmatic, and conceptual impoverishment of Eddie's savant mode of speech contrasts dramatically with the pragmatically astute, conceptually rich, and emotionally colored language of Erwin, the prodigy. Revesz observed that the child often asked if what he was about to say would get "into the book", for in this case, Erwin noted, "I want to express myself correctly, and you must pay great attention to me; for a single wrongly-chosen word may alter the meaning of the whole thing" (Revesz, 1925, p. 42).

Revesz also noted that Erwin, unlike most musicians or artists, grasped with absolute precision questions asked of him about his own experiences or processes of consciousness during creative activity or interpretation,

and responded with incredible insight. For example, when Revesz asked him whether during the whole time he was composing a piece, he maintained the same state of feeling, Erwin replied that he did so as far as possible, adding "When composing, one must not always give way to one's heart, the head must also be consulted. Often it is necessary that the heart should be silenced, pushed into the background, otherwise the composition will become weak" (Revesz, 1925, p. 45).

A FEW FINAL NOTES ON THE PIANO

Overwhelmingly, the piano proves to be the instrument of musical savants. Why?

Miller (1989) points out that the piano keyboard maps its sound producing qualities onto the musical culture in a direct fashion. It contains, in effect, the alphabet of the musical language laid out in a coherent spatial organization. Octaves and various harmonies appear in a recurring, spatial pattern, making it relatively easy to explore sound combinations in both direct and extensive ways. Piano keys release pleasing tones readily—without the application of subtle bowing or fingering techniques such as are needed for string or wind instruments. Finally, the piano is a popular instrument—one which is more commonly available to the young child.

Having explored music a bit, we turn now to consider our second domain of interest: Art.

Art

Treffert notes, in his comprehensive review of the literature on savants, "Musical interest in children, whether they are of normal intelligence or are mentally handicapped, is universal. Musical ability is common. Musical genius is frequent. No so with artistic talent. . . It is not surprising then that among savants musical genius as the special ability is quite common, but phenomenal art ability is rare" (Treffert, 1989, p. 79). The same has been found to be true for prodigies (Goldsmith & Feldman, 1989). Nevertheless, there have appeared within the last two decades two young girls of extraordinary artistic ability: Nadia Chomyn, an autistic savant, and Wang Yani, a child prodigy. Following is a comparison and contrast of these two astonishing talents.

A Case of Savant Artistic Talent: Nadia Chomyn

Nadia was born in Nottingham, England, on October 24, 1967, "after a normal birth and uneventful pregnancy" (Selfe, 1977, p. 4). Although there were no unusual features about the immediate pre- and post-natal periods, development was noticeably slow. Her mother reported that the child was generally unresponsive, and seemed to have poor muscle tone—when sitting on her mother's lap she would lean against her as if she could not sit up.

Nadia's first words appeared at nine months, and she rapidly acquired about ten of them. Two-word utterances—which usually appear at about 18 months—never developed, however, and over time, the single words she had acquired at nine months appeared less and less frequently. Although she stood with support at one year, she did not walk alone until she was two years old.

When Nadia was 4½, she was placed in a special school for severely subnormal children in an attempt to remediate some of her developmental delays. At 6 years of age, however, she had still failed to make any progress, and her mother called the University of Nottingham Child Development Research Unit to seek help.

Thus, Nadia arrived with her mother three weeks later for a scheduled appointment with Elizabeth Newson, who states that Nadia appeared "without any warning of how she was to shatter our beliefs" about "what was possible for a 6-year-old, and what was not" (Selfe, 1977, p. 1). Newson describes the 6-year-old Nadia as "a slow-moving, solidly built little girl with a distant smile, who appeared to accept the novel experience of our playroom with passivity rather than interest" (Selfe, 1977, p.1). When the conversation turned to what Nadia liked doing at home, her mother rummaged in her bag and retrieved a small bundle of half-a-dozen ball-point drawings. Newson describes her reactions to this first exposure to Nadia's talent: "My first reaction to the drawings was to marvel; my second, I am ashamed to say, to doubt" (Selfe, 1977, p. 2). Nadia's case was assigned to Lorna Selfe, the psychologist on duty that day. Selfe began a case study of the child which extended over a period of 6 months, culminating in the remarkable book from which our description of Nadia is taken (Selfe, 1977).

It seems that at 3½ years of age, in the midst of all of her developmental deficits, Nadia suddenly manifested an extraordinary drawing ability marked by a manual dexterity lacking in any of her other activities. She would draw only with ball-point pen or, on occasion when encouraged, fine-tipped felt pen. Her earliest drawings were of horses—an unusual first subject for children, who more commonly choose humans or houses. She had only seen real horses on occasional visits to parks and zoos, and had actually ridden only once. Most of her familiarity with them came from pictures which she had seen. Nevertheless, the representational quality of the drawings was markedly advanced. Selfe notes that. . .

The drawings were in perspective; proportions between and within elements were accurate; she used occlusion or hidden line elimination, and the whole production was not only highly realistic but gave the adult viewer the impression of movement and vitality. The drawings were totally different from drawings produced by normal children of this age (Selfe, 1981, p. 50).

By the time she was 6½, Nadia's choice of subjects had expanded to include horses and riders, cockerels, birds,

pelicans, dogs, other miscellaneous animals, trains, and human figures. Nadia's drawings, although inspired by illustrations from children's books, newspapers, or wall prints, were not copies. Generally, when Nadia first saw the originals, she studied them attentively and perhaps scribbled back and forth on their outlines. Her reproductions usually appeared a day or so later and could be recognized as versions of the original, although her rendering of the image might be a different size or completely reversed. She had the incredible ability to imitate drawings seen only once as much as several weeks in the past. Amazingly, she was capable of reorienting an object's position so as to show a different angle or side of the original—without ever having experienced it as a real object in three-dimensional form. She drew only line drawings, showing no interest in color or shading, although the drawings which had originally inspired her were often highly colored.

As fascinating as were Nadia's artistic productions, equally fascinating was her method of executing them. Left-handed, Nadia would hold the pen between her thumb and index finger, using her second finger for support in a competent and experienced manner unlike what one would expect from a young child. She placed her face very close to the paper and drew swiftly and deftly, giving an animated appearance quite in contrast to her normally lethargic behavior. She would begin drawing anywhere on the paper and might continue to draw lines straight off the edge—never attempting to "squeeze" the object onto the paper, if there was not enough room. This sometimes resulted in the image's being cut at a vital spot, but she seemed more concerned with preserving the shape and appearance of the form than with completing it on the given sheet of paper. Her fine, quickly executed lines were firm, without sign of unintentional wavering. With apparently highly developed motor control, she could stop a line exactly where it met another, despite the speed with which the line was drawn. Occasionally, a line in one drawing would suggest another subject to her and she would transform it into the beginning line for another subject. Thus, two drawings would appear in the finished product—one on top of the other.

Nadia would signal the end of a drawing session by simply stopping abruptly and pushing the paper away. At times, the image would be but half finished, or she would lose interest because the continuation of her drawn image would lay off the edge of the paper.

Explaining Nadia: Selfe's Hypothesis

In seeking to explain Nadia's extraordinary talent, Selfe focused on the difference between "conceptually dominated" drawing (the type of drawing done normally by young children) and "perceptually dominated" drawing (the type of drawing which Nadia did). Normally, young children, when they draw, appear to be dominated by the need to set down what they *know* about their subject

rather than what they actually can see—a form of intellectual realism. For example, in drawing a car they will include four wheels—regardless of the viewpoint from which the car is supposedly being seen—in an effort to be faithful to their intellectual concept of what a car is. Nadia's drawing, on the other hand, was "perceptually dominated" in that it faithfully recorded the visual information which she received. Lacking any conceptual interpretation, it was a form of photographic realism.

Citing Vygotsky (Vygotsky, 1978), Buhler (Buhler, 1930), and other developmental psychologists, Selfe proposed that Nadia's perceptually dominated drawing was intimately related to her impaired language abilities. She postulated that the development of language in young children—leading to the generalization and categorization fundamental to thinking processes—results in the reorganization of mental life so that conceptual knowledge dominates over concrete images. Nadia's language deficits prevented her from developing concepts with which to interpret the world. She was left, by default, with a perceptually dominated reality—and drawings characterized by photographic realism (Selfe, 1977, 1981).

Since Selfe's analysis of Nadia's talent, there have been some other studies which shed light on artistic savant performance. It may be useful to see what they have to offer in the way of explaining Nadia, as well. . .

Teasing Out IQ-Independent Aspects of Artistic Talent

O'Connor and Hermelin conducted a series of intriguing studies geared toward determining what aspects of savant artistic ability are independent of general intelligence. Outlines of these studies and some of the resultant findings are presented below.

THE IMAGE LEXICON

In one study (O'Connor & Hermelin, 1987a), five savant subjects whose artistic output was judged to be at art school entrance standard were matched for performance and verbal IQ with five control subjects who had no special artistic talent. Subjects were tested on (1) copying a complex abstract design and then reproducing it from memory; (2) completing a short-term visual memory task requiring no drawing; (3) reproducing concrete representational and abstract non-representational line drawings from memory; and (4) identifying incomplete pictures.

For assessing identification of incomplete pictures, line drawings were inserted into a display box and line fragments one square centimeter in size were exposed one after another from different locations on the drawing until the complete picture was visible. Five drawings—a shoe, a sailboat, a cot, a bird, and a goat were included,

and the subjects were asked to identify each in the minimum possible number of exposures, each exposure adding more information. All of the drawings had been taken from the Peabody Picture Vocabulary Test on which all of the subjects had been previously tested. It was known, therefore, that all the subjects could name the test items.

Results suggested that the savants performed markedly better than the control group on those tasks in which the subjects depended on a stored "picture vocabulary" or visual lexicon. Performance levels were lower on tests dealing with non-representational and unfamiliar material. The researchers concluded that:

The superiority of the idiot savant artists, apart from any outstanding graphic representational skill, might, in the case of concrete and previously encoded images, depend on a richer or more easily accessible internal "image lexicon" (O'Connor & Hermelin, 1987a, p. 88).

The richer and more accessible this lexicon, concluded O'Connor and Hermelin, the more successful were the artists in identifying incomplete pictures through imaginative construction on the basis of a minimal cue. The results corresponded interestingly with an earlier study (Hermelin & O'Connor, 1986b) in which it was found that artistically gifted children could identify incomplete pictures on the basis of less information than was required by either mathematically gifted children or control groups matched for IQ level but without special mathematical or artistic talents.

The authors further concluded that savant artists were more efficient at extracting essential features from a design in order to reconstruct and reproduce it than were controls matched on performance and verbal intelligence.

MOTOR PROGRAMS FOR REPRESENTING IMAGES

Another finding emerging from the above study (O'Connor & Hermelin, 1987a) was that the savants performed more impressively when *copying* a design than they did when their visual memory alone was tested. Moreover, memory performance not involving drawing did not significantly distinguish the savants from the control group. The researchers concluded:

These findings taken together may suggest the importance of a motor manipulative or motor output facility in the artists, as well as a superior input analysis or picture lexicon superiority. The nature of the output skill may not be well understood, but the availability to the idiot savant artist of a rich variety of appropriate motor programmes for representing images must be assumed. It is possible that the superior ability of the artist group may lie as much in this motor programming capacity as in perceptual editing and analysis (O'Connor & Hermelin, 1987a, p. 89).

Following up on the motor programming notion, a further study (O'Connor & Hermelin, 1987b) compared the performance of normal artists and controls with savant artists and subnormal IQ controls. Findings suggested that testing visual recognition memory through tasks in which no motor manipulation was involved, resulted in group differences reflecting levels of intelligence, but not differentiating artistic competence. When graphic depiction was involved, however,—whether it was direct copying or reproduction from memory—savant artists performed more like artists of higher IQ's than they did like IQ-matched controls.

In explaining the results, the authors posited that "drawing partly depends on an encoded motor programme which can be primed by the sight of a model but may be relatively independent of visual memory for this shape". They concluded further that: "while visual images seem to be more readily evoked by subjects with high rather than low intelligence, the efficient accessing of graphic motor programmes depends more exclusively on artistic competence" (O'Connor & Hermelin, 1987b, p. 316).

In trying to reconcile these findings with their earlier ones in which it was shown that savant artists can identify incomplete pictures on the basis of minimal visual information (O'Connor & Hermelin, 1987a), the researchers propose that "both this identification skill, as well as drawing ability, depend on a generative process presumably based on ready access to the relevant representational systems. Accordingly, the identification of incomplete pictures and the generation of graphic reproductions would not result in separate input and output processes but would both be produced by the cueing of the appropriate representations" (O'Connor & Hermelin, 1987b, p. 316).

ACCURACY AND ARTISTIC MERIT

A final study (Hermelin & O'Connor, 1990) looked at *accuracy* of drawings (the extent to which the location, orientation, and veracity of elements within the reproduction remained faithful to the original), and *artistic merit*, (liveliness and sensitivity to the object drawn, vitality and character of line and texture, presence of distinct style, organization and composition, and the degree to which a compelling and interesting image is produced). Findings showed that while accuracy of drawings may be related to IQ level, the artistic quality of the graphic production is not.

The above findings provide a new framework within which to view the case study of Nadia. Following is a discussion of how they might apply.

A Brief Second Look at Nadia

THE IMAGE LEXICON

While Nadia's choices of subjects were somewhat limited, the concept of a lexicon may well apply. As

was noted previously, if in the midst of drawing a particular subject, a specific line seemed to remind her of a different subject, she was likely to take off and use it as the starting line for a second drawing. It may be that the line in question tapped into her internal lexicon and precipitated an imaginative construction whereby she completed what was, to her mind, an incomplete picture. Such a lexicon would, of course, also allow her to expertly extract from an original picture the major features necessary for a later reproduction.

MOTOR PROGRAMMING CAPACITY

The physical intensity, swiftness, and deftness with which Nadia executed her drawings would support the notion of a motor programming capacity which was cued by the representation to be drawn.

ACCURACY AND ARTISTIC MERIT

As Selfe pointed out, Nadia's reproductions were *not* copies of the originals. Alterations in orientation or size of the subject were frequent. They did, however, have artistic merit. Thus, the research findings relating accuracy to general intelligence, and artistic merit to some IQ-independent ability is supported by Nadia's performance.

Interestingly enough, none of this necessarily detracts from Selfe's earlier arguments that Nadia's drawings were perceptually rather than conceptually dominated. An intriguing contrast is presented by a young artist whose work might well be seen as a delightful melding of the perceptual and the conceptual—the child prodigy, Wang Yani.

Wang Yani: An Artistic Introduction to a Child's World

5 March. It has drizzled all week, preventing Yani from playing outside. This evening she said to me in a serious tone of voice:

"Post a letter for me, (Daddy)."

"(To whom?)" I enquired.

"I'll paint a picture to be sent to the sun."

"The sun?" I repeated in surprise

"Yes. He'll follow my advice and go with me. And so will the moon: didn't it go with me to Shanghai?" Yani went on: "the sun will take me up with him to play in heaven. He'll carry me on his shoulder and fly at great speed!"

"What is heaven like?" I asked.

"White everywhere. Do you want to go there, too, (Daddy)?"

"I wouldn't dare to."

"But I will! And I'll come back, too." Then she whispered in my ear: "The lazy sun! He only cooks his meals at night, and makes the sky black with the

smoke. He cleans it up in the morning, and it becomes light again."

On hearing this, I roared with laughter, but Yani gazed at me in amazement and insisted, "Yes, (Daddy), that's how it is." (As recorded in Ho, 1989, p. 13; Changes from original diary text bracketed by Ho.)

The above conversation between Wang Yani at the age of four and her father, Wang Shiqiang, was recorded by the father in his diary. It allows a glimpse of this visually perceptive and extraordinarily imaginative child.

Born on May 2, 1975, Yani was raised in one of the most scenic areas of China and introduced to the enchantment and complexity of the natural world at a very young age. She would ride on her father's shoulders, roaming with him among mountains and fields or along the riverbank. They also frequented the zoo to admire the sleeping tiger, the fierce lion, or the beautiful plumage of peacocks and storks. But she fell in love with the busy and lively monkeys who were to become the subject of most of her paintings from the time she was 3 years old until she was 6.

It was from her father that Yani first learned to appreciate the sensuous colors and textures of the natural world. It was also from Wang Shiqiang, who was an oil painter, that she learned to capture them on canvas. Yani started painting rather by accident when she was 2½ years old and accompanying her father on a trip to Nanning, the capital of the province where they lived. While Wang Shiqiang was working in his studio with some colleagues, Yani amused herself by looking through some children's books. Becoming bored after a while, she picked up a piece of charcoal and began to draw on the wall. Then, in imitation of her father, she stepped back with her eyes half-closed, left arm akimbo, and surveyed her work with satisfaction. Everyone present laughed.

From that day, with the support of her father, Yani began her painting career with paper and brush. She painted the flowers and pine trees surrounding her house and the chickens, ducks, dogs and cats in the yard. She also painted portraits of her father. These first paintings, however, were symbolic. They consisted only of dots, circles, and unintelligible lines. Her father noted in his diary that in Wang Yani's paintings, "A circle might represent a person, a still-life, a bird, or some other animal, while an apple could stand for fruit in general" (Ho, 1989, p. 14).

Yani's father decided not to give Yani formal lessons for fear of stymieing her creativity. Instead, he let her learn by herself through observation and trial and error, thereby developing her own style. So as not to influence her work and artistic development, he gave up his own painting career in 1983.

Painting became a passionate involvement for Yani. Everyday she painted ceaselessly until she was completely satisfied. Once, when she was four, she worked

nearly until midnight, refusing to go to bed until she got “the best painting”. She was not willing to go to sleep until she had completed more than ten paintings.

By the time she was 6, Yani had produced four thousand paintings, and her work had won international acclaim (Ho, 1989).

Yani at Her Art

Yani possessed an astounding visual memory. Wang Shiqiang taught her Chinese characters by writing them in the air once with his finger. When Yani, on one of her trips to the zoo became charmed by the beauty of the peacocks, her father told her to figure out why they were so lovely. She studied them for several hours, and upon arriving home, produced beautiful renderings of the birds (Ho, 1989).

Yani began her paintings without any sketch or predetermined theme. Ho describes her method of execution:

Depending on the color of the paint that she picks up on her brush, she then decides what subject is most appropriate, executes her first stroke, and develops a story simultaneously as she paints. It is a wonderful experience to watch Yani paint. She keeps the brush moving unhesitatingly, with occasional pauses only to inspect the overall composition (Ho, 1989, p. 16).

Ho (1989) also talks about the “poetic improvisations” which Yani could create on the spur of the moment. For example, once she accidentally tipped over the brush washer, staining most of her paper with the spilled water. Emptying the rest of the water onto the wet paper, she painted pumpkins and vines over it while making use of the blurring effects to suggest that the pumpkins and vines were lost in a morning mist.

Yani’s varied types of brush strokes, carefully chosen colors, and skillfully planned compositions are used to infuse her images with movement, life, and feeling. Contrasting tones of light and darkness serve to emphasize facial expressions or movements and gestures. Her monkeys are realistically presented. They are covered with soft brown fur and appear capable of imminent action, seemingly caught in the middle of swift movement. Yet they, like her other images, are conceptual, abbreviated, and expressionistic (Ho, 1989).

Ho notes that, like most Chinese artists of the past, Yani does not paint directly from life or try to record any particular peacock, monkey, or tree. Instead, by absorbing, analyzing, and synthesizing sensory impressions from nature, she develops in her mind a store of universalized images from which she then draws in creating her paintings. Yani’s painting, Ho notes, “is a result not only of a praiseworthy mastery of the medium but also of her ability to capture the essentials observed in nature and have them so fixed in her mind that she can re-create them in her painting, endowing them with life,

emotions, and personalities and projecting into them her thoughts, feelings, and dreams” (Ho, 1989, p. 18).

Revealing the Magic of Childhood Through Art

Yani does, indeed, project into her creations her own thoughts. This is one of the most enchanting aspects of her art—Yani’s adult-like mastery of artistic techniques are used to reveal a child’s world. The themes of her paintings are centered around childhood issues. One which she painted at age five, shows a baby monkey kneeling on his mother’s back and feeding her a piece of fruit. It is entitled “This Is For Mommy”. Another painted at that same age shows a single monkey looking straight at the viewer with a determined look on its face, its feet planted solidly as if waiting defiantly. He is flanked by two other monkeys caught in incipient motion, holding stylus-shaped objects and about to intrude into the space of the first monkey. It is entitled “I Am Not Scared! (Inoculation)”. Other paintings show monkeys having parties or playing tug-of-war.

Yani’s imagination plays a pervasive role in her creative process. Part of that imagination consists of language-shaped concepts which serve to formulate the story line and relationships between her figures as the painting develops. She is, in this respect, unlike either savants whose drawings emerge isolated from the influence of language, or even normal children, whose drawings are often created in an effort to illustrate a previously developed story or experienced event (Selfe, 1983). Instead, Yani enters the world of her creatures and lives with them the experience she is creating with paper and brush. Thus, Goldsmith and Feldman (1989) write:

... she “fed” her beloved ink monkeys with fruit, in the process creating wonderful compositions of monkeys plucking, scrambling, and yearning for food. Sometimes her father would even hear her chiding the painted images to behave, because she was about to share (that is, paint) their fruit. So, too, her paintings became populated with peacocks, cranes, and butterflies to amuse and befriend the monkeys . . . according to Wang Shiqiang, these companions appeared in her compositions only after Yani’s own social world had expanded to include friends and experiences beyond the family constellation (Goldsmith & Feldman, 1989, p. 57).

Conceptual and Perceptual Influences

The interplay of the conceptual and the perceptual in Yani’s creations is beautifully illustrated by the tale of the leafless trees originally told by her father:

Noting that Yani omitted leaves from her paintings of fruit trees, Wang took his daughter to an orchard so she could observe trees from nature. Yani, however, casually dismissed the arboreal reality, claiming

that she did not paint leaves on her trees because monkeys did not like their taste. Some time later Yani listened carefully as a botanist explained how leaves help supply energy to the tree, thereby allowing its fruit to grow. This sensible explanation was apparently sufficient for Yani to reconsider leaves on her trees. Despite her familiarity with how real fruit trees looked, the botanist's explanation was so compelling that she painted the fruit growing directly from the leaves themselves (Goldsmith & Feldman, 1989).

In her earlier paintings, her monkeys served as playmates or even substitutes for Yani and her family. As Yani grew older and more capable of seeing the world more objectively, however, the subjects of her paintings began to reflect more specific and realistic explorations of the social world. By age seven or eight, she no longer had to rely on psychological activity among her figures to generate interest and coherence, as she had become able to create an integrated composition using only formal elements (Goldsmith & Feldman, 1989).

In thinking about Yani, one senses a number of intriguing likenesses and differences between her artwork and the creative process producing it and the formerly discussed productions of Nadia. Below, these likenesses and differences are considered with a more critical eye.

Yani and Nadia: Comparison and Contrast

Following, a number of likenesses between the work of Yani and that of Nadia are discussed.

THE IMAGE LEXICON, UNIVERSAL IMAGES, AND "ARTISTIC SYNTAX"

Neither Nadia nor Yani painted predominantly from life nor duplicated exactly what was seen. Instead, each drew upon "an image lexicon" (O'Connor & Hermelin, 1987a) or an accumulated store of "universal images" (Ho, 1989) in creating her artwork. This basic store of images provides the elements with which each constructed her artistic creations. Reminiscent of the role played by absolute pitch for Eddie and Erwin (Miller, 1989), these images provide a foundation for the development of higher order visual structures and a basis for higher order pattern extraction from the visual world.¹

We thus find at the core of both music and art a syntactical structure functionally equivalent to the one we find in language. Both Yani and Nadia seem to

have assimilated it intuitively—just as Eddie and Erwin assimilated "musical syntax" (Miller, 1989), and just as the language comprehension and expression of normal children the world over reflects an intuitive grasp of the syntactical rules of language.

Both Nadia and Yani also showed the capacity for imaginative construction on the basis of minimal cues: Nadia would use a line originally drawn to define one subject to begin the outline of a totally different subject. Yani, on the other hand, used the after-effects of spilled water on her paper to give the impression of mist-enveloped pumpkins and vines. While Nadia worked within the confining framework of the structural possibilities inherent in line relationships (White, 1988), Yani included more varied dimensions of visual experience (e.g., color, shading, etc.) as potential "cues".

MOTOR PROGRAMS FOR REPRESENTING IMAGES

Ho's description of the sureness and quickness with which Yani paints—"She keeps the brush moving unhesitantly" (Ho, 1989, p. 16)—suggests that Yani, like Nadia, efficiently accesses a variety of appropriate motor programs for representing images (O'Connor & Hermelin, 1987a, 1987b).

There are, however, important differences between Nadia and Yani.

ARTISTIC DEVELOPMENT

Yani's artistic development began with the symbolic drawings typical of the young child. Her developmental progression in the production of artwork was a normal one, although it took place at a much more rapid pace than we would expect for a young child. This pattern is a typical one for young prodigies (Feldman, 1980, 1986). Nadia's images, however, were depicted with photographic realism from the beginning.

Yani's imaginative intellect and conceptual keenness permeate her artwork. Art becomes a medium through which she expresses her feelings and understanding—interpreting and sharing her inner world with the viewer. And as her own world grows and develops, we find that her artwork reflects these changes in her. Although we are impressed with the technical renderings of Nadia, her inner world remains a mystery. Selfe points out that although Nadia's cockerels might appear fierce and eloquent, there is no indication that Nadia drew them with that intention. The viewer may choose to imbue Nadia's creations with such concepts and interpretations, but it still remains that one has no basis on which to impute such sophisticated notions to her (Selfe, 1983).

¹Just as absolute pitch may have formed a foundation for Mozart's extraordinary musical memory, so an unusually rich and accessible store of universal images may have aided the memory of the artist Michelangelo, who, according to historical accounts, was most probably a child prodigy. In 1550, Giorgio

Vasari, who knew the great Renaissance artist personally, wrote that Michelangelo had such an outstanding visual memory that he could retain in detail the works of other artists which he had only seen once. Since he also remembered everything he had ever produced, he never repeated himself (Vasari, 1957).

THE ARTIST IN ACTION

Finally, of course, seeing each of these children in action is a strikingly different experience. Each involves herself in the art experience with intensity and focus; but each does so in a very different way. Young Yani steps herself in the conceptual story line-in-progress, evoking feelings from her own experience to transfer to canvas, and providing animated on-going commentary. Nadia, on the other hand, is concentrated and mute—seemingly dominated by the perceptual aspects of the task at hand. She is apparently impervious to the external world with its extended meanings, emotions, and metaphors. Not even the edge of her paper can intervene in her fidelity, to perceptual reality and the strangely necessary production of her line drawings.

Each of these young children manifests a sort of perfectionistic involvement with their art. It is evident in the incident where four-year-old Yani, swept up in the passion of her art, refused to go to bed until she produced “the very best painting”. Yani’s perfectionism has to do with trying to reach a self-set conceptual goal: “the very best painting”. Nadia’s “perfectionism” is of a different type—more fundamental, less interpretive, bound up with her fidelity to perceptual rather than conceptual reality—and perhaps less removed from some underlying generative neurological substrate. When faced with the edge of the paper on which she is drawing, she will either continue the lines of her image past it or will stop, thereby abruptly terminating and truncating the image. She *will not* (or *cannot*) compromise by distorting the image so that it fits onto the paper.

ROLE OF ENVIRONMENTAL INFLUENCES

Here is another difference: Nadia’s talent appears suddenly and mysteriously—unevoked by external stimuli, unconnected with family history. It seems driven by biological necessity and constrained and shaped by forces within Nadia. Her mother, who provides paper and ball-point pen at appropriate moments, is a supportive influence, of course. But because of Nadia’s basic impermeability, her mother remains at best a tangential one. Not so with Yani’s father. Like most parents of prodigies, he is a central catalyst for the development of Yani’s talent. He introduces her to the world of art—a world with which he is intimately acquainted—and he sensitively supports and nurtures her growth.

Yani is also subtly—or not so subtly—influenced by the artistic traditions of her culture. Her artwork is executed with traditional Chinese brush and paper. And the animation and vitality characteristic of her figures typifies the Chinese ideal of art (Ho, 1989). Of course, it is clear that Yani’s talents are as rooted in biology as are Nadia’s. But Yani is, as well, enthusiastically responsive to the influences of her society and culture.

Having looked more carefully at Yani and Nadia, it is time to consider the possible neurological substrates giving rise to the talents of prodigious savants and

prodigies. This is necessarily a speculative discussion, since there is not sufficient research to allow for definitive conclusions. Nevertheless, one can make some educated inferences. Perhaps an appropriate place to begin is with Treffert’s analysis of what creates the prodigious savant. . .

The Prodigious Savant: A Possible Explanation

Drawing upon the research of Geschwind and Galaburda (Geschwind & Galaburda, 1987), Treffert (Treffert, 1989) posits an intriguing explanation for the prodigious savant. He suggests that pre- or post-natal injury to the left hemisphere of the brain stimulates compensatory growth in the right hemisphere. This is manifested through deficits in language and analytic thought (both of which are dominated by the left hemisphere) and increased capacity for functions dominated by the right hemisphere (e.g., musical and spatial abilities).

Treffert proposes further that savant memory is the manifestation of compensatory brain circuitry. Injury to the cerebral cortex, which normally manages conscious associative memory, results in memory functions being shifted to the *corticostriatal system*, a more primitive area of the brain. Memory consequently becomes non-associative, habitual, emotionless, and non-volitional. It becomes a conditioned response.

Treffert points out, however, that these alterations in brain function and circuitry still fail to explain the prodigious savant’s extensive access to the structural rules of domains. He speculates that such access may be based on an inherited ancestral memory transmitted across generations. Domain-specific in nature, it is inherited separately from general intelligence. Once the groundwork is laid for savant skills, concludes Treffert, intense concentration, obsessive repetition, external reinforcement, and an unstoppable drive to exercise the special ability combine to produce the prodigious savant.

It would appear from what we have seen of Erwin and Yani, that the prodigy shares with the savant certain underlying neurological characteristics allowing for their “intuitive” connection with specific domains. Perhaps, like the savant, the prodigy enjoys heightened right brain functioning. The prodigy, however, differs in that he or she possesses a well-functioning fully integrated brain. The left hemisphere remains intact. Based on what is known about the savant and on what can be gleaned from accumulated brain research, can one come any closer to understanding the brain functioning of the prodigy? Perhaps one can. And perhaps a short digression into some research on the split-brain is a good place to start.

Insights From Split-Brain Research

It was in the early 1960s that the first in-depth psychological studies of “split-brain patients” were conducted. The individuals being studied had undergone surgery

to treat incapacitating epilepsy by severing the corpus callosum, the bridge of nerve fibres connecting the two hemispheres of the brain. Post surgical studies revealed that after the hemispheres were divided to control intractable epilepsy, each half brain behaved independently—and without knowledge—of the other. Moreover, each half brain seemed specialized for particular kinds of mental activity. The left was specialized for language, while the right seemed more able to deal with other functions (e.g., visuo-spatial tasks) (Gazzaniga, 1992; Gazzaniga & LeDoux, 1979). Some chose to elaborate these differences into a delineation of the verbal left hemisphere as functioning in a sequential, logical, analytic, and rational manner; whereas, the functioning of the non-verbal right hemisphere began to be seen as simultaneous, spatial, holistic, synthetic, and intuitive (Springer & Deutsch, 1981).

As the work has evolved, it appears that only the left hemisphere can make causal inferences, apprehend complex linguistic constructions, or provide the underlying brain organization allowing for high-level consciousness and belief formation. The left brain also serves an integrating and interpreting function for what we now know are the numerous modular subsystems comprising the human brain (Gazzaniga, 1992). The results of one particular study will clarify what this implies. . . .

In the early 1970s, Michael Gazzaniga and his associates devised a simultaneous concept test to be used with split-brain subjects (Gazzaniga, 1992). In the task, the subject is shown two pictures, one exclusively to the left hemisphere and one exclusively to the right, and then asked to choose from an array of pictures placed in full view of him the ones associated with the pictures lateralized to the left and right brain.

In one such test session, a picture of a chicken claw was flashed to the left hemisphere, while a picture of a snow scene was flashed to the right hemisphere. The appropriate selections, of course, would be a chicken for the chicken claw and a shovel for the snow scene. The subject responded by choosing the shovel with the left hand (the left hand is controlled by the right hemisphere) and the chicken with the right hand (the right hand is controlled by the left hemisphere). Thus, the non-verbal right hemisphere matched the shovel with the snow scene. When the subject was asked why he chose these items, his left hemisphere replied, "Oh, that's simple. The chicken claw goes with the chicken, and you need a shovel to clean out the chicken shed." Thus, the left brain, observing the left hand's response, interpreted that response into a context consistent with its sphere of knowledge—which did not include information about the snow scene shown only to the right hemisphere.

The left hemisphere also integrates emotional responses into conscious awareness, providing an interpretive framework for understanding them. For example, in one test, a film of one person throwing

another into a fire was shown to the right hemisphere of a subject. She reacted "I don't really know what I saw. I think just a white flash. Maybe some trees, red trees like in the fall. I don't know why, but I feel kind of scared. I feel jumpy. I don't like this room, or maybe it's you getting me nervous." She then commented to a colleague out of earshot of the researcher "I know I like Dr Gazzaniga, but right now I'm scared of him for some reason." The emotional valence of the stimulus had crossed over from the right to the left hemisphere. While the left hemisphere remained unaware of the content producing the emotional change, it still experienced and had to deal with and interpret the emotion (Gazzaniga, 1992).

The Split-Brain, Savants, and Prodigies

The split-brain research revealing the interpretive and integrative functions of the left hemisphere perhaps provides an expanded vision of brain functioning in savants. The damage to the left hemisphere which Treffert sees as precipitating right hemispheric compensation with resultant savant functioning is seen also as impairing—or destroying (depending on the degree of damage)—the left hemisphere's capacity to interpret and integrate activity within the brain. The result is a lack of metacognitive ability, an example of which is the savant calculating twins who, when asked how they did what they did, simply replied "It's in my head and I do it" (Hamblin, 1966, p. 107). This is a stark contrast to calculating prodigies, who consciously recall exploring the relationships between numbers (Treffert, 1989), and who can often recount rule-based strategies for calculation (Aitken, 1954), and even feel differential emotional responses toward various numbers (Smith, 1983).

Awareness of the left brain as interpreter and integrator also provides a better appreciation of what may be going on in Yani when she paints. In her ongoing verbal commentary accompanying the act of painting, one can see the left brain deftly integrating Yani's recollections of her own experiences and her emotional responses to them with her sensory responses to the possibilities of the media. Meanwhile, the right brain is contributing to the process by accessing Yani's store of universal images and her range of motor programs to allow for the execution of the artwork. As Yani's images appear on the paper, the left brain is simultaneously interpreting the process through an ongoing story about what is going on in the painting. It is a complex multi-dimensional interaction involving the dialectical interplay of right and left-brain functions.

Domain-Specific and General Intelligence: A Reintegration of the Dichotomy

Seeing Yani at work is seeing artistic functioning at its fullest. The infusion of referential meaning and emotion into her work lends it a richness and depth

which touches our hearts while the images please our eyes. While domain-specific skills are involved in the creation of the artwork, the end result is much more than the activation of such skills. It is the expression of the totality of Yani.

We are thus brought back to an original issue: the issue of recasting our beliefs about general intelligence and giftedness in the light of what we know about domain-specific talents. Possibly, the savant provides us with an opportunity to observe domain-specificity in its purest form. Perhaps the purest essence of domain-specific talent is the ability to holistically intuit the syntactic core of rules and regularities lying at the heart of a domain of knowledge: the pattern of relationships between numbers, the pattern of tones in a musical scale, the pattern of images in the visual world, the pattern of words in a language. Other aspects may be necessary, depending on the domain in question—a repertoire of motor programs for the expression of artistic—or musical (Bamberger, 1982)—themes, for example.

In the prodigy, we see this same domain-specific talent. But through the facilitation of general intellectual capacities, it becomes enlarged, embellished, imbued with meaning, intimately connected with both the phenomenological reality of the child (Morelock, 1992, in press; Silverman, 1992) and the materialistic reality of the external world. The gift lies within Yani, and its expression is the product of an integrated brain. This is what real giftedness is all about.

Afterword: Directions for Possible Research

Comparative studies of prodigies and savants may well yield much enlightening information about human cognition. More case studies, such as the one conducted by Miller (1989), need to be completed in music as well as in other domains which spawn both prodigies and savants. Additional longitudinal case studies tracing long-term development of prodigies and savants and aiming for a comprehensive contextual understanding are needed (e.g., Feldman, 1980, 1986). Laboratory research of the type originally designed by O'Connor and Hermelin (Hermelin & O'Connor, 1986a, 1986b, 1990; O'Connor, 1989; O'Connor & Hermelin, 1984, 1987a, 1987b, 1990) needs to be expanded to include prodigies as well as savants and normal gifted individuals. New research designs need to be developed so that domain-specific abilities within a wider variety of domains can be explored.

The use of brain-imaging techniques for the comparative assessment of brain activity, brain anatomy, and behavioral performance in savants and prodigies, as well as in children of extraordinarily high IQ (Morelock, in press) and other gifted individuals (Crist, 1990) could be instrumental in replacing some of our speculative inferences with hard data.

And finally, research into the structural cores of various domains may shed light on the human capacities

which both create those structures and respond to them (Goldsmith & Feldman, 1988).

PART III

Identification of Giftedness and Talent

Procedures for Identifying Intellectual Potential in the Gifted: A Perspective on Alternative “Metaphors of Mind”

ROBERT J. STERNBERG

Department of Psychology, Yale University, New Haven, Connecticut, U.S.A.

Introduction

What do we mean by “giftedness”, and how do we assess it? Why is a child who scores in the top 1% on the Wechsler Intelligence Scale for Children much more likely to be labeled as gifted than a child whose 100-meter sprinting time places her in the top 1% of her age cohort? Why is a physicist who is considered number 1 in the country by his peers or another panel of judges considered gifted, whereas the criminal who is number 1 on the FBI’s most-wanted list is not? Why do contestants in major beauty contests have to answer questions about issues perceived to be of domestic or international importance, whereas contestants in the major scientific competitions do not have to submit to judgments of their personal attractiveness?

In this chapter, I will deal with the questions of how we decide what to assess in the identification of the gifted, and with alternative approaches to such assessment. The chapter is divided into three main parts. In the first,

I will consider the criteria used to assign the label of “giftedness”. In the second part, I will consider alternative perspectives on intellectual giftedness, and the kinds of measures that derive from each. In the third part, I will draw some conclusions.

The Criteria of Giftedness

I have proposed that the label of “giftedness” is assigned on the basis of five criteria (Sternberg, in press). According to this “pentagonal implicit theory of giftedness”, to be judged as gifted, a person needs to meet five criteria (Fig. 1): (1) the excellence criterion, (2) the rarity criterion, (3) the productivity criterion, (4) the demonstrability criterion, and (5) the value criterion.

(1) *The Excellence Criterion.* The excellence criterion states that the individual is *superior in some dimension or set of dimensions relative to peers.*

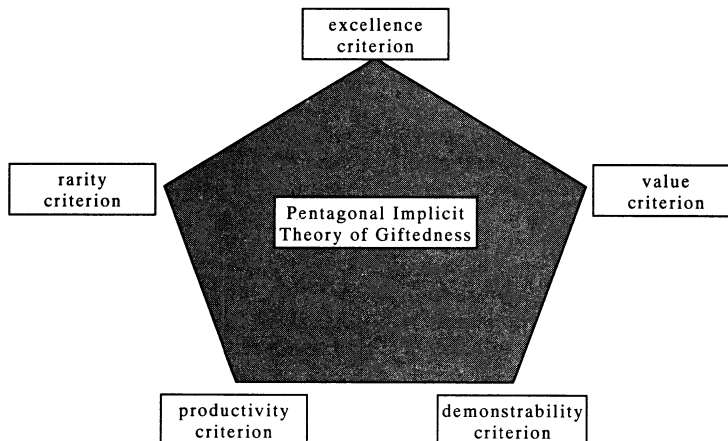

FIGURE 1. The five individually necessary and jointly sufficient criteria of the pentagonal implicit theory of giftedness

To be gifted, one has to be extremely good at something—in psychological terminology, high in a judged dimension or dimensions. How high is “extremely high” may vary from one context to another, but the gifted person is always perceived to be abundant in something, whether it be creativity, wisdom, or another skill or construct. In the present view, excellence relative to peers is a necessary condition for an individual to be labeled as gifted.

The qualification “relative to peers” is necessary because the designation of excellence depends upon the skills of those against whom one is judged. A 10-year-old’s raw score on an intelligence test might convert into a very high score relative to age peers, but would seem unexceptional relative to children five years older than he is. Similarly, a musical performance that would be exceptional for an eight-year-old taking weekly music lessons at school might be quite undistinguished for an eight-year-old who has been trained at a conservatory since age four.

At times, more than one peer group might be relevant. For example, consider all of the children in a class for the gifted. They were all judged as gifted relative to their general age peers, perhaps within a given grade. But relative to each other, the weakest of them might not seem very gifted. Indeed, anyone who has taught a class of gifted children knows that many of them start having self-esteem problems quite quickly when they discover, sometimes for the first time, that they are no longer at the top of the class.

One potentially important issue is that of which direction on a linear scale constitutes excellence, an issue which is usually consensually defined by those making judgments about what kind of work qualifies as “high level”. Most of us have had experiences in which we were scored low in a dimension, though we suspected that the judges had somehow gotten the direction of the scale backward. For example, a painting we believe to be highly creative might be viewed as pedestrian by judges. Or a conservative business might give promotions and raises to employees who toe the company line and never actually do anything on their own initiative. It is worth remembering that judgments may differ as to which direction indicates superior performance, and as to who exhibits it.

(2) *The Rarity Criterion.* The rarity criterion states that in order to be labeled as gifted, an individual must possess a *high level of an attribute that is rare relative to peers.*

The rarity criterion is needed to supplement the excellence criterion because a person may show an abundance of a given attribute, but if a high evaluation of that attribute is not judged to be rare, the person is not viewed as gifted. Suppose we give a test of mastery of the basics of the English language to a class of college seniors at a good university. They should all score very highly on the test, because all are fully proficient in the basics of English. But even if all received perfect scores, we would not say they are all therefore gifted. Even if

one scores very well, unless high scores are rare, the high scorer is not likely to be viewed as gifted.

Consider, for example, a highly platykurtic score distribution, which is flat and spread out. Thus, there are more high scores and low scores than would be typical of the mesokurtic (bell-shaped) normal distribution. Someone with a high score on the platykurtic distribution is less likely to be evaluated as gifted than someone with an equally high score on a mesokurtic and especially a leptokurtic distribution, in which scores are bunched in the middle. What matters here is not just the superior performance, but its frequency relative to peers. Ultimately, we are led back to the old saying that in the kingdom of the blind, the one-eyed man is king. What is high and rare in terms of ability in one milieu may be undistinguished and even below average in another.

(3) *The Productivity Criterion.* The productivity criterion states that *the dimension(s) along which the individual is evaluated as superior must lead to or potentially lead to productivity.*

Consider again the contestants in the beauty contest. Why is it that they must answer questions about issues of the day, rather than merely being judged solely on their appearance? In fact, appearance probably is the major determinant in the contest, so why is it not sufficient? Despite the fact that the contest is really about beauty, beauty in itself is not perceived as productive or potentially productive. The contestant needs to demonstrate that she can *do* something beyond just looking good. In contrast, the contestant in a scientific competition is not judged on other dimensions such as personal appearance, because the scientific work itself—the basis of the contest—is viewed as productive.

The productivity criterion generates disagreements over exactly who should be labeled as gifted. Some, for example, believe that a high score on an intelligence test is not sufficient grounds for labeling a person as gifted. These people see the tests as meaningless (e.g., Gardner, 1983). The high-scoring person hasn’t shown that he or she can “do” anything. To others, getting a high score on the test is viewed as doing something in and of itself. At worst, the high score shows the person’s potential for productivity.

In childhood, of course, it is possible to be labeled as gifted without having been productive. In fact, children are typically judged largely on potential rather than actual productivity. As people get older, however, the relative weights of potential and actualized potential change, with more emphasis placed on actual productivity. Any number of gifted children become rather ordinary adults whom no one thinks of as exceptional. Renzulli (1986) has referred to such adults as “schoolhouse gifted”. At cocktail parties, one may find out their high school standardized test scores in short order, but little by way of accomplishment afterward.

However, the importance of potential probably never disappears as a consideration. For example, when one hires a senior manager, or a senior scholar, one does

so partly on the basis of past accomplishments, but largely on the hope that these past accomplishments are predictors of future performance.

An interesting example of fulfillment of the productivity criterion is Marilyn Vos Savant, who is listed in the Guinness Book of World Records for having the highest recorded IQ. Did this make her a gifted adult? Perhaps not, according to conventional standards of adult giftedness. But Vos Savant has shown that she is a rather gifted entrepreneur, turning a high score in childhood into a small business of sorts, using it to obtain fame and a column in *Parade* magazine. So according to the pentagonal theory, she has shown productivity as an adult, as a quiz-column entrepreneur.

People who do not realize their potential through some kind of productive work may still be labeled as gifted; but with qualifications. They are seen as gifted individuals whose gifts somehow failed to materialize, or stopped materializing at some point. Or these people may ultimately be viewed as having been mislabeled. From our point of view here, the critical issue is that at some time they were being labeled as gifted because of their potential for producing something. They may continue to be labeled as gifted so long as that potential exists, realized or not. If they are viewed as having utterly lost that potential (e.g., through the results of a stroke), they will probably no longer be referred to as gifted, except in the past tense. One is more likely to say of a brain-damaged physicist, for example, that "she was a gifted physicist, but . . .".

In sum, to be labeled as gifted, a person must have the potential for productive work in some domain. People without such potential, no matter how excellent they are in some aspect or how rare that aspect is, are not labeled as gifted.

(4) *The Demonstrability Criterion.* The demonstrability criterion states that the *superiority of the individual on the dimension(s) which determine giftedness must be demonstrable through one or more tests that are valid assessments.*

The individual needs to be able to demonstrate, in one way or another, that he or she really has the abilities or achievements which led to the judgment of "giftedness". Simply claiming giftedness is not enough. Thus, a person who scores poorly on all measures used in assessment, and who is unable to demonstrate in any compelling alternative way that he does indeed have special abilities, will not be viewed as gifted.

The assessment instrument(s) used, however, must be both valid and reliable. Consider the importance of validity and reliability.

Validity means that each instrument is believed to measure what it is supposed to measure. If, for example, a child presents a high score on a new intelligence test that requires only that the child dot i's, the result will not be valid. Dotting is not an acceptable measure of intelligence. Or suppose that a job candidate gives a brilliant job talk, suggesting unusual gifts both in research and in presentation. But then, when asked

about the content of the talk, he is unable even to answer the simplest of questions. Gradually, members of the audience conclude that the job candidate was somehow programmed, probably by his advisor. In fact, he has no idea of what he was talking about. The job talk would then be invalid as a measure of the candidate, because it did not actually reflect his gifts (or lack thereof).

Validity is also critical in cases in which outside factors are taken into account when judging responsibility for a performance or demonstration of ability. For example, personal background is sometimes taken into account in interpreting what scores on an assessment mean. Admissions and scholarship offices often consider the kind of environment a person comes from in making decisions about admissions and financial aid. Two people with exactly the same demonstrated abilities and achievements would very likely not be judged as equal if one comes from an inner-city ghetto providing virtually no opportunities, and the other hails from a very wealthy, upper socio-economic class suburb with practically unlimited opportunities. The extent to which the two individuals may be treated differently is a reflection of the view that identical scores on the same assessments in fact do not necessarily mean the same thing because of external factors.

The validity issue has become extremely important in recent years in the identification of intellectually gifted schoolchildren. In the past, many schools were content to use standardized intelligence tests, and perhaps grades in school and scores on achievement tests, as bases for identifying children as intellectually gifted. As the focus of testing has been shifting more and more toward an emphasis on performance- and product-based assessment, however, some have questioned the validity of the traditional measures (e.g., Gardner, 1983; Renzulli, 1986). Someone who would have been labeled as gifted under traditional measures before might not now be so labeled. The implicit theory of giftedness may not have changed, but what is considered valid as a demonstration of giftedness may have.

Reliability of measurement implies that the same person should receive the same score on a test time after time under similar conditions. It guarantees against strokes of luck or even a rare confluence of circumstances that leads to a high measurement of ability. If an individual performs at a superior level on a multiple-choice military entrance exam, but is never able to repeat anything close to that performance, one is likely to conclude that he simply had a lucky day. Perhaps his guesses just happened to pay off that day. Or perhaps the circumstances of testing were just right and every possible factor that could work in his favor did, something that will never happen again. In the latter case, the test result might even have been valid for that moment, but because the result is not replicable, he does not meet the demonstrability criterion.

(5) *The Value Criterion.* The value criterion states that for a person to be labeled as gifted, *the person must show superior performance in a dimension*

that is valued for that person by his or her society.

The value criterion restricts the label of giftedness to those who hold attributes that are valued as relevant to giftedness. An academic considered to be brilliant may publish papers prolifically, churning out a new article every few months. These papers, however, are rarely cited by other academics. They are being read, but they are not causing any ripples in the surface of the academic pond. Is she gifted? This professor has a rare intelligence and knowledge which she has devoted her life to developing. Certainly she is quite productive. To the outside world she may appear quite gifted. But a hallmark of the significance of an academic journal article is its stimulating effect on other researchers—does it spark fresh perspectives on their own work, or open up new areas of inquiry? If not, then the work may not be valued by peers, and in this case, the academic will not be considered gifted by them.

The individual who is number 1 on the FBI's most wanted list might be superior in one or more dimensions, rare in his ability to perform certain malevolent acts, and able to demonstrate his skills upon demand. He may even be highly productive, if in a criminal way. But because what he is so good at is not valued by society at large, he is not likely to be labeled as gifted by the American populace. Still, it is quite possible that he would be labeled as gifted by a pack of thieves; the pentagonal theory allows that what is prized as a basis for giftedness may differ from one culture or even subculture to another.

Some readers will be uncomfortable with the relativism of this stance. Was Hitler gifted if neo-Nazis believe him to have been? How about Stalin? Is there not some absolute moral basis for screening them out? And what about changing esthetic tastes? We occasionally look back and see cases of unappreciated giftedness. Johannes Sebastian Bach was not viewed as eminently gifted in his day, but now he is; many artists only achieve fame and recognition posthumously. Furthermore, there are cases of people viewed as gifted in their time who ultimately made little mark in history of their field; the composer Salieri, for example. And who is qualified to judge giftedness, anyway?

There is an answer to these problems, but it is not an absolute one.

The pentagonal theory allows us to say that people of another place or time have erred in their evaluations of a person's gifts. If we do so, it is true that we are claiming a privileged position with regard to the identification of someone as gifted. We are arguing that our values are right because those of certain others were wrong, or because these others did not have access to information we now have. In either of these cases, we are claiming the privilege of being in a superior position to judge. What we must realize, of course, is that others may do the same with respect to us in some other time or place.

Implicit theories by nature are relativistic; there is never any guarantee that people's personal values will

match across time and space. But implicit theories, as noted above, provide the best practical form or structure by which to identify the gifted. For a judgment to occur according to strict standards, one needs to add content to implicit theories. This is the role of explicit theories, considered next.

Alternative Views of Intelligence and Giftedness

The remainder of the chapter is divided into two major parts. In the first, I will consider two main historical traditions in the testing of intelligence, both in terms of the theories of intelligence upon which much later work was based, and in terms of the tests that emanated from these theories. In the second part, I will consider alternative metaphors of mind and how they have influenced the testing of intelligence.

Historical Views of Intelligence and Giftedness

If current thinking about the nature of intelligence owes a debt to any scholars, the debt is to Sir Francis Galton and to Alfred Binet. These two investigators—Galton at the end of the nineteenth century and Binet at the beginning of the twentieth century—have had a profound impact on our thinking about intelligence, an impact that carries down to the present day. Many present conflicts regarding the nature of intelligence can be traced to conflicts between Galton and Binet. To understand contemporary thinking about and measurement of intelligence and giftedness, one needs to know how Galton and Binet conceived of intelligence.

Sir Francis Galton's View of Intelligence

GALTON'S THEORY

Galton (1883) believed two general qualities distinguished the more from the less intellectually able. The first was *energy*, or the capacity for labor. Galton believed that intellectually gifted individuals in a variety of fields were characterized by remarkable levels of energy. His second general quality was *sensitivity*. Galton observed that the more sensitive the senses are with respect to differences in luminescence, pitch, odor, or whatever, the larger is the range of information on which intelligence can act. Galton also believed that intellectual gifts were inherited rather than environmentally determined.

GALTON'S TESTS OF INTELLIGENCE

For seven years (1884–1890), Galton maintained an anthropometric laboratory at the South Kensington Museum in London where, for a small fee, visitors could have themselves measured on a variety

of psychophysical tests. One such test was weight discrimination. The apparatus consisted of a number of cases of cartridges, filled with alternative layers of shot, wool, and wadding. The cases were all identical in appearance, and differed only in their weights. Subjects were tested by a sequencing task. They were given three cases, and with their eyes closed, had to arrange them in proper order of weight. The weights formed a geometric series of heaviness, and the examiner recorded the finest interval that an examinee could discriminate. Galton suggested that similar geometric sequences could be used for testing other senses, such as touch and taste. With touch, Galton proposed the use of wire-work of various degrees of fineness, whereas for taste, he proposed the use of stock bottles of solutions of salt of various strength. For olfaction, he suggested the use of bottles of attar of rose in various degrees of dilution.

James McKean Cattell brought many of Galton's ideas across the Atlantic to the United States. Cattell (1890) proposed a series of fifty psychophysical tests, such as the greatest possible pressure one could achieve by squeezing one's hand and the distance on the skin by which two points must be separated in order for them to be felt as separate points. Thus, Cattell took Galton's theory and refined the measures that could be used to assess intelligence, based on this theory.

Psychophysical tests find little or no place in modern-day tests of intelligence as administered in schools and in industry. The coup-de-grace was administered by a student in Cattell's own laboratory. Clark Wissler (1901) proposed that Cattell's tests should correlate both with each other and with external criteria of academic success, such as grades in the undergraduate program at Columbia University. Wissler found a sample of Cattell's tests to correlate with each other only at the level that would be expected as a result of a distribution corresponding to the laws of chance. Moreover, he found that whereas students' grades in college correlated with each other at a very high level, they showed only trivial correlations with the mental tests of Cattell, as based on the work of Galton. Wissler concluded that his tests told us nothing about the general ability of college students, and indeed, he interpreted his results as casting doubt on the notion that there even exists such a thing as general intelligence. Ironically, the relative intellectual giftedness of the students tested (Columbia was and still is a highly selective university) may have restricted range and resulted in correlations lower than the true ones.

Let us approach the Galtonian view from the standpoint of the pentagonal implicit theory discussed earlier. According to Galton's theory, the *excellence* and *rarity* criteria discussed earlier were in terms of psychophysical skills. *Demonstrability* was easy: Subjects took psychophysical tests that measured these skills. But was Galton (and later Cattell) *valuing* the kind of skill that would later give rise to intellectual *productivity* (the two other criteria of the pentagonal

implicit theory)? Many people thought not, among them Alfred Binet.

Alfred Binet's View of Intelligence

BINET'S THEORY

Binet and Simon (1916) theorized that intelligent thought is composed of three distinct elements: direction, adaptation, and criticism. Direction consists of knowing what has to be done and how it is to be accomplished. When we are required to add two numbers, for example, we give ourselves a series of instructions on how to proceed, and these instructions form the direction of thought. The direction need not be conscious. Adaptation refers to one's selection and monitoring of one's strategy during the course of task performance. Criticism, or control, is the ability to criticize one's own thoughts and actions. Binet and Simon (1916) believed much of this ability to be exercised beneath the conscious level. The above formulation should make clear that, contrary to the contemporary conventional wisdom, Binet was not atheoretical in his approach to intelligence and its development. On the contrary, he and Simon conceived of intelligence in ways that were theoretically sophisticated—more so than much of the work that followed theirs—and that resembled in content much of the most recent thinking regarding metacognitive information processing. Whatever may be the distinction between the thinking of Binet and that of Galton, it is not that Galton was theoretically motivated and that Binet was not. If anything, Binet had a more well-developed theory of the nature of intelligence than did Galton. Instead, the distinction was in the way these scientists selected items for the tests that they proposed to measure intelligence, and in the degree of correspondence between theory and test.

BINET'S TEST OF INTELLIGENCE

The Binet tests, as revised in the United States by Lewis Terman, consisted of a variety of exercises that measure higher order thinking abilities. For example, at the two-year-old level, children might be required to put circular, square, and triangular pieces into holes on a board of appropriate shape, or to identify parts of the body. At age eight, tests include defining words, recognizing why each of a set of statements is foolish, and requiring children to say how each of two objects is the same as, and different from, the other. By age fourteen, tests have become more complicated, and include, beside vocabulary, tests such as reasoning, requiring solution of arithmetic word problems, and ingenuity, requiring individuals to indicate the series of steps that could be used to pour a given amount of water from one container to another.

Galton chose test items so that they would correspond quite closely to his theory of intelligence in terms of

psychophysical ability. Binet chose items to measure the judgmental abilities upon which his theory focused, but these items were also chosen so that they would differentiate between the performance of children of different ages or mental capacities as well as be intercorrelated with each other at a reasonable level.

Binet's tests were not as closely allied to his theory as were Galton's. Binet valued and sought *excellence* and *rarity* in judgment. Although the items do measure judgmental abilities, the judgments that need to be made are somewhat artificial, and are generally removed from real-world judgmental tasks. At best, they mimic simple school tasks, but they capture little of the richness of the kinds of judgments we need to make when we make important business or life decisions, such as whether to buy a house or a car. Thus, the *demonstrability* of judgment was in a relatively limited domain. Binet's theory was much closer in its conception to real-world intelligence than was Galton's. His test items, distant as they were from real-world problem solving and decision making, were better predictors of these things than were Galton's test items. But it wasn't clear that people who produced top-quality responses to his test items would necessarily be those who produced top-quality work in their lives outside a testing situation.

Modern Metaphors and Their Implications for Testing

In this section of the chapter, I consider various alternative modern metaphors of mind, and their implications for the testing of intelligence and giftedness. I will consider seven metaphors: the geographic, the computational, the biological, the epistemological, the anthropological, the sociological, and the systems metaphors. Each views the mind in a different way, and has somewhat different implications for how intelligence should be tested.

The important message in the consideration of these metaphors is that intelligence tests are no more a unitary phenomenon than is intelligence itself. Boring's (1923) view that intelligence is what the tests test, an operational view that has been oft-repeated since Boring suggested it (e.g., Jensen, 1969), is meaningless. The way in which intelligence is tested will depend upon a theory of intelligence, and this theory will in turn depend upon a metaphorical theory of mind. Boring's view of intelligence being what the tests test was probably based on theories generated by the geographic metaphor (i.e., a metaphor of intelligence as a map of the mind). But there are alternative metaphors that can generate theories and tests of intelligence, and none of these metaphors is privileged with respect to the others in terms of any kind of validity for the tests so generated. Most tests have been based upon the geographic metaphor, but this is an historical accident rather than a logical or psychological necessity. Any metaphor is capable of generating theories and tests,

and indeed, most have done so. Thus, the message of the metaphorical approach is that our conceptualization of intelligence needs to be broader than it has been, and more receptive to alternative viewpoints. The alternative metaphors are not mutually exclusive, but rather, in large part, complementary. They deal with different aspects of intelligence, as seen from different points of view. Metaphors are not right or wrong, but rather more or less useful for a particular purpose. A full understanding of intelligence needs to embrace multiple metaphors.

Metaphors Viewing Intelligence as Internal to the Individual

The Geographic Metaphor

The geographic metaphor views a theory of intelligence as providing a map of the mind. This view extends back as least to Gall, perhaps the most famous of phrenologists. Gall implemented the metaphor of a map in a literal way, investigating the topography of the head. The measure of intelligence, according to Gall, resides in a person's pattern of cranial bumps.

During the first half of the twentieth century, the metaphor of intelligence as something to be mapped dominated theory and research. However, the metaphor of the map became more abstract, and less literal, than it had been for Gall. The psychologist studying intelligence was both an explorer and a cartographer, seeking to chart the innermost regions of the mind. Visual inspection and touching just would not do. The psychologists needed tools such as factor analysis to understand the mind's structure.

GEOGRAPHIC THEORIES

Geographic theories of the mind are, for the most part, factor based. They view intelligence in terms of factors, which Vernon (1971) likened to lines of longitude and latitude. The factors produce a space that comprises the various mental abilities proposed to constitute intelligence.

The earliest of the major geographic theories, that proposed by Charles Spearman (1927), proposed a "two-factor" theory of intelligence. The theory posits a general factor, common to all tasks requiring intelligence, and one specific factor unique to each type of task. Godfrey Thomson (1939) later criticized Spearman's theory, arguing that it was possible to have a general factor in the absence of a general ability in the head. To Thomson, *g* was not a statistical reality but a psychological artifact resulting from the workings of an extremely large number of what Thomson called "bonds", all of which are sampled simultaneously in intellectual tasks.

Later, Thurstone (1938) proposed the theory of primary mental abilities, according to which intelligence

comprises seven such abilities: verbal comprehension, verbal fluency, number, memory, perceptual speed, inductive reasoning, and spatial visualization. Thurstone was antagonistic to Spearman's theory of *g*, because he believed that Spearman's general factor was obtained only because Spearman failed to rotate his factorial axes upon obtaining an initial solution. Thurstone suggested that the general factor was merely an epiphenomenon of the correlations among the primary mental abilities.

Some of the more recent theories of intelligence based on the geographic metaphor have been hierarchical. For example, Vernon (1971) proposed a hierarchical theory, with *g* at the top of the hierarchy and two major group factors, verbal-educational ability and spatial-mechanical ability, below general ability. Cattell (1971) proposed a theory similar to Vernon's, although the theory is much more detailed. The two abilities of greatest interest for present purposes are what Cattell referred to as crystallized and fluid abilities. Crystallized ability is essentially the accumulation of knowledge and skills throughout the life course, whereas fluid ability is flexibility of thought and ability to reason abstractly. Gustafsson (1984) has used confirmatory factor analysis to study the model of Cattell, and has come to the conclusion that the general factor of Spearman is essentially identical to Cattell's fluid ability factor.

Not all recent theorists have taken the hierarchical approach. Guilford (1967; Guilford & Hoepfner, 1971) posited 120 distinct abilities (increased to 150 by Guilford, 1982), organized along three dimensions. These dimensions are operations, products, and contents. As there are five operations, six products, and four contents, at least in an earlier version of the theory, there are a total of $5 \times 6 \times 4 = 120$ abilities.

Yet a different organization of abilities was proposed by Guttman (1954), whose radex, or radial representation of complexity model, consists of two parts. The first part is what Guttman refers to as a simplex. If one imagines a circle, then the simplex refers to the distance of a given point (ability) from the center of the circle. The closer an ability is to the center of the circle, the more central it is to human intelligence. Thus, *g* could be viewed as being at the center of the circle, whereas the more peripheral abilities, such as perceptual speed, would be nearer to the periphery of the circle. The second part of the radex is called a circumplex. It refers to the angular orientation of a given ability with respect to the circle. Thus, abilities are viewed as being arranged around the circle, with abilities that are more highly related (correlated) nearer to each other in the circle. Snow, Kyllonen, and Marshalek (1984) have used non-metric multidimensional scaling in order to demonstrate that the Thurstonian primary mental abilities can actually be mapped into a radex.

GEOGRAPHIC TESTS

Intelligence testing has been dominated almost exclusively by the geographic metaphor. Indeed, intelligence testing and the main methodology through which the

geographic metaphor has been operationalized—factor analysis—grew up hand in hand. Not only is it difficult, historically, to separate testing from the geographic metaphor, but for many if not most of the people who do testing, there is no other way with which they are familiar. The goal of testing, for these people, is to obtain one or more scores corresponding to levels of ability with respect to each of the regions of the mind posited by a given theory, whether it is just a single region or multiple regions. Even those who do not subscribe to the geographic metaphor often end up using tests generated under the geographic metaphor as the criterion by which the validity of their tests will be judged.

Although geographically-based tests bear some resemblance to each other, the content of a given test will depend on the theory from which it is derived. For example, tests based upon Spearman's (1927) notion of *g* tend to measure what Spearman (1923) called "apprehension of experience", "eduction of relations", and "eduction of correlates". In more modern terms, these might be called encoding of stimuli, inference of relations, and application of relations. They tend to be measured by test items such as analogies, number series, classifications, and matrix problems. Frequently, figural (abstract) content is used in order to minimize effects of knowledge. Tests based on Thurstone's (1938) theory, including Thurstone and Thurstone's (1962) own test of primary mental abilities, measure skills relevant to each of the seven posited abilities, such as vocabulary (verbal comprehension), mathematical computation in problem solving (number), and mental rotation (spatial visualization). Consistent with the notions of Gustafsson (1984), tests based upon Cattell's (1971) notion of fluid ability tend to look very similar to tests of Spearman's *g*, including Cattell and Cattell's (1963) own test. Tests that measure crystallized ability as well, such as the Stanford-Binet or Wechsler, are likely to be more heavily loaded with items measuring vocabulary and general information.

In terms of the pentagonal implicit theory, geographic tests *value* the kinds of abilities emphasized by Binet, including judgment, reasoning, and problem-solving abilities. *Excellence* and *rarity* are measured by Binet types of items, with the exact items used determined by the theory. I would argue that there are good reasons for *valuing* abilities and having tests based on metaphors other than the geographic one.

First, it is not clear that the tests generated under the geographic metaphor really should serve as the standard against which other tests are measured. The fact that such tests have been in existence for a number of years does not in itself make them a (or *the*) viable standard. Second, new tests might provide an operational basis for expanding our concept of intelligence—for valuing other abilities that might lead to greater *productivity* in a variety of domains. To the extent that the tests do not correlate highly with conventional ones, we need at least to be open to the possibility that the new tests

are measuring an aspect of intelligence that the old ones do not measure. There may be kinds of giftedness that conventional tests do not identify.

Third, new tests can give us kinds of information that are not yielded by conventional psychometric tests, regardless of the correlation of the new tests with the conventional ones. They cannot only give us new information, but can help us conceive of individual people's intelligence in new ways. Let us therefore consider other metaphors, and both the theories and tests that they have generated.

The Computational Metaphor

During the last decade, the predominant metaphor for studying intelligence has probably been that of the computer program. Researchers have sought to understand intelligence in terms of the information processing that people do when they think intelligently. Information-processing investigators have varied primarily in terms of the complexity of the processes they have sought to study. They have taken rather widely differing approaches.

Computational theorists tend to be highly critical of geographic approaches and especially of the individual who is seen as the originator of the geographic approach, Charles Spearman. It is therefore ironic, as few computational theorists realize, that the computational approach to intelligence, like the geographic one, dates back to none other than Charles Spearman.

COMPUTATIONAL THEORIES

Spearman (1923) proposed what he believed to be three fundamental qualitative principles of cognition (mentioned earlier). These principles—apprehension of experience, education of relations, and education of correlates—are mental processes that Spearman believed to be components of general intelligence. Programs devised under the banner of artificial intelligence have used these processes heavily, and in some cases have even been built around these processes (e.g., Evans, 1968).

Historically, the greatest impetus for the computational approach to understanding intelligence can be traced to the pioneering work of Newell, Shaw, and Simon (1958) and others who constructed computer programs that could perform "intelligently". These AI programs are summarized in books such as Boden (1977) and Stillings et al. (1987), and will not be reviewed here. Rather, I will concentrate on more recent human-experimental work that has had more direct implications for the testing of intelligence.

Hunt, Frost, and Lunneborg (1973) suggested that one way to understand intelligence would be to test subjects in their ability to perform tasks that contemporary cognitive psychologists believe measure basic human information-processing ability. The proximal goal in this research would be to estimate parameters

(characteristic quantities) representing the durations of performance for information-processing components constituting each task, and then to investigate the extent to which these components correlate across subjects with each other and with scores on measures commonly believed to assess intelligence. Sternberg (1977) later expanded upon this logic in his approach called "componential analysis". The overall purpose of componential analysis is to identify the component mental operations underlying a series of related information-processing tasks and to discover the organization of these component operations in terms of their relationships both to each other and to higher order constellations of mental abilities. The fundamental unit of analysis in componential analysis is the component, which is an elementary information process that operates upon internal representations of objects or symbols (see also Newell & Simon, 1972). The components may translate a sensory input into a conceptual representation, transform one conceptual representation into another, or translate a conceptual representation into a motor output. Componential analysis can be used to decompose task performance into (a) the component processes that combine to produce it, and (b) the strategies into which these component processes integrate themselves. Using componential analysis, the investigator can determine the length of time a given person spends on each mental process and the susceptibility of the process to an error.

Various information-processing theories of intelligence have been proposed, based on the computational metaphor. Brown (1978; Brown & Campione, 1978) has divided processes of cognition into two kinds: metacognitive processes, which are executive skills used to control one's information processing; and cognitive processes, which are nonexecutive skills used to implement task strategies. She suggests that five metacognitive processes are of particular importance: planning one's next move and executing a strategy, monitoring the effectiveness of individual steps in a strategy, testing one's strategy as one performs it, revising one's strategy as the need arises, and evaluating one's strategy in order to determine its effectiveness.

Sternberg (1980) distinguishes among metacomponents, which are similar to Brown's metacognitive processes, performance components, and knowledge-acquisition components. Thus, Brown's cognitive processes are subdivided into two categories in Sternberg's theory. Whereas performance components are lower order processes used in the execution of various strategies for task performance, knowledge-acquisition components are processes involved in learning new information and storing it in memory.

Hunt (1980) has distinguished between mechanical processes that are relatively content-free and processes that are more knowledge-based. Hunt has emphasized mechanistic processes as, in many cases, being rather general across information-processing tasks.

Baron (1985) has proposed a theory of intelligence whereby rational thinking is the cornerstone of intelligence. Baron defines intelligence as the set of properties that make for effectiveness, regardless of the environment a person is in. Although intelligence is based on rational thinking, it goes beyond rational thinking in including personal endowments such as capacities of knowledge that can lead to success.

COGNITIVE TESTS

Computationally based tests, regardless of their particular content, give information that is quite different in kind from the information obtained from geographically-based tests. Typical information yielded by such computational tests would be the processes used to solve problems; the strategy or strategies into which these processes are combined; the amount of time spent on each process, and, in some cases, the susceptibility of each process to errors; and also, in some cases, the form of representation of information in the mind (see, e.g., Hunt, Lunneborg, & Lewis, 1975; Sternberg & Gardner, 1982). Geographically-based tests do not give us these kinds of information, except perhaps in a confounded fashion. Indeed, psychometric factors are often a combination of process and content that makes it difficult to separate the effects of the two. In this view, a gifted individual may be gifted in one or more of several aspects of information processing: strategy selection, speed of strategy execution, formation of effective mental representations, and so on.

The tasks that are used in the computational approach depend upon the particular computational theory under consideration. Jensen (1982), for example, emphasizes very low levels of information processing in attempting to understand the computational bases of intelligence. He will typically present subjects with a choice reaction-time task, which requires subjects to select among various buttons upon the presentation of the choice stimulus. Jensen is a believer in the notion that intelligence largely derives from sheer mental speed, and his use of relatively simple tasks reflects this theoretical disposition. Hunt (1978) uses somewhat more complex tasks, believing that intelligence involves more complex operations. For example, he relates verbal ability to the speed of retrieval of lexical information from long-term memory. In order to measure this speed, he uses tasks such as the Posner and Mitchell (1967) Letter-Matching task, in which subjects are asked to state as quickly as possible whether the letters in a pair such as "A a" constitute a physical match (which they don't) or (in another condition) a name match (which they do). As a measure of speed of memory scanning, Hunt uses the S. Sternberg (1969) memory-scanning task, in which subjects are asked to state as quickly as possible whether a target digit or letter, such as 5, appeared in a previously memorized set of digits or letters, such as 3 6 5 2. Individuals are usually tested in these situations either via a tachistoscope (a machine that provides rapid stimulus

exposures) or a computer terminal, and the principal dependent measure of interest is response time.

Sternberg (1977; see also Sternberg, 1983) has used more complex tasks to measure intelligence (see also Simon, 1976). Indeed, the tasks are generally those that are found on conventional psychometric intelligence tests, such as analogies, series completions, classifications, and syllogisms of various kinds. In his information-processing work, Sternberg emphasized the difference from the geographic approach not in the tests used, but in the way in which test performance was analyzed. Thus, the computational approaches have in common not any one particular content that might appear on the tests, but rather their allegiance to understanding the computational processes involved in intelligence—how a person processes a problem requiring intelligence, from when she first sees that problem to the time that she reaches a solution.

In terms of the pentagonal implicit theory, computational tests *value* quality of information processing, and not just the products of such processing. *Excellence* and *rarity* are assessed in terms of aspects of processing (such as speed of strategy selection) rather than in terms of products of various kinds of judgments. Quality of information processing is *demonstrated* through measurement of speed and profiles of errors in various kinds of information-processing tasks, which tend to be simpler than those found in geographically-based tests. Because of the simplicity of many of these tasks, *productivity* on the tasks may be even less related to everyday performance than is the case for the geographically based measures.

The Biological Metaphor

The biological metaphor provides a basis for understanding intelligence by studying the brain and the operation of the central nervous system. It is the most reductionist of the various metaphors, in that one seeks understanding of intelligence directly in terms of biological function, rather than indirectly through molar levels of processing. According to these views, the gifted individual is biologically superior to others. However, I will argue that the inferences that can be made from the biological approach, both about intelligence in general and about giftedness in particular, are often as indirect and even, at times, more indirect than are the inferences that are made from alternative approaches. Although adherents to the biological metaphor have in common their interest in studying intelligence in terms of the brain and central nervous system, they differ fairly widely in the approaches they take for studying intelligence.

BIOLOGICAL THEORIES

Biological approaches are of three main kinds: neuropsychological approaches, which seek to understand intelligence in terms of the size and structure of the brain; electrophysiological approaches,

which seek understanding of intelligence in terms of electroencephalographic measurement; and blood-flow approaches, which seek to understand intelligence in terms of the flow of blood to various portions of the brain during thinking. I will consider each of these approaches briefly in turn.

Neuropsychological approaches to intelligence are often traced back to Hippocrates, who in the fifth century BC suggested that the brain might be the basis of human intelligence. In more recent times, one of the earlier general theories of brain function was proposed by Halstead (1951). He suggested four biologically-based abilities: the integrative field factor (C), the abstraction factor (A), the power factor (P), and the directional factor (D). More influential in recent times has been Hebb's (1949) theory. Hebb proposed the concept of the *cell assembly*. Repeated stimulation of specific receptors slowly leads to the formation of an assembly of cells in the association area of the brain. These cells can act briefly as a closed system after stimulation is stopped. Hebb assumes that the process accompanying synaptic activity makes the synapse more readily traversed. Any two cells or systems of cells repeatedly active at the same time tend to become associated. If collections of cells become associated, they form cell assemblies. An individual cell or other unit of transmission may enter into more than one assembly at different times. Moreover, over time, it may enter into new cell assemblies or drop out of old ones. The cell assembly acts on an all-or-none basis. In other words, it fires or it does not. Hebb uses the concept of a cell assembly to account for many different psychological phenomenon, among which is intelligence.

Another theory that has had great impact on the field of intelligence research and testing has been that of a Russian psychologist, Alexander Luria (1973, 1980). Luria believed that the brain is a highly differentiated system whose parts are responsible for different aspects of a unified whole. In other words, separate cortical regions act together to produce thought and action of various kinds. Luria (1980) suggested that the brain comprises three main units. The first, a unit of arousal, includes the brain stem and midbrain structures. Included within this first unit are the medulla, reticular activating system, pons, thalamus, and hypothalamus. The second unit of the brain is a sensory-input unit, which includes the temporal, parietal, and occipital lobes. The third unit includes the frontal cortex, which is involved in organization and planning.

Some of the most interesting theorizing within the neuropsychological approach has been done by those who study hemispheric specialization. This work goes back to Marc Dax, an obscure country doctor in France, who in 1836 presented a little-noticed paper to a medical society meeting in Montpellier. Dax had treated a number of patients suffering from a loss of speech as a result of brain damage. He noticed the connection between loss of speech (aphasia) and the side of the brain in which damage had occurred. Indeed, having

studied more than forty patients with aphasia, Dax noticed that in every case there had been damage to the left hemisphere of the brain. The paper aroused no interest. In more recent times, the father of split-brain research has been Roger Sperry, who has argued that each hemisphere behaves in many respects like a separate brain (e.g., Sperry, 1961). It would be hard to overstate the contribution of Sperry to modern split-brain research, especially because so many of the people working in the area have been graduate students of Sperry or have worked at one time or another in his laboratory.

Although there are arguments as to the exact functioning of each hemisphere, it is generally agreed that visual and spatial functions are primarily localized in the right hemisphere, and language functions in the left. One of the most interesting experiments demonstrating this localization was done by Jerre Levy and her colleagues (Levy, Trevarthen, & Sperry, 1972). They showed that when split-brain patients (those with their corpus callosum severed) are shown so-called chimeric faces—faces that have one appearance in the left half and another appearance in the right half—they are unaware that the information in the two halves of the picture conflicts. When asked to respond vocally to what they see, they choose the picture from the right-field half of the chimeric stimulus, because the left hemisphere controls language processing and controls the body contralaterally. But when asked to point, subjects choose pictures from the left-field, indicating right-hemispheric control of their movement. In other words, the task that the subjects are asked to perform is crucial in determining what face the subject will believe him or herself to have seen.

Gazzaniga (1985) has argued that the brain is organized modularly, into relatively independently functioning units that work in parallel. His view is in the spirit of present connectionists models of human performance (McClelland & Rumelhart, 1986). There exist many discrete units of the mind, each operating relatively independent of the others. Moreover, many of these modules operate at a level that is not conscious. They operate in parallel to our conscious thought, and contribute to conscious processing in identifiable ways. In particular, the left hemisphere assigns interpretations to the processing of these modules. Thus, the left hemisphere may perceive the individual operating in a way that doesn't make any particular sense or that is not particularly understandable, and its job is to assign some meaning to that behavior. This view is also largely consistent with that of Fodor (1983), who also believes that information processing is largely determined by independent modules operating in parallel.

A very different biological approach is the electrophysiological one. Early studies tended to use electroencephalogram (EEG) measurements. The idea was to relate patterns of EEG activity to intelligence or other cognitive functions. For example, Galin and Ornstein (1972) showed a link between amount of EEG

activity in each of the hemispheres and the type of tasks performed by a subject. In particular, they found that the ratio of right to left hemisphere EEG processing was greater in verbal than in spatial tasks. This pattern of results might seem to be the opposite of what would be expected. However, Galin and Ornstein were measuring alpha activity, which tends to be associated with the brain at rest. Therefore, higher ratio indicates less active processing by the hemisphere of the brain being measured at a given time.

Some of the most interesting electrophysiological work has been done by Emanuel Donchin and his colleagues at the University of Illinois. Much of this work has utilized the P-300 wave form. The label P-300 refers to a positive component of evoked potentials that has a latency of anywhere from 300 to 900 milliseconds after the presentation of a stimulus. P-300 has been linked to processes of stimulus identification and classification (McCarthy & Donchin, 1981). The amplitude of P-300 seems to reflect the allocation of cognitive resources to a given task. P-300 seems to be stronger, the greater the amount of surprise that a subject experiences as a result of the presentation of the stimulus.

Schafer (1982) has suggested that a tendency to show a large P-300 response to surprising stimuli may be an individual-differences variable. Schafer believes that a functionally efficient brain leaves fewer neurons to process a stimulus that is familiar and more to process a stimulus that is novel or unfamiliar. In other words, according to Schafer, more intelligent individuals should show a greater P-300 response to novel stimuli than would less intelligent ones. At the same time, more intelligent individuals should show smaller P-300 to expected stimuli than should less intelligent ones.

Hendrickson and Hendrickson (1980) have conducted a program of theory and research attempting to link electrophysiological responses to observed intelligence. Their measurements are obtained while the subject is at rest. Their basic theory suggests that errors can occur in the passage of information through the cerebral cortex. These errors are alleged to be responsible for variability in evoked potentials. Thus, it would follow that individuals with normal circuitry that conveys information accurately will form correct and accessible memories more quickly than individuals with "noisy circuits", who will make errors in transmission. Moreover, the Hendricksons have suggested that individuals with low IQs will have noisy channels of information processing. When evoked potentials are averaged out, the potentials will have a smoother appearance (because of averaging over the noise) than those produced by individuals with more consistent and less noisy channels.

The third of the biological approaches relates cerebral blood flow to intelligence. The idea is that blood goes to portions of the brain that are being used in the processing of a task. It is possible to use radioactive tracers that are inhaled in order to monitor flow of blood during information processing. Using this approach, one could monitor blood flow as a function

of the task being performed and who is performing it.

BIOLOGICAL TESTS

Biologically-based tests provide information that is different in kind from either geographically-based or computationally-based ones. Biological tests may indicate specific neuropsychological deficits, patterns of hemispheric specialization, performances of different regions of the brain, or in the case of evoked-potential measurement, patterns of brain waves. The interpretability of this information, as in the case of any test information, will depend upon the quality of the theory upon which the test is based. But biologically-based tests are, for the most part, the only ones that really map onto brain functioning, whether directly or indirectly.

Halstead constructed a test of functioning based upon his theory, and more recently, J. P. Das and Jack Naglieri have been working on a test based on Luria's theory. Das and his colleagues have constructed an impressive array of tests that measure all three aspects of functioning in Luria's theory, namely, attention-arousal, planning, and mode of processing. With respect to the last, Das's tests measure both simultaneous and successive processing. Simultaneous processing refers to the parallel processing of multiple chunks of information at a time. Successive or sequential processing refers to serial processing of chunks of information, one following the other. Tests such as Raven Matrices and Gestalt Closure would measure simultaneous processing, whereas serial-recall tests would measure successive processing.

Das and Naglieri are not the first to construct a test based on Luria's theory. Two other such tests are the Luria-Nebraska Neuropsychology Battery (LNNB) (Golden, 1981) and the Kaufman Assessment Battery for Children (K-ABC) (Kaufman & Kaufman, 1983). This latter test does not measure the attention-arousal and planning function separately, but it does measure simultaneous and successive processing and provides separate scores for each. I have reviewed this test elsewhere in some detail (Sternberg, 1985). The K-ABC also has a separate achievement section, which is similar to what one would find on other tests of verbal intelligence, such as the Stanford-Binet.

Measurement of evoked potentials has been especially popular among adherents to the biological metaphor who are interested in testing. For example, Schafer reported a correlation of 0.82 between an individual-differences measure of evoked potential and IQ. In line with his theory, the higher the IQ, the greater the difference in evoked potential amplitude between expected and unexpected stimuli. This result suggests that more intelligent individuals are more flexible in responding to novel stimuli than are less intelligent individuals. The Hendricksons (1980) have published pictures of what they reported to be typical wave forms for subjects with high and low IQ. The wave forms for subjects with high IQs are more complex than the wave

forms for subjects with low IQs, consistent with their theory. The Hendricksons used a string to measure the length of the wave forms over a given period of time, on the view that greater string length would reflect greater complexity in the wave form and hence higher IQ. Somewhat oddly, given the reliabilities of the measures, they obtained a correlation of 0.83 between an evoked potential measure and scores on the Wechsler Adult Intelligence Scale. A replication of this study has been reported by Blinkhorn and Hendrickson (1982), using Raven's Advanced Progressive Matrices as well as a variety of verbal intelligence tests. In this study the correlation was 0.84, corrected for restriction of range. These correlations are so high as to be troubling to some, myself included.

Blood flow has also been used in the measurement of intelligence (see Horn, 1986). It is actually possible to relate blood flow to different regions of the brain for tasks requiring crystallized versus fluid abilities. This approach is more direct than the evoked-potentials approach, because it is possible to determine in just what portion of the brain processing is taking place.

The biological metaphors have generated a substantial amount of research relating functioning of the brain to cognition, in general, and to intelligence, in particular. The relation between biological measures and psychometrically assessed intelligence is by no means straightforward. For example, what does it mean to show a relationship between average evoked potentials and psychometrically-derived intelligence test scores? Do the evoked potentials somehow cause intelligent cognition? Or equally plausibly, does intelligent cognition lead to certain patterns of evoked potentials? Or do both intelligent information processing and evoked potentials depend on some aspect of the brain, whether conceived biologically or cognitively? As one reflects on the correlation, one is reminded of the rule one learns in school that one cannot infer causation from correlation.

Despite the striking magnitude of some of the correlations, we are a long way from understanding the neural mechanisms that are actually responsible for them. Indeed, it is possible that when given instructions simply to sit and not perform any particular task, the more intelligent subjects may be busy thinking about issues that are on their minds, whereas the less intelligent subjects may be less likely to be thinking in this way, or at all! This difference might generate a correlation. Indeed, the evidence suggests that the correlation between evoked-potential measures and conventional intellectual measures goes down as subjects perform more and more complex tasks. In other words, when subjects are actually doing a complex task, one no longer obtains so easily a correlation between average evoked potentials and scores on that test. I believe that biologically-based measures have a bright future, but we need to avoid jumping to premature, and often reductionist conclusions. At the present time, biological approaches provide another means for obtaining dependent measures. They do not provide a means

that is somehow privileged with respect to every other kind of measure. Returning to the pentagonal implicit theory, we find that what is *valued* by biological tests are *excellence* and *rarity* of various forms of psycho-physiological functioning, *demonstrability* via means such as evoked-potential wave forms that are complex, or increased P-300 amplitude in the face of novel stimuli. The geographic tests emphasized products, the computational tests, the presumed processes underlying these products, and the biological tests, the presumed brain activity underlying the processes. Thus, each approach goes one step further back down the actual *productive* behavior in everyday life. Indeed, in many of the biological tests, the test-taker produces nothing at all! A measurement may be made while the individual is at rest, as in the case of the evoked-potential studies.

The Epistemological Metaphor

The epistemological metaphor draws very heavily upon philosophy, and especially the philosophy of knowledge, for its conceptualization of intelligence. Epistemological theorists, influenced heavily by Jean Piaget, tend to be developmental in the range of issues they consider.

EPISTEMOLOGICAL THEORY

Piaget (1952) thought there were two interrelated aspects of intelligence: its function and its structure. Piaget, a biologist by training, saw the function of intelligence to be no different from the function of other biological activities. That function is adaptation, which includes assimilating the environment to one's own structures (be they physiological or cognitive) and accommodating one's structures to encompass new aspects of the environment.

Piaget further proposed that the internal organizational structures of intelligence and how intelligence will be manifested differ with age. It is obvious that an adult does not deal with the world in the same way as does a neonate. For example, the infant typically acts on his or her environment via sensory-motor structures and, thus, is limited to the apparent, physical world. The adult, on the other hand, is capable of abstract thought and, thus, is free to explore the world of possibility. Much of Piaget's research was a logical and philosophical exploration of how knowledge structures might develop from primitive to sophisticated forms. Guided by his interest in epistemology and his observations of children's behavior, Piaget divided the intellectual development of the individual into discrete, qualitative stages. As the child progresses from one stage to the next, the cognitive structures of the preceding stage are reorganized and extended to form the underlying structures of the equilibrium characterizing the next stage (Piaget & Inhelder, 1969).

In Piaget's theory, there are four main stages. The first stage is the sensory-motor one, which occupies

birth through roughly two years of age. The new-born baby exhibits only innate, preprogrammed reflexes, such as grasping and sucking. Intelligence begins to exhibit itself as the innate reflexes are refined and elaborated. The second stage is the pre-operational one, which takes place roughly in the ages two through seven. The child is now beginning to represent the world through symbols and images, but the symbols and images are directly dependent upon the immediate perception of the child. In the third stage, that of concrete operations, the child becomes able to perform concrete mental operations. In this stage, lasting approximately between the ages of seven through eleven, the child can now think through sequences of actions or events that previously had to be enacted physically. It is now possible for the child to reverse the direction of thought. The child comes to understand subtraction, for example, as the reverse of addition, and division as the reverse of multiplication. The period is labeled one of "concrete operations", because operations are performed for objects that are physically present. In the last stage, that of formal operations, the child learns to think abstractly and hypothetically, not just concretely. In this stage, which begins to evolve at around the age of eleven, the individual can view a problem from multiple points of view, and can think much more systematically than in the past.

Other, neo-Piagetian theorists have built on the ideas of Piaget while at the same time not accepting all of his assumptions and contentions. For example, Case (1984, 1985), like Piaget, believes that cognitive development proceeds through four general stages that take place between age one month and adulthood. Case's stages are not exactly the same as Piaget's, however. In his recent work, Case has been particularly concerned with the control structures for thought, that is, how problem situations are represented and how these representations are acted upon. In his earlier work, Case drew heavily on Pascual-Leone's (1970) concept of the *M*-space for understanding the amount of mental processing space that can be allocated to various cognitive tasks at different ages.

Another of the neo-Piagetian theories is that of Fischer (1980; Fischer & Pipp, 1984). Fischer assumes that development can be understood primarily in terms of two key concepts, which provide instantiations for the notions of competence and performance as they have been discussed by others. The first concept is that of optimal level, which specifies the upper limit on the complexity of skill that an individual can bring to bear upon a problem. The second concept is that of skill, which appears to be a set of processes that can be brought to bear upon problems. Skills differ in complexity, and indeed, the complexity of skills that can be brought to bear upon a problem is a key source of development in Fischer's theory.

Other neo-Piagetian theories include those of Siegler (1981, 1984, 1987) and Pascual-Leone (1970, 1987).

EPISTEMOLOGICAL TESTS

The epistemological metaphor has lent itself to a number of assessment devices, most of them based upon the thinking of Piaget. Indeed, Tuddenham (1970) constructed a Piagetian test of cognitive development that is roughly analogous to an intelligence test, except that it is based upon the kinds of tasks Piaget used in his research. What are some examples of such tasks?

Some of the most well-known tasks are those used to measure conservation, a test of concrete-operational function. In one task, children are shown a jar of liquid. The liquid is poured from this first jar into another jar, which is higher and narrower. The child is then asked whether the second jar contains more liquid than the first jar, less liquid, or the same amount. A conserver would recognize that the amount of liquid has not changed. A non-conserver would typically label the second jar as containing more liquid, because the liquid in the second jar reaches a higher level. Conservation of liquid is only one of several kinds of conservations. For example, clay might be molded into different shapes, and children asked whether the amounts of clay in each shape are the same. Children who do not conserve view the different shapes as containing different amounts of the clay substance.

Another task that has been extensively used, especially by Siegler (1978), is the balance-beam task. In this task, children are presented with a balance beam that contains differing numbers of weights at differing distances from the center of the beam. The children must indicate whether the beam will balance, or whether instead one side or the other will be higher. Siegler has done an elegant and elaborate analysis of different stages in the development of information processing in the performance of the balance-beam task. Yet another related task is that of class inclusion. Children might be shown three green marbles and eight blue marbles, and then be asked whether there are more blue marbles or more marbles. The idea is to assess whether the children are concrete-operational in the sense of being able to recognize that blue marbles are a subset of marbles as a whole.

This last task highlights one of the difficulties with Piagetian measurements. At least in some cases, children may not understand the task in the same way that examiners do. For example, it may seem odd to be asked whether there are more blue marbles or more marbles, and children may reinterpret the question to mean: Are there more blue marbles or green marbles? They would then answer this second question appropriately, but be marked as incorrect. Of course, this problem of misinterpretation applies to other approaches as well.

An example of a task used to measure formal operations would be the permutations task. Examinees might be given four or more objects or sets of numbers, and be asked to generate all possible permutations of these objects (or numbers). The question here is whether they go about performing this task in a systematic way.

Formal-operational children will generate all possible permutations by systematically varying the positions of items in the array.

The epistemological approach provides a fourth kind of theoretical framework for assessing intelligence. The scoring of epistemologically-based tests is theory-based, and relates to developmental stages in a child's mental growth. Note that one is asking different kinds of questions about mental functioning than would be asked in typical tests. Here one is attempting to assess stages of the development of schemas for organizing the world, rather than seeking to assess how one child compares to another of the same age. As has been true with each approach, the epistemological approach provides a unique perspective on the individual's intellect, with this perspective determining both the kinds of questions one would ask and the way in which responses to the questions would be scored.

In terms of the pentagonal implicit theory, the epistemological approach shifts the *valuing* criterion more toward competence, especially logical competence, and more away from that performance emphasized by the other approaches. *Excellence* and *rarity* are largely *demonstrated* through performance on logic-based tasks. Whereas psychometric tests have more of an inductive character, many Piagetian ones have more of a logical-deductive character. There is more of a *productive* orientation on these tasks than on some of the others we have considered. The problems require more thought, say, than is required in some of the simple information-processing tasks. The problems, however, are still not those encountered in everyday life.

Metaphors Viewing Intelligence as External to the Individual

The Anthropological Metaphor

The basic idea of the anthropological metaphor is what Irvine and Berry (1988) refer to as the law of cultural differentiation. It is based on a statement by Ferguson (1954): "Cultural factors prescribe what shall be learned and at what age; consequently different cultural environments lead to the development of different patterns of ability" (p. 121).

ANTHROPOLOGICAL THEORIES

Anthropologically-oriented psychologists differ in the extent to which they believe that culture affects the nature of intelligence. There are four positions of varying degrees of extremity, each of which will be considered in turn.

The most extreme position, radical cultural relativism (Berry, 1974), entails the rejection of assumed psychological universals across cultural systems, and requires the generation from within each cultural system of any behavior concept that is to be applied to it. Specifically, for the concept of intelligence, this position requires

that indigenous notions of cognitive competence be the sole basis for the generation of cross-culturally valid descriptions and assessments of cognitive capacity. According to this view, a person who is gifted in one culture may literally be an idiot in another one.

In this approach, it is essential to understand how context shapes intelligence. Berry and Irvine (1986) have described four levels of context that can affect intelligence and the way it is evaluated. At the highest level is ecological context. This kind of context comprises all of the permanent or almost permanent characteristics that provide the back-drop of human action. It is the natural cultural habitat in which a person lives. A second kind of context is the experiential context, or the pattern of recurrent experiences within the ecological context that provides the basis for learning and development. When cross-cultural psychologists try to determine independent variables that affect behavior in a particular habitat, they are usually dealing with the level of experiential context. A third kind of context is the performance context, which is itself nested under the two kinds described above. This context comprises the limited set of environmental circumstances that account for particular behaviors at specific points in space and time. Finally, nested under the above three levels of context is the experimental context. This context comprises environmental characteristics manipulated by psychologists and others to elicit particular responses or test scores. Although this context should be nested within the three described above, it often is not, in which case the experimental context will not represent appropriately the conditions under which a given set of people lives.

A less extreme form of anthropological theorizing is what might be called conditional comparativism. Those who adhere to this point of view believe it is possible to do some kind of conditional comparison in which an investigator sees how different cultures organize experience to deal with a single activity such as writing, reading, or computing. This comparison is possible, however, only if the investigator is in a position to assert that performance of a task or tasks under investigation is an achievement that is attained in every culture being compared.

This is the view taken by, among others, Michael Cole and his colleagues in the Laboratory of Comparative Human Cognition (1982). Cole and his colleagues assert that the radical cultural-relativists' position does not take into account the fact that cultures interact. They assume that learning is context-specific, and the context-specific intellectual achievements are the primary basis for intellectual development. They state specifically that they do not deny the existence of any intercontextual generality of behavior. But they further state that such intercontextual generality is a secondary phenomenon, and one in which the cultural organization of experience plays a major role. The idea in this view is that each experience within a cultural context can be linked to a specific task performance. There is no central

process or general ability intervening between experiences and behavior. Learning is viewed as primarily event- or context-specific. A gifted individual, then, is one who successfully acquires culture-based knowledge and skills.

A still less extreme position is what might be referred to as a dualistic one. Dualistic positions generally do not rely exclusively on the anthropological metaphor. Theorists such as Keating (1984), Jenkins (1979), Baltes, Dittmann-Kohli, and Dixon (1984), and Charlesworth (1979) have in one way or another attempted to incorporate both cognitive and contextual elements into their models of intelligence.

In his ethological approach to studying intelligence, Charlesworth (1979) has focused on what he refers to as the "other part" of intelligence—intelligent behavior as it occurs in everyday life rather than in test situations—and how these situations may be related to developmental changes. Keating (1984), in his research, has investigated how intelligence can be studied through a number of cognitive-psychological paradigms, but more recently has suggested that these paradigms are more or less vacuous when it comes to understanding how cognition interacts with culture. Baltes (e.g., Dixon & Baltes, 1986) argues that it is necessary to look at both the mechanics and the pragmatics of intelligence. For example, his studies of wisdom suggest that wisdom cannot be understood outside the context of the environment in which one develops.

At the opposite extreme from radical cultural relativism is universalism. Its primary tenet is that there are significant commonalities in the nature of intelligence and of the mind in general across cultures. For example, Levi-Strauss (1966) argued that there are no differences between how the mind works in one culture and how it works in another culture, or even in how it works from one time to another. Primitive and Western systems of thinking merely represent different ways by which people try to understand nature and make it susceptible to rational inquiry. According to Levi-Strauss, cultures do not differ in their levels of mental development. All seek knowledge about the universe, and seek to order and systematize. What differs across cultures is the content of thought. Primitive systems of classification are more likely to be based on attributes that are readily perceived or otherwise experienced. Modern scientific classification systems rely on attributes that are inferred from relations in the structures of objects. Thus, structurally there are no differences among cultures. What differs is content. In this view, there should be universal abilities underlying giftedness, although exactly how they are measured might vary from one culture to another.

ANTHROPOLOGICAL TESTS

Adherents to the anthropological metaphor tend to eschew tests in the traditional sense. Rather, they try to devise cognitive tasks that are culturally relevant.

Their attempts at cultural relevance go beyond the naive attempts of many psychometricians and their so-called "culture-fair tests" (Cattell & Cattell, 1963), which are often more culturally loaded than the tests they are designed to replace. An example of an investigator using the anthropological approach is Berry (1974). Berry conducted a study of ten subsistence-level groups to test the hypothesis that people in a hunting culture should possess good visual discrimination and spatial skills. Their cultures are expected to support the development of such skills through the presence of many geometric and spatial concepts. To test this hypothesis, Berry ranked cultural groups according to the importance of hunting to their existence, and compared these rankings with test scores for perceptual discrimination and other related skills. For example, he used the embedded-figures test, often used as a measure of psychological differentiation. He found, as predicted, that the more central the role of hunting to a culture, the better the psychological test scores.

Anthropologically oriented psychologists often suggest that the differences in performance across cultures are based on enculturation practices rather than on any internally-based "intelligence". For example, Super (1976) found evidence that African infants sit and walk earlier than do their counterparts in the United States and Europe. But Super also found that mothers in the cultures he studied made a self-conscious effort to teach babies to sit and walk as early as possible. Other motor behaviors were not more advanced. For example, infants found to sit and walk early were actually found to crawl later than did infants in the United States.

In another follow-up of this kind of logic, Serpell (1979) tested a notion of McFie (1961) that lack of toys and construction games encouraging accurate standards of orientation and imitation might lead to inferior perceptual abilities on the part of African infants. Serpell designed a study to distinguish between a generalized perceptual-deficit hypothesis and a more context-specific hypothesis. He selected four perceptual tasks that, by a general-process interpretation, should result in lower performance for Zambian than for English children. But he suggested that performance would depend on enculturation practices. Serpell hypothesized that whereas English children would have more experience with two-dimensional representations of pen-and-paper tasks, Zambian children would have more practice molding wire into two-dimensional objects. Serpell therefore predicted that English children would score higher on a pen-and-paper task, but not as high on a wire-shaping task as Zambian children. Serpell's data supported his prediction.

Another study showing the effects of the kind of training one receives on how one performs was done by Greenfield (Bruner, Olver, & Greenfield, 1966). Greenfield and her colleagues studied children of the Wolof Tribe in rural Senegal. Children received sets of pictures mounted on cards. The cards were designed so that within each of the sets, a child could form pairs

based on various attributes—color, form, or function. The child was first asked to show the investigator which of the two pictures in a given set were most alike. The child was then asked why they were most alike. Subjects were selected from children in three populations: Bush children who had not attended school, children in school from the same town as the Bush children, and school children living in Dakar, the capital of Senegal. Greenfield found that children who had attended school, regardless of where, performed much as American children did. Preference for color decreased sharply with grade, whereas preference for form and function increased. Moreover, an increasing proportion of older children justified their classifications in terms of subordinate categories. Children who had not attended school and lived in the Bush responded quite differently. They showed a greater preference for color with increasing age, and rarely justified responses in terms of subordinate language structure.

Even when the objects to be dealt with are familiar, the way they were typically used or thought about may have once helped people perform with them. When Cole and his colleagues (Cole, Gay, Glick, & Sharp, 1971) asked adult Kpelle tribesmen to sort twenty familiar objects into “groups of things that belong together”, the subjects separated the objects into functional groups (a knife with an orange, for example), as children in Western societies do. The researchers had expected to see taxonomic groupings (tools and foods, for example) from these adults, because Western adults typically sort taxonomically. The Kpelle proved to be perfectly capable of taxonomic sorting: When the subjects were asked to sort the objects the way a fool would do it, they immediately arranged them into neat piles of tools, foods, clothing, and utensils. Taxonomic sorting of these objects seemed stupid to the Kpelle because it was inconsistent with the way they deal with these objects in everyday life, that is, functionally. In another classification task, the Kpelle sorted leaves taxonomically (as either “tree” leaves or of “vine” leaves) with ease. In this case, the taxonomic approach seemed completely appropriate. As farmers, the Kpelle are frequently called upon to make such discriminations, and hence were comfortable adopting the taxonomic sorting strategy.

In sum, tests based upon the anthropological metaphor need to be tailored, not just translated or adjusted, to the culture in which the testing is taking place. Tests based upon the internally-oriented metaphors have been used with almost no modification across cultures, under the assumption that what they measure should be universal. But this is a big assumption. Changing the content vehicle or the format of a test, or even the location in which the test is given, can have a major effect upon test scores. Thus, children who might look quite stupid on tests based upon metaphors that view intelligence as inside the head, might look quite smart on tests based on metaphors that are oriented toward the outside. What is of greatest interest is that adherents of

the anthropological metaphor, who make a living out of studying intelligence across cultures, almost all believe that mere translation or minor modifications do not adequately control for cultural differences in intelligence testing, whereas adherents to the geographic metaphor, most of whom do not specialize in cross-cultural work, are happy just to translate or make minor modifications in their tests. So the metaphor under which one works can have profound implications for how intelligent a person will appear when tested, because the metaphor determines what will be tested and how testing will be done.

From the standpoint of the pentagonal implicit theory, *valuing* is quite different under the anthropological metaphor. Indeed, what is valued may differ radically across cultures. What one culture considers excellent, another may consider unacceptable. The *demonstrability* of intelligence must be in terms of culturally valued products. The behavior that is *rare* and *excellent* in one culture may be rare but eccentric in another. The anthropological approach does consider this issue seriously. Indeed, those who follow this approach will not consider seriously any test that does not directly relate to *productivity* within the culture.

The Sociological Metaphor

The sociological metaphor differs only subtly from the anthropological one. Whereas the anthropological metaphor deals with the effects of enculturation, the sociological metaphor deals with the effects of socialization. Adherents to the anthropological metaphor concern themselves primarily with how culture affects intelligence. They deal with the question of whether intelligence is the same thing across cultures, and if it is not, how it is different. Adherents to the sociological metaphor care about cultural effects, but tend to be less interested in the question of how intelligence differs from one culture to another than in the question of how socialization within any culture affects the development of intelligence. Although they may look at socialization across cultures, their main interest is in the socialization process itself, and especially how it is similar across cultures even though the content of the socialization may vary quite substantially. In this view, the gifted individual is a product of superior socialization in the environment.

SOCIOLOGICAL THEORIES

The sociological approach is due largely to Lev Vygotsky. Vygotsky (1978) made several important contributions to the theory of intelligence, the two most important of which are probably his theory of internalization and his concept of the zone of proximal development.

In his theory of internalization, Vygotsky turned the views of Piaget on their head. Although Piaget

and Vygotsky were both interactionists, they were interactionists who believed that individual intelligence started at essentially opposite points. Piaget believed that intelligence matured from the inside, and directed itself outward. Vygotsky, in contrast, believed that intelligence begins in the social environment, and directs itself inward. The process of the direction of intelligence from the outside to the inside is what Vygotsky refers to as internalization.

Internalization is the internal reconstruction of an external operation. The basic notion is that we observe those in the social environment around us acting in certain ways, and we internalize their actions so they become a part of ourselves. For example, we might learn how to teach young children by watching how our parents teach us; or we might learn how to speak or ride a bicycle or even read a book by watching how others do it. Internalization does not occur, for the most part, simply as the result of mimicry of a single action. Rather, it is a process that continues over time. First, the action may be perfectly imitated, or its meaning not quite understood. Moreover, even after an action is internalized, its linkage to other internal acts may take quite some time. Some functions are never internalized: They remain forever as external signs. According to Vygotsky, the internalization of socially based and historically developed activities is what distinguishes humans from animals.

Perhaps Vygotsky's most exciting contribution to the psychology of intelligence is his notion of the zone of proximal (or potential) development. Consider a situation posed by Vygotsky.

Take two children whose chronological age is ten years and whose mental age is eight years. Ask whether one can characterize them as being of the same age mentally. On the face of it, of course, one can. But this means that both children can deal with tasks up to the degree of difficulty characterized by what eight-year-olds can typically do. One could say that the actual developmental level of the two children is the same. But, Vygotsky asked, can one thereby ascertain that the subsequent course of their mental development and their school learning will be the same, because both depend on their intellect? Naturally, there are nonintellectual factors that may influence their school learning or their mental development. But for the time being, consider these nonintellectual factors as being comparable for the two children. Most people would assume that one could make comparable predictions about each of the children, and indeed, the whole predictive use of intelligence tests in the United States is based on this assumption. Vygotsky argues that this view is incorrect.

Suppose that a teacher-examiner provides guided assistance to each of the two children in order to help them solve a given problem. It turns out that, with this guided assistance, the first child can deal with problems up to the level of a twelve-year-old, whereas the second child can only deal with problems up to the level of a

nine-year-old. Would we still want to conclude that the two children are mentally the same? Vygotsky suggests that we would not, for the first child has been shown to be better able to profit from instruction than the second child. Hence, it is reasonable to suppose that with regard to future as opposed to past development, the first child is superior to the second child and has a better prognosis. The difference between mental age twelve and mental age eight, for the first child, and between mental age nine and mental age eight, for the second child, is what Vygotsky refers to as the zone of proximal development. It is the distance between the actual developmental level as determined by independent problem solving and the level of potential development as determined through problem solving under adult guidance or in collaboration with more capable peers. According to Vygotsky, there may be many gifted children who are not so identified because, although they have the potential, they have yet to realize it.

Another sociological theorist is Reuven Feuerstein, whose basic premise is that intelligence is modifiable. The key concept in Feuerstein's conception of intelligence and its development is *mediated learning experience* (Feuerstein, 1980). Mediated learning experience is

the way in which stimuli emitted by the environment are transformed by a "mediating" agent, usually a parent, sibling, or other caregiver. This mediating agent, guided by his intentions, culture, and emotional investment, selects and organizes the world of stimuli for the child. The mediator selects stimuli that are most appropriate and then frames, filters, and schedules them; he determines the appearance or disappearance of certain stimuli and ignores others. Through this process of mediation, the cognitive structure of the child is affected. The child acquires behavior patterns and learning sets, which in turn become important ingredients of his capacity to become modified through direct exposure to stimuli (Feuerstein, 1980, p. 16).

Feuerstein believes that mediated learning experience can occur either through the intervention of a particular individual, such as the parent, or through general cultural transmission. Children who are culturally deprived—who have inadequate exposure to their own culture—will tend to receive inadequate mediated learning experience. Feuerstein believes that cultural deprivation is not in terms of a mainstream or host culture, but in terms of the culture of the child and his family.

SOCIOLOGICAL TESTS

The concept of the zone of proximal development is clearly related to mediated learning experience, as mediated learning experience seems to be what helps children achieve their level of potential development. Brown and French (1979) give a fairly detailed example

of how the zone of proximal development can be measured, and Ferrara, Brown, and Campione (1986) illustrate the use of the zone of proximal development in considerable detail. Brown and her colleagues have devised tests that use the Vygotskian concept in order to measure the zone of proximal development.

Feuerstein (1979) has developed a test called the Learning Potential Assessment Device (LPAD), which follows directly from his ideas about mediated learning experience. The test also fits very well with Vygotsky's notion of the zone of proximal development. In the test, an examiner gives children rather difficult tasks to solve. Initially, he or she looks at how the children solve the tasks without any intervention on the part of the examiner. Then, children receive carefully graded, sequential hints, and the examiner observes the children's ability to profit from these hints. In this way, it becomes possible to observe the children's zone of proximal development.

Although I initially had some doubts as to whether the tests of the zone of proximal development measure what they are supposed to measure, the results of Brown and her colleagues and of Feuerstein are very encouraging. I remain concerned, however, that the operationalization of the zone of proximal development may not sufficiently take into account individual differences in abilities and styles of learning. The instruction that works well for one child might work only poorly for another child, with the result that the first child might appear to have a larger zone of proximal development than the second. In order for the measure to be fair, we would have to make sure that the form of instruction used was equally suitable for all children receiving that instruction, and it is unlikely that any form of instruction will be equally suitable for all. Hence, I believe that we do have to be careful in our interpretation of results of tests that measure the zone of proximal development. Moreover, we need to recognize that there may be zones of proximal development that are domain-specific rather than domain-general, and that may differ not only as a function of domain but as a function of how learning takes place. For example, some children might learn quite well with the kind of direct instruction given in tests of the zone of proximal development, whereas other students might learn better on their own.

These concerns notwithstanding, the zone of proximal development is one of the more exciting concepts in the psychology of intelligence, because it gives us a way of addressing the question of what will happen in the future, not based just upon retrospective measurement, but based upon simulations of prospective processing of information. The dynamic form of testing is quite different from the static form used under the geographic metaphor. Dynamic testing may well be the wave of the future in terms of understanding not only to what point people have arrived, but also to what point they are going.

In terms of the pentagonal implicit theory, the sociological metaphor emphasizes the *value* of socialization,

both in theory and in assessment. For example, the assessment paradigms of both Vygotsky and Feuerstein involve mini-socialization procedures in which an examiner interacts extensively with an examinee. *Excellence* and *rarity* are in terms not just of performance, but of the ability to improve one's performance with guided instruction. Whereas tests under other approaches use *productivity* in the testing situation as a predictor of productivity in life, tests under this approach use potential productivity *demonstrated* in the testing situation (the zone of proximal development) as a measure of potential productivity outside testing situations.

Intelligence as Viewed Internally and Externally to the Individual

The Systems Metaphor

The systems metaphor is an attempt to bring together various other metaphors by viewing intelligence in terms of a complex interaction of various cognitive and other systems. I will describe here two attempts to understand intelligence in terms of interactioning systems: Gardner's (1983) theory of multiple intelligences and Sternberg's (1985, 1988) triarchic theory of human intelligence. Both theories imply that a gifted person is not gifted by virtue of just high levels on one or more abilities, but also by virtue of the way these abilities interact as a system.

SYSTEMS THEORIES

The two systems theories to be considered here are similar in viewing conventional theories of intelligence as too narrow, but are different in the way they propose to expand our conception of intelligence. Consider each theory in turn.

Howard Gardner's (1983) theory of multiple intelligences may be viewed as having three fundamental principles. First, intelligence is not a single thing, whether viewed unitarily or as comprising multiple abilities. Rather, there are multiple intelligences, each distinct from the others. The multiple intelligences Gardner proposes in his 1983 book are linguistic, logical-mathematical, spatial, musical, bodily-kinesthetic, interpersonal, and intrapersonal. In some ways, the distinction between positing one intelligence comprising multiple abilities and positing multiple intelligences, each distinct from the others, is subtle. But the positing of multiple intelligences emphasizes the separateness of each set of skills, and also emphasizes Gardner's view that each intelligence is a system in its own right, rather than merely one aspect of a larger system, namely, what we traditionally call "intelligence". The second fundamental principle is that these intelligences are independent of each other. In other words, a person's abilities as assessed under one intelligence should not, in theory, be predictive of that person's abilities as assessed under another intelligence.

Obviously, the claim of independence is a strong one, but Gardner believes that it is justified by what we know about the mind. The third fundamental principle is that the intelligences interact. Although they are distinct from each other, no one could ever get anything done if their distinctness and independence meant that they could not work together. In such an instance, a mathematical word problem requiring, say, the application of both linguistic and logical-mathematical intelligences would be insoluble.

Gardner defines an intelligence as “an ability or set of abilities that permits an individual to solve problems or fashion products that are of consequence in a particular cultural setting” (Walters & Gardner, 1986, p. 165). How do we know what constitutes an intelligence? In other words, what criteria can one use to identify the multiple intelligences in Gardner’s theory, or other possible intelligences that have not yet been identified? Gardner proposes eight criteria for distinguishing an independent intelligence: potential isolation by brain damage; the existence of idiots savants, prodigies, and other exceptional individuals; an identifiable core operation or set of operations; a distinctive developmental history, along with a definable set of expert “end-state” performances; an evolutionary history and evolutionary plausibility; support from experimental-psychological investigations; support from psychometric findings; and susceptibility to encoding in a symbol system.

Sternberg’s (1985, 1988) triarchic theory, as its name implies, has three parts. The first, “componential subtheory”, relates intelligence to the internal world of the individual, or the mental mechanisms that underlie intelligent behavior. It specifies three kinds of information-processing components: metacomponents, which are higher order executive processes used to plan what one is going to do, to monitor it while one is doing it, and to evaluate it after it is done; performance components, which are lower order processes that execute the instructions of the metacomponents in order to perform tasks; and knowledge-acquisition components, which are used to learn how to do what the metacomponents and performance components eventually do.

Components of information processing are always applied to tasks with which one has some level of prior experience (including the null level) and in situations with which one has some level of prior experience (including the null level). Hence, these internal mechanisms are closely tied to one’s experience. The second, “experiential subtheory”, specifies that the components are not equally good measures of intelligence at all levels of experience. Assessing intelligence requires one to consider not only the components, but the level of experience with which they are applied.

According to the experiential subtheory, intelligence is best measured at those regions of the experiential continuum that involve application of information-processing components to tasks or situations that are either relatively novel, on the one hand, or in the process of becoming automatized, on the other. If a task is too unfamiliar, such as a trigonometry problem presented to a first-grader, it

will not measure intelligence because the individual will have virtually no mental resources to bring to bear on the problem. If the task is already automatized, one will have no sense of the history of how efficaciously that automatization was accomplished—whether it took one week or one year. The ability to deal with novelty and the ability to automatize information processing are interrelated. If one is well able to automatize, one has more resources left over for dealing with novelty. Similarly, if one is well able to deal with novelty, one has more resources left over for automatization. Thus, performance at the various levels of the experiential continuum are related to one another.

These abilities should not be viewed in a vacuum with respect to the componential subtheory. The components of intelligence are applied to tasks and situations at various levels of experience: coping with novelty is via the components, and what is automatized is a set of components of information processing.

According to the third, “contextual subtheory”, intelligent thought is directed toward one or more of three behavioral goals: adaptation to an environment, shaping of an environment, or selection of an environment. These three goals may be viewed as the functions toward which intelligence is directed: Intelligence is not aimless or random mental activity that happens to involve certain components of information processing at certain levels of experience. Rather, these components are purposefully directed toward the pursuit of these three global goals, regardless of the level of experience at which the components are executed. The nub of the triarchic theory of intelligence is that intelligence involves recognizing and capitalizing on one’s strengths, and recognizing and either compensating for or remediating one’s weaknesses. Thus, people may differ widely in how they are intelligent, but they find some way in which they excel, and then make the most of it.

SYSTEMS TESTS

In the systems approaches, the actual testing that is done will depend on the way the system of the mind is conceived. Howard Gardner and David Feldman, in their project Spectrum, are developing tests based on Gardner’s (1983) theory of multiple intelligences. These tests, unlike the conventional ones, are not paper-and-pencil, but rather measure children’s thinking skills in an enriched classroom environment where children are performing criterion activities. Thus, linguistic intelligence might be measured by having children write a poem, or bodily-kinesthetic intelligence by having them dance or play a sport.

Sternberg is currently developing a test based on his triarchic theory of intelligence, which measures each of the componential skills, coping with novelty skills, automatization skills, and practical-intellectual skills in verbal, quantitative, and figural domains. The test, for kindergarten through adulthood, is at multiple levels,

and is a group test. The componential items are most similar to those on a standard intelligence test, including things like learning meanings of words from context, number series, and figural analogies. The coping with novelty tests require subjects to solve problems that are based on a novel premise. For example, novel verbal analogies have students solve analogies that are preceded by a premise that may be either factual (e.g., canaries sing songs) or counterfactual (e.g., canaries play hopscotch). In each case, the subjects would have to solve the analogies as though the premise were true. The novel number matrices, used to measure coping with novelty in the quantitative domain, require subjects to complete number-matrix problems in which numerals and symbols that have been set equal to various numbers are freely interchanged. The figural coping with novelty task requires solving figural series in which the series show a discontinuity in the middle, and the subject must infer how to extrapolate from the first domain in the series to the second. All three automatization subtests—verbal, quantitative, and figural—require subjects rapidly to indicate whether two different symbols are of the same class or not, for example, whether two numbers are both even or both odd. Practical verbal problems require everyday inferences, practical math problems require everyday math, and practical figural problems require planning of routes in a way that is time-efficient and effective. In the triarchic approach, the testing of intelligence is closely linked to the teaching of intelligence, and there exists a program at the high school-college level, *Intelligence Applied* (Sternberg, 1986), which can be used in conjunction with testing in order to enhance intellectual skills.

Returning to the pentagonal implicit theory, we find that the *valuing* of the systems theories is not so much of one ability or another, but of how the abilities work together. The *excellent* person is someone who can make his or her abilities work together in harmony, and such persons are *rare*. The systems theories are very concerned with the relation between *productivity* in tests and in everyday life, and indeed, Gardner has been a leader in the so-called “authentic-testing” movement, which seeks to evaluate children’s gifts in terms of the products they produce. In this movement, children must *demonstrate* their abilities not just by the potential to produce significant products, but by actually producing them.

Conclusion

The testing of intelligence can be as diverse and multifaceted as is intelligence itself. One cannot beg the question of “What is intelligence?” by saying, as did Boring, that intelligence is what the tests test, because there are as many different kinds of tests as there are metaphors for understanding intelligence. “Giftedness” can be viewed as quite broader than a high score on a conventional intelligence test. There can be different

sorts of tests within each metaphor, depending upon the particular theory within the metaphor that generates the test. The conventional individual and group tests we use to measure intelligence represent only a small sampling of the ways in which intelligence might be tested. Almost all of the conventional tests are based upon the geographic metaphor, but there is no reason in principle why we need to test intelligence on this basis. Other metaphors could help us assess aspects of performance that heretofore have been neglected.

It is worth emphasizing again that metaphors are not right or wrong, but more or less useful for particular purposes. Similarly, the theories within the metaphors can be more or less useful for particular purposes. Theories, unlike metaphors, can be proven to be wrong, although, of course, we cannot prove them to be right, but can only gather evidence that is consistent with them. In comparing theories, we need to keep in mind whether or not they were generated under the same metaphor, because theories generated under different metaphors do not readily lend themselves to comparison, any more than apples and oranges do. They deal with different aspects of intelligence and accomplish different goals, and hence are not, strictly speaking, comparable. Even within the same metaphor, noncomparabilities can exist. For example, within the biological metaphor, there were three distinct approaches that were viewed—neuropsychological, electrophysiological, and blood flow—and it would not be possible directly to compare across these procedures of measurement. Each deals with a different class of phenomena.

The direction that most applied research has taken over the past decade or so has been toward successively more refined psychometric theories of measurement, and successively more refined delivery systems for measurement. Thus, we now have tailored tests, which typically use computer technology to present existing tests in more efficient ways. I am all in favor of psychometric and technological development. But I personally believe that we need to apply more resources to questions of what we want to measure before we apply resources to how we are going to measure it. Historically, the link between theories and tests of intelligence has not been as strong as I believe it should be. The link is always there, to some extent, but even when it is there, we have often not been conscious of it. We need more explicitly to state what we are assuming about intelligence when we measure it through a given vehicle, and more seriously to consider the alternatives to the vehicles we are using. The metaphorical approach to understanding intelligence helps chart the universe of possibilities for more informed and self-conscious testing of intelligence.

Ultimately, the “metaphorical approach” combined with the pentagonal implicit theory shows the importance of *valuing* to the identification of the gifted. What is valued by one approach to theory and assessment may or may not be by another. In identifying the gifted, we

need to pay much more attention than we have to the question of what we mean by "giftedness".

Methodological Problems and Issues Concerning Identification

ERNST A. HANY

University of Munich, Germany

Introduction

The paradigm of the special education of the gifted in the school years involves the classification of individual members of a limited sample as “gifted” and then their participation in a giftedness nurturing program. The identification of gifted individuals therefore takes a place of considerable importance for the establishment of programs, alongside program design. The first part of this contribution will be an overview of recommendations on identification design made by experts on gifted education. In the next step these recommendations will be considered scientifically. To this end, the decision theoretical model of selection decisions will be presented. Its properties and methodological consequences for practice will be discussed. Finally, insights on the construction of social judgments and group decision making will be presented because the available research on this topic has often been neglected when identification procedures are designed.

This contribution is restricted by and large to formal aspects of identification. Questions on the nature of giftedness and on concrete measuring instruments are dealt with in other contributions to this handbook and in further publications (e.g., Davis & Rimm, 1985; Gallagher, 1985; Khatena, 1982). A special mention should be made of the contribution from Feldhusen and Jarwan (Chapter 13), since there theoretical considerations and practical applications are effectively combined.

Overview of Recommendations on Identification

Most authors writing on the identification of gifted school students (e.g., Clark, 1992; Feldhusen & Baska, 1985; Hagen, 1980; Swassing, 1985; Tannenbaum, 1983) agree on the following points:

(1) The identification of gifted school students is a goal-driven process for locating students whose potential is not sufficiently challenged by regular teaching.

(2) The indicators and measuring instruments used for identification must reflect the contents of the proposed nurturing program. Tannenbaum (1983, p. 366) puts it

like this: “the identification procedures have to conform to the scope and objectives of the curriculum”.

(3) The identification of gifted children should begin in such a way as to include as many candidates as possible. Many different kinds of information should be gathered in order to reduce the chances of incorrectly excluding suitable school students. Special attention should be paid to members of special groups (members of different cultures, disabled children, underachievers, and girls—in the case of programs in mathematics and sciences). This attention is facilitated by use of different sources of information (Hadaway & Marek-Schoer, 1992).

(4) Admission to a nurturing program should be regulated by a committee of experts after discussion of the individual case and consideration of all available documents. The giving of different weights to different kinds of data in respect of the final decision cannot be avoided, but should at least be justified and made explicit.

(5) The learning progress made by the program participants should be repeatedly investigated (Feldhusen & Baska, 1985, suggest as often as every two months) in order to assess the admission decision on the one hand and to validate the decision strategy on the other.

Hagen (1980) suggests that these recommendations can be realized by following the steps given below in the planning of an identification procedure: First, the school should determine which concept of giftedness is to be adopted. Indicators are selected for this concept, and in the next step information sources (school records, teachers, parents, the school students themselves) and measuring instruments (tests, checklists, observation protocols, product ratings) are identified for them. Rules governing how the resulting information is to be applied should be specified before the beginning of data collection. This is particularly important for the guidelines concerning the combination of information for the final admission decision.

According to B. Clark's (1992) recommendations, a co-ordinator should be appointed for the carrying out of the identification procedure. His or her task is to initiate the search for talent and to structure it with a multidimensional screening procedure. After as much information as possible has been gathered, the

co-ordinator combines this data to give a profile of the individual child's abilities, performance and interests, his or her strengths and weaknesses. A preselection of the candidates is then presented to the selection committee in the form of case studies. A selection decision is made which in some cases may only have provisional status. Sometimes a trial period may be necessary in order to assess the suitability of the student for the program unequivocally. After admission to the program, further diagnostic steps are necessary. The child's individual interests and learning style must be recorded in order to be able to tailor the individual support as closely as possible to his or her learning needs and learning skills.

There is some dispute about some aspects of the identification procedure. One such problem is the choice of indicators and instruments. Some authors recommend using general indicators (e.g., intelligence and creativity) for the selection, whereas others speak out for specific indicators directly related to the program which follows. Feldhusen and Baska (1985) argue that the search for generally gifted children and their identification using intelligence tests is acceptable when numerous varied activities for general intellectual stimulation are planned, as is often the case in elementary school or kindergarten. Hagen (1980) points out that general and specific indicators can often be assigned to the dimension "fluid-crystallized". General intelligence tests represent a "fluid" feature, which is however, according to Hagen, often no less suitable as predictor of success in a nurturing program as specific "crystallized" achievement prerequisites such as existing knowledge on a particular area of the program. Mention is often made of the value of ability tests when the identification of gifted underachievers is under discussion (Peters, 1992). B. Clark (1992) and Swassing (1985) point out the advantages of criterion-referenced measuring procedures when concrete prerequisites for coping with course demands are to be defined.

Another point of dispute alongside the use of general intelligence tests is the utility of the teacher's opinion. Richert (1991) lists numerous studies on the weaknesses of teacher judgment and advises largely against their use. In contrast, Tannenbaum (1983) praises the unique advantages of teacher judgment. We will deal with this topic later in more detail.

The question of how the collected data should be combined to form the overall judgment on a school student is also controversial. What is clear is that in practice data are often carelessly and irresponsibly combined (Alvino, Richert, & McDonnell, 1981). One reason for this problem is that recommendations are often made to gather as much data as one possibly can in order to eliminate the possibility of missing even one gifted child (B. Clark, 1992; Richert, 1991). Contrasting this, Perrone and Male (1981) and Tannenbaum (1983) warn against unmanageable floods of information and against the overinterpretation of subtest results whose significance cannot be persuasively empirically certified. Feldhusen, Baska, and Womble (1981) make

an urgent call for the sample-related standardization of the information on the basis of z or T values before measurements are compared or processed. In the literature there is little help on the design of the final decision or on the mathematical combination of data. For this reason, the present chapter is concerned above all with these questions.

In the surveyed literature there is little discussion of the fact that the identification of gifted school students for the admission to a nurturing program is accompanied by the rejection of less gifted students. Some recommendations seem to suggest that nearly all available school students should be considered for giftedness nurturing (Richert, 1991). In order to avoid having to make rejections, the taking of decisions in any form is called into question; suitable candidates are supposed to select themselves (Gourley, 1984; Shore & Tsiamis, 1986). If unsuitable children then do indeed take part in a program and fail, they are themselves held responsible. This argument overlooks the fact that special programs for the gifted are only effective when a child meets the conditions set by the program. The admission of a child to a program which is really too difficult can lead to frustration and feelings of inadequacy and negatively influence personality development.

Many authors indeed focus the problem that suitable students could be incorrectly rejected or that only partly suitable students take part in a nurturing program for too long. The solution offered by Renzulli (Renzulli, 1984; Renzulli, Reis, & Smith, 1981) to this problem seems especially effective. The *Revolving Door Identification Model* combines the construction of a broad Talent Pool with a limited period of nurturing. The admission to special programs takes place on the basis of very effective indicators of the process of learning and performing, called "Action Information". This procedure offers a number of advantages: (1) a large number of gifted children are nurtured; (2) process oriented behavior data, which Hagen (1980), Lupart (1992) and Tannenbaum (1983) assess as especially revealing, is collected about the members of the Talent Pool; (3) the short nurturing periods offer a lot of children the chance to receive special support during a school year; (4) the nurturing of an individual school student is based on the current individual needs. Renzulli's model has because of its popularity often been discussed and criticized. A recent overview of the state of the discussion is provided by MacRae and Lupart (1991) who conclude with a mainly positive evaluation of this model. This identification model assumes that a considerable proportion of the whole sample can be considered gifted and therefore requires nurturing; in addition, the assumption is made that sufficient personnel and other resources are available for the continuing diagnostic measurements.

Alternative models start from completely different assumptions: The *Talent Search model* which is presented, e.g., by George (1979) and VanTassel-Baska (1984) assumes that there is a large number of possible

applicants and a relatively small number of qualified applicants. It also assumed that there are restricted resources for applying individual-centered diagnostic measures. In addition, this approach focuses on a very high level of a narrowly defined talent. Therefore, it is more important to use a standardized and relatively difficult measurement instrument which sufficiently differentiates at the highest levels of ability than to collect a huge number of "soft" data in order to assist to the selection process (Keating, 1975; Stanley, 1984).

The concrete form that the identification procedure takes depends on the definition of the concept of giftedness and on the restrictions of the practical situation of the selection process. In the next section, elements of this situation shall be introduced which generally constitute the selection decision. Before that, the previously described recommendations are reflected on a theoretical and methodological basis. In addition, reflections about a typology of identification procedures are presented.

Methodological Basis for The Identification of Gifted School Students

The Individual Approach in Giftedness Nurturing

In the first part of this chapter, recommendations were presented on how the identification of gifted children as a prerequisite for, and a part of, gifted education has to be designed. These recommendations all assume that giftedness is a phenomenon which can be observed in the individual. Giftedness is a label for people and not for groups of people or for a particular learning situation. This assumption leads to the attempt to measure aspects of the individual and then to derive a statement on his or her giftedness. The planning and design of nurturing programs are also carried out with individual features in mind. Topic specific knowledge, learning potential, creativity, etc., are considered during planning, execution, and evaluation of programs to be properties of the individual. The fact that giftedness nurturing often takes place in groups (courses or classes), i.e., in a social context, is explained purely on grounds of organization (the number of available teachers).

This view of the education of the gifted, which takes the individual as its measure, would seem to be a consequence of the educational philosophy of the Western world: The individual's potential for self-actualization and for shaping his or her environment, i.e., individual freedom and independence, is a very important educational goal. That gifted people should also apply their talents to the benefit of society which educated them is a demand which is often subordinate to the aim of self-fulfilment. This requirement, that talent should also be used to benefit society, implies

a partnership between individual and society, i.e., it already accepts that individual and society are to be seen at least as equals.

At first glance, this preoccupation of giftedness nurturing with individual features seems to be perfectly natural. After all, the call for special nurturing for the gifted arose after individual differences (between children) were given a firm measurement methodology, and were thus made verifiable, by the development of psychological tests. A further argument was provided by the observation that the putting together of children into (heterogeneous) groups and giving them all the same lessons did not always take individual learning differences into account. So the establishment of special programs for the gifted arose out of the observation of individual differences.

Precisely these two arguments can however be interpreted differently: Giftedness only becomes a problem where a feature relevant to giftedness shows a large variance in the group in question (cf. the criteria for subjective theories of giftedness according to Sternberg, in Chapter 12) and where the school cannot adequately respond to this high variance. B. Clark (1992, p. 204) stresses that the need for nurturing must always be seen in relation to the nurturing resources available: "We are especially concerned about gifted children who show their intelligence through high performance in abilities in the cognitive, specific academic, creative, leadership areas, or ability in the visual and performing arts, *when such ability cannot be furthered in the program ordinarily provided by the schools*" (emphasis added). Feldhusen and Baska (1985) also seem to assume that regular lessons are not sufficient for gifted students. They explain (Feldhusen & Baska, 1985, p. 81): "The purpose of the identification process in gifted education is to identify youth whose abilities, motivation, self-concept, interests, and creative talents are so far above average that special education program services are needed to meet their needs."

For this reason, a need for identifying gifted individuals arises only when the existing educational measures are overtaxed. A consequence of this point is that identifying the gifted is useful only when other, better suited educational programs are available. This is reflected in Feldhusen's remark (Feldhusen, 1992, p. 10): "The identification process then serves to select youth who should receive and *will profit from special educational experiences* (. . .)" (emphasis added). Two conditions have to be met if identification measures are to be justified: Firstly, the regular educational program is not helping gifted students to develop in an optimal way, secondly, there is an alternative program to hand which does more justice to the developmental potential of those students. However, the performance of the regular educational program can only be measured with an investigation design which focuses the interaction of characteristics of the person and features of the program. It follows that identification of gifted students would ideally not start with the characteristics of the students

but with the features of the interaction between student and instruction.

In conclusion, the concept of "educational needs", and therefore the concept of giftedness, proves from a theoretical point of view to be constituted by a number of factors: (1) the heterogeneity of the characteristics of the population which are relevant for learning; (2) the ability of the regular instruction to respond to different levels of learning aptitude; and (3) the suitability of the special educational program to address the learning needs of those students who are not optimally supported by regular instruction. However, in practice, only personal characteristics are used for the identification of gifted students. The consideration of these three constituting factors leads to different approaches to identification. These approaches are presented in the next section. This discussion attempts to make clear the different assumptions on the nature of giftedness on which existing programs are based.

A Typology of Concepts of Giftedness From an Educational Perspective

The most widely used approach toward the identification of gifted students is based on the heterogeneity of the reference group (first constituting factor). Those characteristics of students which are relevant for the learning progress are assumed to be variable; usually they are modeled with normal distributions. There are accordingly only a few people with very high and very low values of the characteristic. If these characteristics represent individual potentials which are valued by society (as is the case with intelligence or creativity) because they are (statistically or causally) correlated with achievement in later life, the extreme values of these characteristics are labeled "giftedness" (cf. Sternberg, in the previous chapter).

Characteristics of this kind most often do not give clear information about the future development of individuals showing high values; in the same way, concrete evidence about these persons' behavior in special programs cannot be deduced from these characteristics. However, definitions of this kind, based on abstract characteristics of persons, are met frequently. An arbitrarily chosen percentage of the population is then named "gifted". A giftedness threshold, e.g., 2% or 5% of the population, can however never be justified on an empirical basis because continuous variables do not offer any obvious cuts.

It is difficult to design adequate education for a group of gifted students when giftedness is defined in such a way. High intelligence, for example, does not allow any conclusion about whether a student with high scores is appropriately challenged by regular classroom instruction or about which learning setting may be better suited to realizing and developing his or her reasoning ability. Conclusions of this kind must be derived from empirical investigations. Such

a distribution-related (norm-referenced) definition of giftedness does not have a direct relation to existing educational programs. Of course, this is a disadvantage if a prognostic statement has to be made on whether or not the gifted will be successful in the programs offered. On the other hand, this may be an advantage because existing programs can be evaluated on how well they fit the characteristics of the gifted. For this reason, a definition of giftedness which is constructed independently of existing programs can contribute to the optimization of the program. This was expressed by Renzulli (1984, p. 163) in the following way: "the way in which one views giftedness should be a primary factor in both constructing a plan for identification and providing services that are relevant to the characteristics that brought certain youngsters to our attention in the first place".

A second method of defining giftedness explicitly refers to existing educational programs (this corresponds to the third factor constituting the concept of giftedness as described earlier). A person is classified as gifted if he or she fits well into a concrete educational program, that is, if he or she best reaches the goals of the program. This strategy for conceptualizing giftedness follows the example of aptitude assessment as practiced in personnel selection. The use of a strategy of this kind is intended to guarantee that the persons selected profit most from being accepted for the position or the training. This paradigm of personnel selection is widely accepted. At the same time it is conceded that this kind of definition of giftedness can vary from program to program: "We have emphasized that the identification procedures themselves operationally define exactly who is gifted and talented for any particular program. Furthermore, the strategies described in this chapter do not always agree, that is, they will not identify the same students as 'gifted' or 'talented.' Therefore, it is important that identification be related not only to one's definition of giftedness, but to the purpose and goals of the program" (Davis & Rimm, 1985, p. 82f.).

This concept of giftedness is based less on the abilities of the individuals than on the demands made by the program. Labeling of the program participants as having special (relatively permanent and generally valuable) characteristics can be avoided because the participants show only features which are relevant in relation to the nurturing program. To establish an adequate methodology for selecting program participants requires comprehensive empirical studies of those features of the participants which allow the best prognosis of success in the program. Only features with high criterion validity are included in the selection strategy.

If one proceeds in this way, two problems arise. The first problem is the determination of a criterion of individual success in the program. Renzulli and Delcourt (1986, p. 20) argue that in the field of gifted education there is no generally accepted criterion: "The essence of the problem is the absence of an ultimate criterion to which any predictor variable can be compared." The

authors distinguish between creative productivity in the field covered by the program and long-term creative productivity in areas which individuals enter only in later life. Considered more specifically, cognitive or affective learning goals or the full development of one's personality can be emphasized as effects of the program and taken as a criterion. Generally, the development of learner characteristics which are already present at the beginning of the program or the compensatory nurturing of developmental deficits can be used as criteria depending on the goals of the program. A criterion or several combined criteria which represent the successful completion of the program must come first. Then suitable predictors and the combination of variables to form a complex predictor variable (e.g., to a linear combination; cf. Feldhusen & Jarwan, in this book) can follow.

The second problem arises if the program does not optimally correspond to the characteristics of children with high learning potential. It can happen, for instance, that children with very high intelligence do not benefit as much as children with average intelligence from completing the program. A consequence of empirical results indicating such a tendency would be a decision procedure which rejected children with very high intelligence from attending the program.

If there is no way of improving the program, this result has to be accepted. However, in general one should try to combine the norm-referenced definition and the definition based on an outside criterion. In this case, the participants of a program are initially selected according to their abilities or suitability. Then, during the formative evaluation of the program, the selection procedure which has been empirically determined on the basis of the external criterion is examined to see if it does select the same children who seem to be best suited for special nurturing on the basis of a norm-referenced definition of giftedness. In a nutshell, an investigation is carried out on whether the highly intelligent (or creative or otherwise talented) children are those who are nurtured best through the program.

A third identification strategy is possible, but it is hardly used in its purest form. This method is based on the criterion-referenced approach to the assessment of learning results (Hambleton & Novick, 1973; Klauer, 1987). This approach examines in relation to an internal criterion whether or not children have mastered a certain domain of knowledge. Criterion-referenced testing was developed as a method to evaluate the effects of instruction based on the mastery teaching approach: "In many of the new instructional models, tests are used to determine on which instructional objectives an examinee has met the acceptable performance level standard set by the model designer. This test information is usually used immediately to evaluate the student's mastery of the instructional objectives covered in the test, so as to locate him appropriately for his next instruction" (Hambleton & Novick, 1973, p. 160). This methodological approach is often applied when

internal differentiation is used during regular classroom instruction, that is, when students are assigned to small learning groups for a short period of time. After completion of a teaching or learning unit, the teacher can determine which children have mastered the learning goals and which have not. Children who have already mastered the contents are provided with additional learning material which can enrich or reinforce the knowledge acquired. The other children who have failed to master that domain are assigned to repetitions and additional exercises. In this case, where the mastery of a knowledge domain (which can be labeled expertise) is used as a basis to define giftedness, the second constitutional factor of the concept of giftedness (see earlier presentation) is being used.

At a macro-level, this approach seems to be that applied by *The Study of Mathematically Precocious Youth* despite that the tests which are used there have not been strictly designed in a criterion-referenced way. However, Stanley (1984, p. 179) explains that the premature mastery of a content domain serves as the actual criterion for the selection to continuous nurturing: "For example, the best way to 'enrich' Algebra I for students who already know it, or could learn the rest of it in a few hours, is probably to help them get smoothly into the best-available Algebra II class." The assessment of the mastery of a content domain serves two functions: Firstly, it demonstrates that these children would not profit from repetitions and exercises of the same topics; this kind of instruction would be less than optimal for them. Secondly, this assessment points out the direction which the subsequent education should take—be it enrichment/reinforcement of the knowledge or be it a continuation of the accelerated learning speed. Stanley (1984) and his coworkers seem to implicitly apply a procedure which was demonstrated by Bart and Read (1984). The participants of a special educational program were given a test on completion which served as an external criterion. Then the children who passed and who failed this final test were compared on the basis of the test which was given as the final examination of the unit preceding the special program. A cut-off score in this test was found which best separated the children who succeeded in the subsequent program from those who failed. This procedure combines that approach to the definition of giftedness which focuses on an internal criterion (second constituting factor) with that which focuses on an external criterion (third constituting factor). From a methodological point of view, the most important thing is that the content validity of the measurement instruments is guaranteed. This content validity can be determined by expert judgment (see Harty, Adkins, & Sherwood, 1983/84, and the following sections).

As we have seen, identification and nurturing of the gifted always takes place in a triangle formed by the characteristics of the person, features of the available classroom instruction, and properties of the special program of the gifted. If characteristics of

the person are regarded as particularly important, a distribution-oriented (norm-referenced) model is given which most often results from a percentage-based definition of giftedness. The emphasis put on features of the available classroom instruction leads to content-related conceptions which are methodologically mirrored by criterion-referenced testing procedures. If most emphasis is given to properties of the nurturing program which is intended or realized, identification of the gifted takes the form of personnel selection with relation to criteria of success given by the program.

It is just as fruitless to search for a criterion of truth for the different approaches to identification as it is to search for one for the definition of giftedness in general. Sternberg and Davidson (1986, p. 3f.) express this problem very precisely: "Ultimately, usefulness may be the only test we have of what makes for a better or worse conception of giftedness. Giftedness is something we invent, not something we discover. It is what one society or another wants it to be, and hence its conceptualization can change over time and place."

If we want to judge the utility of a selection procedure in the field of gifted education, we need first of all to know what features and consequences selection procedures have. In the next section a general model of selection is presented on the basis of decision theory. When compared to this general model, selection procedures used in practice can be evaluated and suggestions for optimization can be discussed. As we will see, many of the recommendations which were presented in the first part of this chapter are supported by theoretical considerations.

Procedures of Identification and Selection, Considered from a Decision Theoretical Point of View

The structure of the decision which underlies the selection of gifted students will be generally described in the following section. Concepts like validity and correlation are assumed to be familiar to the reader. Short explanations of these and other concepts are given by Swassing (1985) and by Murphy and Friedman (1991).

A GENERAL MODEL OF THE DECISION SITUATION

Every situation in which decisions on individuals have to be made is determined by the following characteristics:

(1) The individuals concerned possess a feature Θ which allows for a classification of the individuals into two (or more) groups. Either there are only two values of the feature (θ_0 and θ_1) which simply separate the two groups of individuals, or the feature has more values, in which case it is divided into two domains of values ($\theta_0 < c$; $\theta_1 \geq c$). In the context of the identification of gifted persons, θ_1 can be regarded as the existence of a high level of ability or of a need for special education,

or as suitability for the program in question. θ_0 can be seen as the lack of this ability, of this need, or of this suitability.

(2) The decision to be made takes the form of one of two (or more) available alternatives: a_1 : the person is gifted (or: the person should be taken into the program; or: the person has mastered the content of a certain domain), and a_0 : the person is not gifted (should not be taken into the program; has failed to master the content). Using the terminology of personnel selection, one can say that a person is "accepted" (a_1) or "rejected" (a_0).

(3) The feature Θ is not known (otherwise all decisions would be clear and error-free). However, there is a variable X available which can be observed. On the basis of these observations certain assumptions about the value of Θ can be made. The relation between X and Θ is probabilistic because X can be afflicted with measurement errors (lack of reliability) and because X is usually only an approximate measure of Θ (imperfect validity).

(4) Both values θ_0 and θ_1 of the feature Θ can occur together with both decisions a_0 and a_1 (Table 1). However, the four possible events $e_{ij}=(a_i, \theta_j)$ are not uniformly preferred by the person who has to make the decision. The events e_{00} (person who does not fulfill the criterion is correctly rejected) and e_{11} (person who fulfills the criterion is correctly accepted) are generally welcome but the events e_{10} (person who does not fulfill the criterion is mistakenly accepted) and e_{01} (person who fulfills the criterion is mistakenly rejected) would be regretted. A particular decision strategy, that is a rule specifying which values of X are to lead to the decisions a_1 or a_0 , can only be justified in the case where a preference order on these four events is given. If all four events are seen as equally advantageous or disadvantageous, the decision may be made randomly or on the basis of irrelevant aspects.

(5) The advantages and disadvantages of a decision strategy must be evaluated in order to arrive at a decision on the value of a particular decision strategy. Practically speaking, the utility resulting from the four events e_{ij} has to be quantified. However, decision makers often refuse to quantify utilities especially in the field of education. They believe that they decide without such a quantification. However, in most cases it can be demonstrated by a close inspection of their decision strategy that they implicitly use a certain quantification

TABLE 1

Table of results for correct and incorrect decisions

		Value of the feature		
		θ_1	θ_0	Sum
Decision	a_1	A	B	A + B
	a_0	C	D	C + D
		A + C	B + D	S

of utilities without being conscious of it. This problem will be discussed in more detail later.

(6) If values for the utility of the possible events are given, the decision procedure should then be designed to maximize expected utility, or to minimize expected loss. (In decision theory, utility is usually quantified as gains and losses. Statistical computations consider only losses because the losses are determined in such a way that the gains can be set to zero.) However, additional information is still required concerning the probabilities of the occurrence of θ_0 and θ_1 , and concerning the relation between Θ and the observable variable X . Putting all this information together, a domain of values $x_l < x_i < x_u$ can be statistically defined. The decision a_1 is made if an observed x_i lies within this range; if not, the alternative a_0 is preferred. If this "field of acceptance" of a_1 is located at the upper end of the scale of X , so that the scale is divided into two parts, the value x_c which divides the scale into the two areas for a_0 and a_1 is named "cut-off score". If $x_i < x_c$, a_0 is chosen. If $x_i \geq x_c$, a_1 is chosen. x_c (or the boundaries x_l and x_u) is chosen in such a way that the average utility which results from the application of a decision strategy is maximized.

(7) Once a particular decision strategy has been accepted, one can determine how many correct and how many incorrect decisions would be made on the basis of theoretical assumptions about the distribution of the variables and on the basis of empirical data. The events which result from the application of a particular decision strategy can be displayed using a table with four fields (Table 1).

The proportion of persons (with θ_0) unsuitable (for the program) but mistakenly classified as suitable to the total number of unsuitable persons, $B/(B+D)$, is named "alpha error", the proportion of suitable persons (with θ_1) who were mistakenly classified as unsuitable to the total number of all suitable persons, $C/(A+C)$, is named "beta error". The proportion of correctly classified suitable people to the total number of all suitable persons, $A/(A+C)$, is named "effectivity" (Pegnato & Birch, 1959) or "predictive value" of the procedure (Fineman & Carran, 1986). The proportion of selected suitable persons compared to all accepted persons, $A/(A+B)$, is named "efficiency" (Pegnato & Birch, 1959) or "sensitivity" of the strategy (Fineman & Carran, 1986).

(8) Each of the four events A to D results in a certain utility. The total utility of a decision strategy is obtained by summing the utilities (or losses; not necessarily in dollar units) over all S persons as has been described. There are, however, alternatives to this procedure: Some authors do not take into account all of the four cells in Table 1; it is possible for instance only to select the value of $(A+D)/S$ and then to try to maximize it. An overview of different forms of evaluation is given by Hollmann (1991). Several authors (e.g., Hany, 1991; Hollmann, 1991) point out that the value of a newly established decision strategy has to be determined in comparison to decisions made by chance

or in comparison to the decision strategy previously in use. A decision strategy which allows only for a β error of 5% can be judged as very good if the probability of being suitable $p(\theta_1) < .50$. However, if $p(\theta_1) = .90$, a reduction of the β error from 10% (when selecting by chance) to 5% (when selecting on the basis of the decision strategy) cannot be judged as very positive.

An overall consideration of the basic model of decision theory presented here leads to the following requirements on a decision strategy:

- Quantitative utilities have to be determined for correct and false decisions.

- A variable X which shows a relation as close as possible to the unknown feature Θ has to be determined.

- The values of the variable X have to be separated in two ranges by a cut-off score. These two ranges correspond to the alternative decisions a_0 and a_1 . The cut-off score has to be determined mathematically so that the application of the decision strategy minimizes the overall loss.

- Measures which help to minimize decision errors have to be applied. The fewer false decisions are made, the lower the resulting overall loss when it is summarized over all false decisions.

- When a certain decision procedure has been established, its characteristics and the consequences of its application should be investigated and disclosed to all participants. Special attention should be given to the number of false decisions which cannot be avoided.

These settings are discussed in more detail in the following sections. Recommendations for the design of procedures for the identification of gifted students will be made with reference to the relevant research literature.

SETTING THE LOSS FUNCTION

Decisions are only of importance if the consequences of the decision are of different value. Accepting or rejecting a child for a giftedness program can result in different, serious, consequences. Thus the best possible decision has to be made. Direct costs, psychological costs, and costs for the society can be distinguished (Emrick, 1971; Klauer, 1987). Direct costs for the participant consist of the time invested for taking a special course and of the money invested for the learning material, particularly if the child has been mistakenly selected for the course, i.e., if the child fails to master the demands. Costs can be time and money invested for remedial or compensatory instruction which the student does not require, following a mistaken admission decision. Long-term costs include lower chances of being admitted to good and renowned institutes of higher education which may result for a child erroneously rejected from a sought-after giftedness course. As a consequence, this child may suffer a relative income loss in the future. The psychological costs for missed career opportunities are certainly more severe than the material losses because the total arrangement of life,

including the choice of a partner and the choice of later residence, may depend on the professional career. In the same way, the psychological costs of rejecting a capable child from a program for the gifted also have to be taken into account. The child's self-concept may be negatively affected. However, this consequence can also result if the child is erroneously accepted for the educational program and fails to complete the course.

Costs to the institution which offers the educational program are, to begin with, the costs for carrying out the program which, however, shall not be considered here. Costs for carrying out the selection procedure (for testing material, travelling costs for the participants, reimbursement for the members of the selection committee) and for the recruitment of the applicants (advertising efforts) can be important factors which influence the decision regarding the establishment of the selection procedure (Brodgen, 1949; Cronbach & Gleser, 1956; Martin & Raju, 1992). Avoidable costs result when unsuitable applicants are mistakenly accepted. These costs are material (fees for the teacher and the course materials) and psychological (conflicts for the teacher on how to proceed didactically, delay in the course of instruction for all students). Costs for society emerge if an educational program for the gifted works ineffectively, i.e., if it contributes only slightly to the "educational productivity" of the local school system (Walberg, 1981), if it discriminates against minorities, or if unsuitable individuals get unjustified access to privileges provided by society due to their having been accepted for the educational program. The positive effects of correct decisions could be constructed in a similar way.

When evaluating the consequences of using a decision strategy in the field of education, one cannot proceed in the same way as in the model for personnel selection because there the only issue considered is utility for the selecting institution; the disadvantages for rejected applicants are ignored (Brodgen, 1949; Naylor & Shine, 1965). Disadvantages for rejected and wrongly assigned candidates have to be considered in the same way as advantages for the correctly classified subjects because the educational system has to provide all learners with the best support possible. With special reference to grading in schools, Klauer (1987) argues that, in the educational context, both types of errors have to be handled with equal weight. Otherwise, one of the errors is accepted more often than the other. This may, e.g., cause grading to follow a tendency of leniency which could change the overall function of grading. If Klauer's argument is extended to the education of the gifted, the intention never to exclude gifted students from programs especially designed for them would result in many unsuitable applicants being mistakenly accepted because the cut-off score for the decision would have to be set at a very low level. This problem will be discussed again later.

It is by all means possible to establish utility or loss functions in domains of life which cannot be

assessed in dollar units. One approach uses subjective estimates which can also be averaged over individual judges (Novick & Lindley, 1978; Vrijhof, Mellenbergh, & van den Brink, 1983). Using the method of pair comparison, loss functions on at least the ordinal level can be obtained. In principle, the ultimate goal is to establish a decision strategy which results in the least loss possible, rather than having to determine losses for every event. For this reason, it is sufficient to determine two values a and b so that the value k in the equation $k = a \times \alpha + b \times \beta$ is minimized by the choice of an appropriate cut-off x_c (Hambleton & Novick, 1973). α and β are the probabilities for the two kinds of wrong decisions and a and b are their weights. In the case of the education of the gifted, the β error, i.e., the erroneous rejection of a gifted student, may be taken as being more serious than the erroneous acceptance of an unsuitable student. In any case, all practical recommendations aim at taking as many students as possible into the identification procedure in order not to overlook any of the qualified persons. If the value of b in the equations shown above is chosen adequately high, the value of k can only be minimized if β is fixed at a very small number. However, the α error will inevitably grow as a consequence, that is, the incorrect acceptance of unsuitable applicants. Put simply, if the optimal decision strategy is to be computed statistically, one has only to fix the just barely acceptable relationship between α error and β error.

It has to be added that the weight of each error of decision can be fixed separately for different subpopulations. This results in correspondingly differentiated decision strategies (Gross & Su, 1975; Mellenbergh & van der Linden, 1981). Furthermore, it should be mentioned that decisions of a certain kind (e.g., the correct acceptance of suitable individuals) need not be weighted equally in all cases. The acceptance of a highly suitable candidate can be taken as more desirable than the acceptance of a candidate whose true score θ_i lies barely above the critical threshold score. In those cases, a linear or quadratic loss function is used instead of a so-called threshold loss function. In every case optimal decision strategies can be determined computationally (van der Linden & Mellenbergh, 1977).

CHOOSING A VARIABLE AS THE BASIS FOR THE DECISIONS

The selection of gifted students has to be based on one or more variables. These are measured with the aim of collecting information on an ability construct, on a level of knowledge related to a course of instruction, or on the success which can be expected in a program for the gifted. In this section, the selection of adequate variables is discussed.

(1) *Ability related variables.* If students are selected and nurtured by a program according to their abilities, it may be practical to use standardized ability tests which contain recent norm tables and which fulfil the usual requirements regarding reliability and validity.

In the simplest case, intellectual ability, this will be an intelligence test (Rost, 1991; Shore et al., 1991; Stanley, 1984; Terman, 1954). Structured ability tests, tests of creativity and instruments measuring special talents, e.g., in sports, in music or in the performing arts, can all be chosen so that they are in agreement with the underlying concept of giftedness (cf. Hany & Heller, 1991, and the chapters which follow). The theoretical assumptions on the concept of giftedness should be mirrored in the selection and application of the measurement instruments. This requirement is of highest priority if an acceptable array of instruments (Urban, 1990) is to be achieved.

Those instruments which were developed on psychometric principles allow, however, relatively few conclusions to be drawn regarding the development and the adequate nurturing of the ability measured (Borkowski, 1987; Howe, 1990). Many of the instruments currently in use were developed without explicit theories of cognitive-intellectual performance—or the theory has been forgotten by those concerned. Recent analyses of the cognitive basis of intelligent performance including problem solving, transfer of learning, and knowledge acquisition (Chi, Glaser, & Rees, 1982; Gray & Orasanu, 1987; Neber, 1992; Necka, 1991; Sternberg, 1977; Singley & Anderson, 1989) will stimulate the development of new instruments with higher validity for the processes of knowledge acquisition and knowledge application than traditional tests (Sternberg, 1991). The application of traditional ability tests can lead to systematic discrimination against certain subgroups of the population if the historical and cultural background of content and form of the test items is not carefully considered (Goldstein, Haldane, & Mitchell, 1990; Irvine & Berry, 1988).

For use in the education of the gifted, instruments should be developed which aim at uncovering the potential for development of the ability in question and which, at the same time, offer indications for its nurturing. A promising approach is given by the assessment of the learning potential as developed by Guthke (1974, 1982) and, recently, by Feuerstein (1979) in the Soviet tradition. These instruments (cf. the overviews given by Brown & French, 1979; Tyerman, 1986) try to measure not only the current status of a reasoning ability but also how far it can be changed by particular interventions. Although this approach has so far found its most fruitful applications in the diagnosis of learning disabilities, its application in the field of giftedness is certainly also possible (Guthke, 1992; Skuy et al., 1990). This development is supported by a tendency to use measurements of giftedness not only for identification purposes but also for the design of educational programs focusing on individual characteristics of the learner (e.g., Lupart, 1990). Expressed in the language of scientific diagnostics, this means that the modification strategy is favored against a selection strategy (Krapp, 1986).

It has to be conceded that the diagnostic foundations of the learning test concept have not yet been completely

clarified (Perleth & Sierwald, 1991). Attempts should be made to identify subjects of different learning ability, that is of different “zones of proximal development”, by means of a latent class analysis (cf. the overview given by Rindskopf, 1987). On this basis, the applicants for an educational program could be separated into two groups with different learning needs and learning aptitude. This methodological approach would probably provide the best method of testing the assumption which has often been expressed that gifted persons are qualitatively different from other persons regarding their reasoning processes (Davidson & Sternberg, 1984; Facaoaru & Bittner, 1987; Rogers, 1986).

(2) *Choosing predictors for an external criterion of success.* A slightly different approach is required if giftedness is defined on the basis of successfully completing a program for gifted learners. In this case, the selection procedure has to find predictors for later success and has to design a decision strategy on their basis. The problem of an adequate criterion for success has to be addressed once again. The question of which and how many criteria should be considered for evaluating the effects of an acceptance decision has been extensively discussed in training research (Klauer, 1992) and in personnel selection for work positions. Following Smith (1976), criteria for success in professional settings can be described on the basis of three dimensions.

- The time perspective (short-term measurements of behavior as against successes many years after completing the program or working in the field).
- The specificity desired (a global measure as against detailed information).
- The proximity to the employer's goals (pure descriptions of behavior as against estimates of the pay-off for the company).

Despite the variety of possible criteria, it seems to be practical to use a single global criterion for acceptance decisions (Roe & Greuter, 1991). This criterion can be a continuous variable (e.g., scores obtained in the final test of a course; evaluation of the originality of a project carried out by the participant; level of difficulty of the courses which were selected next by the individual) or a simple pass-fail criterion (as a measure for θ_0 and θ_1).

Although criteria for long-term success in life could in principle be taken into account here, it seems to be very difficult to find suitable predictors. Retrospective (Bloom, 1985; Wallace & Gruber, 1989; Yewchuk & Edmunds, 1992) and longitudinal observations (Freeman, 1991; Trost, 1992; Trost & Sieglén, 1992) of individuals of high intellectual productivity have aimed at isolating single variables which might serve as predictors of the long-term development of achievement. However, the results of those efforts were mostly unsatisfactory (Schneider, 1992). Nor do longitudinal or meta-analytical investigations of the long-term effects of special educational measures (e.g., pull-out programs: Vaughn, Feldhusen, & Asher, 1991; acceleration: Swiatek & Benbow, 1991; Van Tassel-Baska, 1992; Kerr, 1992; grouping: Feldhusen & Moon, 1992; Kulik

& Kulik, 1992; early admission to elementary school: Proctor, Black, & Feldhusen, 1986) seem to offer clear indications for exactly which variables should be considered when selecting candidates for giftedness programs.

There would therefore seem to be more justification in using criteria which indicate short-term success, that is, the successful mastering of the educational program. However, here too a decision has to be made on which criteria of success, that is, which learning goals should be preferred (Passow, 1992). After a criterion has been chosen, a predictor variable X has to be found which should be as valid as possible. This need not to be a single variable; it is often practical to combine several predictors. A composite score often shows a higher reliability than a single measurement. The prognostic validity, however, can be taken as the most important feature of the predictor. The higher the validity of the predictor, the less often wrong decisions are made. Figure 1 shows the relationship between α error and β error for measurement instruments with different validities (cf. Cronbach & Gleser, 1965).

If a continuous criterion variable has been chosen, a linear combination of several predictors can be formed by means of regression analysis. A combination results which shows a very close correlation to the criterion, i.e., it is highly valid (an example of an empirical study is given by Rust & Lose, 1980). If the criterion is dichotomous and discriminant analysis is used, several predictors can be computed for a discriminant function (e.g., Harty et al., 1983/84; Pyryt, 1986). The linear combination or the discriminant function then constitute the variable X which forms the basis of the decision function. In the case of a continuous criterion, two

domains of values θ , have to be determined which form the two groups of masters and non-masters or of successful and unsuccessful participants.

Regression analysis has often been recommended as a means for combining several predictors (Feldhusen, Asher, & Hoover, 1984). However, in special cases it can lead to problems. To begin with, it must be said that a number of predictors of low validity cannot replace one predictor of high validity. Figure 2 shows the results of a simulation on the basis of $n = 1001$ subjects. Several sets of predictors with a fixed correlation to a criterion were formed. Then, these predictors were taken step by step into a multiple regression. The course of the multiple correlations is demonstrated in Fig. 2. However, it can be clearly seen that adding more and more predictors of the same validity leads to successively lower relative gain. Furthermore, one can see that a single predictor with a correlation of $r = .80$ between predictor and criterion is of higher prognostic validity than the simultaneous consideration of seven predictors with a correlation of $r = .40$.

In addition, it should be acknowledged that multiple regression can represent only linear relationships between predictors and criterion and only those which are valid for the total sample. Different validities for different subsamples do not show up in the results of the overall analysis. Regression analyses separately performed for subsamples (e.g., for girls and boys, or for members of different ethnic groups) are recommended in order to determine the differential validity of predictors. Statistical procedures which can help to determine suitable moderator variables are available (e.g., Flaugher & Rock, 1969; Rock, Evans, & Klein, 1969). Interactions between predictors can be deter-

FIGURE 1. Minimal combinations of α and β errors shown for different levels of validity of the predictor. These minimal levels can only be reached by using optimal cut-off scores.

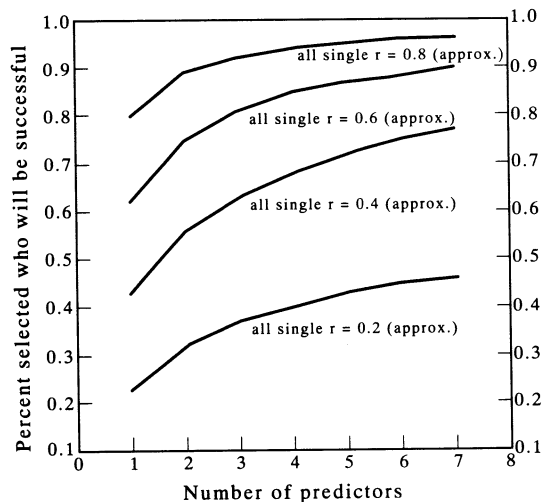

FIGURE 2. Changes in the multiple correlation coefficient R for sets of 1-7 predictors with fixed validities (results of simulations based on fictitious data).

mined well by multivariate techniques (Pyryt & Heck, 1991), whereas they remain undetected in regression analyses.

Another problem of regression analysis arises from the fact that the resulting linear combination allows for the compensation of low scores in some predictors by high scores in other predictors. If, for example, the results of a test of general intelligence, the grade average of the most relevant school subjects, and subjective statements on personal free-time activities in several science domains (measured by a biographical inventory) are all included in a regression analysis, a student can compensate low intelligence scores by merrily checking answers in the biographical inventory. This can result in the same final score as it is obtained by a highly intelligent student who answers the inventory in a highly self-critical way. Sometimes compensatory effects are desired. In cases where compensations would not make sense, a sequential decision procedure would be required which considers different aspects of giftedness in separate decision phases.

Rules for allowing or prohibiting compensation can frequently be found in the decision patterns applied by committees. If candidates are evaluated on the basis of numerous pieces of information by committees or commissioners, the resulting ranking of the candidates frequently cannot adequately be described by means of regression analysis. For this reason, a suggestion made by Moore and Betts (1987) is unlikely to meet with much success. They suggested that the evaluations of candidates made by different committee members should be compared on the basis of correlation tables and regression analyses. When judges make assumptions about causal or correlational relationships between the variables on the basis of their subjective theories, linear analyses cannot adequately represent the different weights ascribed by these judges to scores and to combinations of these scores. It is of course important to allow complex decision rules and to support complex decision behavior by displaying the available data clearly (Weber & Battaglia, 1985), but the quality of the resulting decision strategy still has to be evaluated. Configural judgment behavior can be most practically modeled by expert system technology (Hany, 1991b). The candidates' characteristics profiles are compared and are categorized together with the experts' judgments into typical patterns of evaluation by means of computer-supported analyses. In contrast to statistical optimization procedures, expert systems do not require representative samples. Missing case material is replaced by heuristic rules which allow for diagnostic reasoning even when information is missing.

The non-linear processing of information assumed to be undertaken by experts is however not always any more efficient than the linear combination of data. Dawes and Corrigan (1974) have demonstrated that the linear combination of data is not only frequently superior to complex forms of data processing but also especially resistant to changes in the weighting of

the variables. Furthermore, the linear combination of data seems to be particularly suitable for reflecting the structure of diagnostic decisions (Ramsey et al., 1986). A very readable overview of the relationship between statistics-based judgment and the expertise paradigm/expert systems is provided by D. A. Clark (1992).

Typological approaches to the combination of data can be regarded as an alternative to statistical procedures which combine data linearly. Candidates are grouped according to their categorial or ordinal scores obtained on predictor variables. Sometimes the criterion variable is included in the analysis. For instance, all applicants for an educational program could be asked to provide information on several dimensions. The scores on these dimensions are then preliminarily classified as "acceptable", "intermediate" and "not acceptable". These trichotomous variables are then subjected to a configural frequency analysis (Krauth, 1985; Lienert & Krauth, 1975). This procedure can lead to the identification of certain types of candidates with special profiles of characteristics (empirical examples are demonstrated by Perleth, Sierwald, & Heller, 1993, and by Steffens & Perleth, 1990). Continuous characteristics can be subjected to a cluster analysis. In contrast to configural frequency analysis, however, quite drastic decisions regarding distance measures and the agglomeration of clusters have to be made here. If it is possible to arrive at types of applicants empirically, these types can be compared on the basis of the external criterion of success. A decision can be made on which types should be accepted for the program in question and which should not. Empirical data can be used to judge the average disadvantage due to varying decision strategies which variously accept members of the separated types for inclusion in the program.

(3) *Setting standards on an internal criterion.* Earlier in this contribution it was argued that an individual need for special educational measures is present when a student has successfully passed a unit of instruction earlier than his or her classmates and when that student would not profit from further regular instruction. Criterion-referenced tests are used to measure whether or not a learner has mastered a unit of instruction. According to the postulate of content validity, these tests contain a representative selection of tasks which cover the knowledge domain. Decisions about which student has mastered that knowledge require the setting of a critical value θ_c which the student has to pass. The setting of the critical value cannot be made on the basis of the empirical distributions of values in the student sample. It must be made on the basis of the demands which the contents of the test items put on the students.

For this reason, Nedelsky (1954), Angoff (1971), and Ebel (1972) developed methods which require experts to judge each test item according to the probability that a student on the borderline between masters and non-masters would solve it correctly. Adding these estimated probabilities for all test items, a critical

score results that separates θ_0 from θ_1 . Additionally, the cut-off score x_c has to be set for the test scale (cf. next section). Angoff's method seems to be the most reliable of those mentioned here (Berk, 1976; Maurer et al., 1991).

Zieky and Livingston (1977; see also Livingston & Zieky, 1982) developed a procedure which is not based on fictive borderline students but uses real samples. Experts in a knowledge domain are told to identify subjects out of a sample (e.g., a given class of students) who border between non-masters and masters. These students work on the test. The median of the number of their correct solutions is set as the critical threshold score. An alternative procedure requires experts to identify masters and non-masters. Then the test is given to both groups. Based on the tests results of both groups, the critical score is set at a point that minimizes the number of wrong classifications. If a reference group is available for which an estimate of the distribution of masters and non-masters can be made, this knowledge can be immediately used to set the critical score. For example, if 20% of the sample are assumed to be masters, the threshold score of the empirical distribution of scores is fixed at a point which is only passed by 20% of the students. These procedures are discussed by Shepard (1980) and Klauer (1987). If one accepts that experts can determine who can be regarded as a master of a content domain or of a particular skill, one can develop a more positive attitude toward observations that "homemade" measurement instruments are often developed locally for identification purposes (e.g., Harty et al., 1983/84). From a criterion-referenced point of view, it is not necessary to use intelligence tests or other norm-referenced instruments for acceptance decisions. Tests which directly assess the knowledge which has been previously learned or which will be required later can be of higher diagnostic value (van der Linden, 1991).

The methods which have been presented up to now all require subject matter experts providing a subjective estimate in order to determine the threshold between masters and non-masters. However, other procedures have been developed which pay more attention to empirical data than to subjective judgment. Berk (1976) reviews many of these methods and in conclusion recommends the contrasting groups method for classroom use. This method consists of lessons which are given to one group but not to a second group. Afterwards, both groups work on a test which is valid for the teaching goals of that lesson. The results of both groups are compared; the test score which best separates the two groups is taken as the cut-off score. However, this procedure requires that most members of the instructed group master the content, that is, that they have learned what they have been taught.

Other methods (Block, 1972; Huynh & Perney, 1979) compare learning success in sequential units of instruction. The mastery of the following instruction unit (measured by a dichotomous variable) is used to deter-

mine the minimum competence which has to be demonstrated in the test which completes the previous unit of instruction. Only individuals who show this minimum competence are accepted for the later unit. It has been possible to realize this method in giftedness education in the following way: Before being admitted to an advanced course, e.g., in mathematics, the participants attempt a test on particular knowledge prerequisites. A certain proportion of the children then take part in the advanced course. Based on the results of the final test (or a judgment made by the teacher) at the end of the course, it is possible to determine who completed the course successfully and who did not. Then the score a person would have had to have achieved in the previous test in order to be successful in the advanced course is calculated. Though this procedure seems quite plausible, some problems are revealed when it is viewed from a perspective of educational psychology. Giftedness education is based on the principle that previous achievement should not be the sole precondition for being accepted for further special education. If nurturing of the gifted is only based on the "Matthew principle" of education (Walberg & Tsai, 1984), underachieving children and learning disabled gifted students are rejected from advanced educational programs (Butler-Por, 1987; Heller, 1987, 1989; Yewchuk, 1986; Zorman, 1991). To prevent this, the individual learning potential and the motivating effect of the nurturing program should be considered in addition to existing knowledge and skills when future learning progress is to be predicted.

SETTING CUT-OFF SCORES

When percentages, group sizes, or minimum requirements for criterion-referenced tests are obtained from expert judgments or empirical studies, the critical value θ_c which gives the threshold between mastery and non-mastery still cannot immediately be converted to a cut-off score x_c on the measurement scales used (Klauer, 1987). Measurement errors in the procedures and their perhaps unsatisfactory validity have to be taken into consideration when cut-off scores are determined. It is not defensible to simply use cut-off scores which have been computed on the basis of one student sample, as happened in many studies which tried to design a short form of the WISC-R which were intended to be as far as possible equivalent to the full form (e.g., Dirks et al., 1980; Elman, Blixt, & Sawicki, 1981; Fineman & Carran, 1986). The analysis of individual WISC profiles of gifted children shows that they vary enormously in some subtests (Hollinger & Kosek, 1986). The procedure detailed below seems to be more appropriate.

If the true score θ_i of an individual has to be determined on the basis of a single measurement x_i , a regression analytic measurement following Lord and Novick (1968) can be made which accounts for the reliability r_{xx} of the variable X :

$$\hat{\theta}_i = \bar{x} + r_{xx} \times (x_i - \bar{x})$$

This formula shows that the estimate of the true score $\hat{\theta}_i$ approaches the mean score \bar{x} of the measurement as the reliability r_{xx} decreases. If X and Θ are variables with standard normal distribution (mean: 0, standard deviation: 1), the formula reduces to

$$\hat{\theta}_i = r_{xx} \times x_i$$

Then, given a critical value θ_c , the cut-off score is determined as follows:

$$x_c = \theta_c / r_{xx}$$

According to van der Linden (1980), this formula is valid only when a normally distributed loss function is given which weights α error and β error equally. In the case of linear loss functions which allow for different weights for the two kinds of errors and which also account for the distance between θ_i and θ_c , the following formula is valid (van der Linden & Mellenbergh, 1977):

$$x_c = [\theta_c - (a_0 - a_1)(b_0 + b_1)] / r_{xx}$$

with $(b_0 + b_1) > 0$.

In this case, the loss function $l(\theta)$ for all rejections, i.e., when $x < x_c$, is determined as $b_0 \times (\theta_i - \theta_c) + a_0$, and for all acceptances, i.e., when $x > x_c$, as $b_1 \times (\theta_c - \theta_i) + a_1$. These formulae show that the cut-off score is set low if a_0 , the general loss caused by rejection, is weighted relatively highly. If the losses caused by a strong deviation of x_i from x_c are assumed to be very high, the difference of the levels of the two losses $a_0 - a_1$ have to be weighted conservatively because only then can the danger be avoided that extreme deviations $\theta_i - \theta_c$ coincide with wrong decisions.

The simplest case of a loss function is the threshold loss function. In this case, the loss $l(\alpha)$ caused by incorrect acceptance and the loss $l(\beta)$ caused by incorrect rejection are determined by constant values. These should be determined numerically in such a way that "gains" caused by correct decisions are set to zero. The cut-off score for the variable X is computed so that first of all the proportion of losses $\lambda = l(\alpha)/l(\beta)$ and $z(\lambda) = \Phi^{-1} \times [1/(1+\lambda)]$ are determined. Φ^{-1} is the inverse of the distribution function of the standard normal distribution z . The cut-off score x_c , given a variable X which has a standard normal distribution, and given Θ as the latent property, is determined as

$$x_c = \frac{\theta_c - z(\lambda) \times \sqrt{1 - r_{xx}}}{\sqrt{r_{xx}}}$$

(Vijn & Molenaar, 1981; see also Klauer, 1987). If both losses are weighted equally, $\lambda = 1$ and $z(\lambda) = 0$ result. The cut-off score is then determined as

$$x_c = \frac{\theta_c}{\sqrt{r_{xx}}}$$

All methods described here assume that first a critical value θ_c of the property Θ has to be set before the cut-off score x_c can be computed. Furthermore, content validity is assumed for the measuring instrument. If norm-referenced instruments are used, poor instrument validity can cause problems as is discussed in the next section. A special problem results if a continuous

property Θ is given and if the number of persons who have to be selected is fixed (fixed quota, e.g., if there is a maximum number of participants of an enrichment course). In this case, the simplest procedure is to build a rank order of applicants based on a linear combination of the predictors or on some other weighting of the data. Starting with the applicant who has received the highest rank, the best available applicants are accepted in a "top down" manner for as many as positions as are free. This procedure, which does not require a previously fixed cut-off score, looks very simple. However, this strategy has been accepted even by courts and professional associations (Casio, Alexander, & Barrett, 1988).

It should be noted that Richert (1991) takes a strong position against the use of cut-off scores. She argues that underachievers and other subgroups of children are too hastily rejected by the strict use of cut-offs on performance scales. In the present article however the position is taken that the use of inadequate indicators of giftedness and irrelevant measurement instruments is more likely to lead to unjustified rejections than the use of cut-off scores. The use of a cut-off score can be demonstrated empirically in every decision strategy which deserves the name and which is based on quantitative data even if the decision makers deny using a cut-off score.

REDUCTION OF DECISION ERRORS

The choice of a suitable cut-off score for the decision strategy helps to minimize the disadvantages which result from wrong decisions by reducing the frequency of wrong decisions. Other methods can serve the same purpose. Following Mills and Simon (1981), Klauer (1987) points to the following relationships:

- The more reliable a test is, the fewer misclassifications result.
- The more items a test has (or the more data items are available which together are used to compute the variable X), the fewer misclassifications result (Hambleton, Mills, & Simon, 1983).
- The more homogeneous the item difficulties and the higher the item-scale correlations are, the more efficient the test is.
- The greater the number of subjects who have to be classified, the more efficient is the reduction of decision errors.

The validity of the measurement instrument in relation to a given external criterion is of highest relevance for the quality of classification. The validity coefficient sets a lower bound to the extreme minimization of loss which can be achieved by setting a suitable cut-off. Figure 1 showed the correlation of α and β error as they appear in classification decisions when different validities for the relationship between predictor and criterion are given. Figure 3 shows the effects of different settings of λ given two different levels of validity ($r = .30$ and $r = .90$). For a fixed loss ratio, a straight line can be drawn in Fig. 3 (shown as dotted lines). If the line

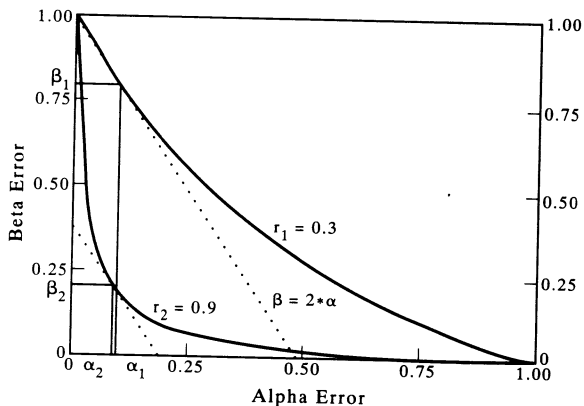

FIGURE 3. Relationships between the validity of the instrument and the frequency of unavoidable errors: The same ratio of accepted errors (the β error is ascribed only half of the loss value ascribed to α ; this ratio is shown by the slope of the dotted lines set at -2.0) results in different error frequencies (indicated by lines parallel to the axes) depending on the validity of the instrument (represented by the two curves).

touches one of the curves drawn for a given validity, the minimally possible classification errors can be read off (shown as lines parallel to the axes). Given a λ of 2.0, about 8% incorrect acceptances (α error) and about 20% incorrect rejections (β error) result from a validity coefficient (between predictor and criterion) of $r = .90$. If the validity coefficient is as low as $r = .30$, an α error of 10% and a β error of about 80% result. Figure 3 may also help to clarify why different weightings of the two kinds of errors results in substantial changes of the number of errors accepted only when a low validity of the predictor is given. To put it another way: only if the variable X is of low validity do different values ascribed to both kinds of errors lead to different frequencies of incorrect classifications.

Increasing the validity of a predictor for a criterion of success is therefore of special relevance. Computing a linear combination out of several predictors or combining information by configural integration as has been recommended in the previous text may increase validity. It may also help to separate subgroups of applicants and to use different sets of predictors or different weights of predictors for each group separately.

Another strategy for decreasing decision error is the reduction of the selection quota (Taylor & Russell, 1939). If only few applicants are to be selected from a large number, even an instrument having only medium validity can be very useful. As shown in Fig. 4 (from Taylor and Russell), an instrument with a validity of $r = .30$ may actually result in an efficiency of about 75%, given a 50% quota of acceptable applicants and a selection ratio of 5%. Therefore, recommendations made by many giftedness experts that a large talent pool should be created as the selection population seem to be acceptable at least from the perspective of

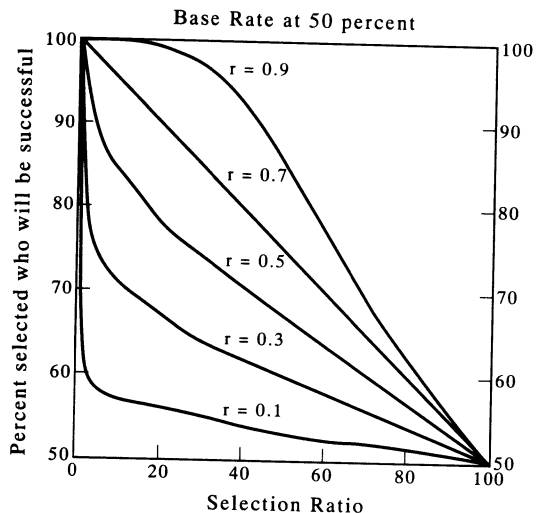

FIGURE 4. The relationship between the selection ratio and the percentage of selected persons who are suitable for the program for different predictor validities (theoretical data).

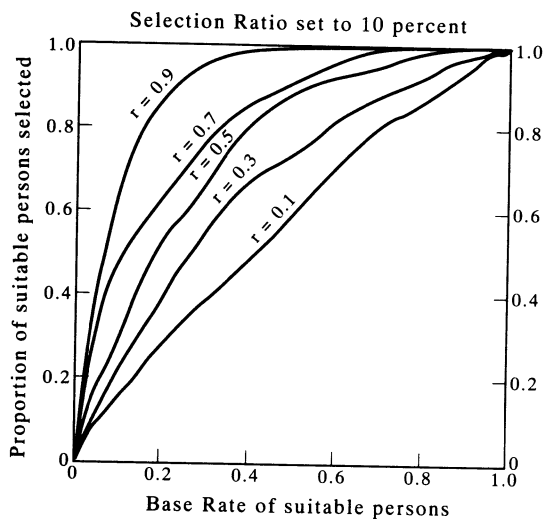

FIGURE 5. The relationship between the base rate of suitable persons and the percentage of selected suitable persons for different predictor validities (results of simulations based on fictitious data).

the selecting institution. However, the costs emerging from the recruiting of a large number of applicants have to be accounted for when the identification procedure is comprehensively evaluated (Martin & Raju, 1992).

It should also be recognized that fewer unsuitable candidates are accepted if the group of applicants mainly consists of suitable individuals. Figure 5 shows that a high ratio of suitable candidates (horizontal axis)

automatically results in a high percentage of suitable persons in the accepted group (vertical axis). However, if the ratio of suitable persons is low, only a highly valid instrument identifies many acceptable persons and reduces the β error. In practice, this means that only a large number of suitable candidates from which a small number of participants are to be selected for a program allows for an optimal selection of candidates and, thus, for a high level of learning in that program. The frustration arising from being rejected from the program can be reduced if several program courses are offered so that the candidates can apply for more than one course. In addition, a special course could be offered more than once so that all interested school students have several chances of applying for it. This not only enhances the individual chance of being accepted, but also allows the selection committee to collect information from the applicants several times and to aggregate them to an overall judgment of perhaps very high validity.

MAKING THE DECISION PROCEDURE APPLIED MORE TRANSPARENT

Every selection procedure used for giftedness education programs has to be in tune with the demands made by the program and the definition proposed by those responsible for it. In addition, calls are often heard that the procedure should be easy to use, that the statistical values should be easy to compute, and that it should be possible to explain and justify the overall method convincingly to lay-people (Berk, 1976). In pursuing this goal it may be helpful if the persons who apply the selection procedure are accountable for its consequences. This includes the calculation and discussion of acceptable levels of classification errors. Here are not only the α and β errors and the accepted loss function to be considered but also the base rates for suitable and unsuitable applicants. A committee, for example, may prefer to accept three unqualified candidates to the program rather than to incorrectly reject one in fact gifted child. However, if this ratio 3:1 is applied to every decision, that is, to every applicant, it could turn out that up to twelve unsuitable persons are accepted for every suitable person who is rejected. This may happen when the ratio of unsuitable to suitable persons in the applicant group takes a value of 4:1. To accept a high ratio of unsuitable candidates for a program for gifted children cannot be justified. The intended high level of learning cannot be reached in a course filled with too many average students. Such a program would frustrate the gifted students' expectations and would perhaps do more harm than if a few of them had not been accepted to the course. A strategy which radically minimizes or completely avoids β error (erroneously rejecting gifted persons) is undesirable because it would cause an irresponsibly high rise in α error. However, if a substantial β error is accepted, members of minorities are in particular danger of suffering first from decision errors. The strategy of accepting equal error frequencies separately in all relevant subgroups of the

population as was proposed by Richert (1991), is therefore to be welcomed from an educational point of view. From the perspective of educational productivity, however, this approach may be questioned and detailed justifications for its use may be required. It may be helpful to learn from a comparable discussion opened by research on personnel selection and economic growth (Schmidt, Ones, & Hunter, 1992).

The rejection of some gifted children for programs especially designed for them despite their being suitable cannot be avoided completely. These children may erroneously attribute their being rejected to their being of low ability. Therefore, the education of gifted children in special programs has to be supplemented with individual counseling in order to avoid such effects. In counseling settings, abilities and skills are measured independently of a given program or course of instruction (Heller, 1987; Wiczerkowski & Wagner, 1985). If a child has been rejected from a special program, individual counseling should assist in developing alternative educational pathways which may equally or better be suited to fostering personality development and realizing the individual's talents and interests. Mistaken decisions made by program committees may be compensated in these ways even if they cannot be reversed.

SUBJECTIVE CONCEPTIONS OF GIFTEDNESS AND SUBJECTIVE DECISION STRATEGIES

One additional aspect of selection procedures has to be clarified in advance before further recommendations for the identification of the gifted can be deduced from theoretical considerations. Since the pioneering work done by Meehl (1954) and Sawyer (1966), the demand has often been heard that diagnostic decisions should be made on a mathematical and statistical basis. However, the so-called "clinical judgment" prevails in practice and dominates decisions regarding the selection of gifted individuals. In many cases, teachers, program coordinators and other experts are in charge of making the decisions (Adderholdt-Elliott et al., 1991). Test scores and the results of statistical computations are often only used as the information basis for the subjective decisions. Calls are often heard for comprehensive individual case studies to be used as the basis for admission decisions (Renzulli & Smith, 1977; Weber & Battaglia, 1985; for school-career counseling in general: Heller, 1982).

The following questions have to be answered before this procedure can be evaluated:

- Do teachers and other persons who make admission decisions have acceptable ideas of the concept "giftedness" and "gifted student"?
- Can teachers and the other persons involved process complex information adequately?
- Do group decisions show features which make them superior to decisions made by individuals?

A short review of the literature regarding these questions follows.

(1) *How teachers understand the concept of "giftedness"*. The question of whether teachers can identify gifted students has always been controversial and causes conflicts even today (Rost, 1991 vs Hany & Heller, 1991). In fact, numerous studies have evaluated teacher judgments as being inadequate. If one compares those students who were identified by teachers as "gifted" with those who are judged by standardized tests to be highly intelligent, little agreement is found (Baldwin, 1962; Gear, 1976; Jacobs, 1971; Pagnato & Birch, 1959). Not very much attention has been paid to an early counterexample (Chambers, 1959). In the few last years, however, there has been much criticism of the fact that only simple nominations and scales were used for recording teacher judgment. In many of these studies, the kind of giftedness that teachers should focus on was not even defined. Hoge and Cudmore (1986) conclude that judgments made by teachers offer valuable information if it is placed on a methodological basis comparable to standardized intelligence tests. This assumption is empirically supported by results reported by Ashman and Vukelich (1983) who used detailed checklists for teachers and found positive correlations between the results of intelligence tests and evaluations made by teachers. In the same vein, Egan and Archer (1985) reported positive correlations between teacher judgment and subject-specific achievement tests. On the other hand, Sharpley and Edgar (1986) found only average correlations between subject-specific teacher judgments and the results of ability tests. These authors used, however, rather simple scales for recording teacher judgment. Hany (1991b), in contrast, found that teacher judgment separated two groups of students (of average and of high intelligence) better than statements gained from the students through questionnaires and even better than ability tests. In this study, the teachers were asked detailed questions and their answers were combined using complex decision rules.

So it seems that research to date on the quality of teacher judgment has been impaired by two phenomena which have been surprisingly rarely discussed: Firstly, simple judgment scales are used—often only nominations or single-item scales with five response levels for assessing an entire giftedness area. Such scales cannot be compared with intelligence tests test-theoretically. Secondly, in these studies it is assumed without further reflection that giftedness can be measured by means of a simple intelligence test. The insight that giftedness is more than intelligence has found its place in numerous theoretical models (e.g., Gardner, 1983; Renzulli, 1978; Sander, 1967) but not in studies evaluating the usefulness of teacher judgment. However, it is fair to assume that teachers make recourse to other, more complex, concepts than the abstract concept of intelligence when making a giftedness judgment. In any case, there is continual confirmation that teachers are capable of selecting suitable students for "giftedness courses" (Hany & Heller, 1990), and that they judge students quite consistently (Ashman & Vukelich, 1983). It can

be concluded from these observations that any disagreement between teacher judgment and intelligence test results is caused not by a lack of reliability but by poor construct validity.

The cognitive processes applied by teachers when they judge gifted students can be deduced from studies which focus on the subjective conceptions of giftedness held by teachers. Some of these studies investigate the quality of the prototype (or stereotype) of a gifted student represented in the teacher's long-term semantic memory. In two studies, one in Turkey and one in Germany (Hany, 1992a; Sahin & Düzen, 1992), teachers were presented with lists of characteristics. The teachers were asked to estimate how well these features characterize gifted students. It was found in both studies that teachers take logical thinking, quick understanding, and intellectual curiosity to be typical for gifted persons. The results of a German-American study (Busse et al., 1986a,b) can be interpreted in a similar way. In this study, the structure of the subjective concept of giftedness was also investigated. American and German teachers were asked to evaluate their gifted students on the basis of 84 given characteristics. A factor analysis of their evaluations showed that the teachers perceived their gifted students in a very detailed way. Five factors were extracted for the US teachers. Three of them were interpreted as being in accordance with the three-ring model proposed by Renzulli (1978). Seven factors were extracted for the German teachers, among them "logical problem solving", "verbal proficiency", "achievement orientation" and "artistic skills".

Similar results were obtained by Guskin, Peng, and their coworkers (e.g., Guskin, Peng, & Simon, 1992), who demonstrated in several studies that teachers do have a differentiated concept of giftedness. They identified five facets of the concept of giftedness: analytic or cognitive ability, social skills, creative arts, verbal ability, and motor skills. The authors were able to relate these factors to Gardner's (1983) model of multiple intelligences. Studies of this kind demonstrate that teachers are able to judge giftedness in a differentiated way if they are given a detailed instrument which allows for fine-grained judgment. However, more experienced teachers perceive gifted students differently than less experienced teachers do (Copenhaver & McIntyre, 1992; Schack & Starko, 1990). This fact calls for specific teacher training.

One study still in progress (Hany, 1992b) is based on research on concept acquisition which shows that the elements of a category are stored in memory either as single exemplars or in summarized form as prototype (Medin & Smith, 1984; Medin, Altom, & Murphy, 1984). This approach has since been transferred from general psychology to the psychology of social judgment (Smith & Zárate, 1992). It can be assumed that teachers who have only had contact with a few gifted students in their classes develop an exemplar-based concept of giftedness. These teachers judge a new student as gifted only when he or she closely resembles one

of the gifted students who were previously stored in memory as being gifted. Teachers who have had contact with a greater number of gifted students will tend to use a summarized representation, i.e., they hold a prototypical concept of gifted students and judge new students in a different way. If this assumption could be supported empirically, it would be possible to conclude that the decision behavior, particularly of those teachers who have had only little contact to gifted students, cannot be satisfactorily described by regression analytic or discriminant analytic models. Instead, configural decision rules must be assumed, based on the concrete contacts of the teachers to individual gifted students. If a group of teachers has to decide whether a student is gifted or not, very different opinions will emerge as a result of the different previous experience of the participant teachers. For this reason, Feldhusen, Asher, and Hoover (1984), Moore and Betts (1987), and many other authors recommend that the participants of a decision committee should come to an agreement about the concept of giftedness to be used. A written text would be very helpful there.

(2) *The subjective processing of complex information.* When confronted with difficult decisions, individuals tend to: (a) decide erroneously, (b) erroneously perceive their decision behavior, and (3) perceive decision problems inadequately. These facts were revealed by numerous investigations focusing on individual decision behavior (Einhorn & Hogarth, 1982; Pitz & Sachs, 1984; Rapoport & Wallsten, 1972; Slovic, Fischhoff, & Lichtenstein, 1977; Slovic & Lichtenstein, 1971). Human beings tend to be very economical with their information processing, particularly when faced with numerous and complex pieces of information. In this case, qualitative thinking replaces the quantitative combination of data, extreme information is weighted too heavily and hypotheses once set up are not likely to be revised. Particularly vivid key cases and recent memories govern decision behavior rather than an integrative summary of the mass of experience gathered by oneself and by others (Tversky & Kahneman, 1973). If decisions have to be made between numerous alternatives or when numerous aspects of information about the alternatives are available, individuals tend to use two strategies (Montgomery & Svenson, 1976). Either they concentrate on the most important information and neglect the rest (lexicographic decision rule) or they successively delete alternatives on the basis of limited information (aspect related deletion rule). For this second strategy, a cut-off score marking the minimum requirement is set on the most important characteristic. All alternatives which do not pass the cut-off score are immediately deleted from the list of acceptable alternatives (for more details, cf. Hany, 1991a).

In view of the weaknesses of individual decision behavior, the question should be raised of whether it is really appropriate to collect as much information as possible before a decision is to be made. Under special circumstances, this flood of information may

lead to more biased decisions than those made on the basis of limited data of high relevance. On the other hand, feeding the computer with all information and expecting an automatic decision may be an unwarranted alternative. It must be asked whether the measurement instruments available and the statistical procedures which are usually applied do justice to the complexity of student personalities. Perhaps it is merely an illusion to believe that quantified decision rules can be established for all individual cases. This objection seems to be justified by the very observation that in practice students turn up again and again who show very rare characteristics or combinations of characteristics which have not been seen by the judges before. Ready-made decision rules for these cases cannot be provided on an empirical-statistical basis; these decisions have to be deduced from meta-rules or from general heuristics for the practical decision process.

(3) *Group decisions.* It is often assumed that group decisions lead to better results than decisions made by individuals. It is claimed that the more persons involved in discussion, the more arguments are exchanged, the more carefully arguments are weighed up, and finally a solution to the problem at hand is accepted whose quality is higher than that obtained by individuals. Earlier empirical research on these questions was able to show that democratic rules are followed in many groups, thus favoring the opinion held by the majority of the group members (Davis, 1982). Further, it was confirmed that groups end up with better decisions than the average participant. However, as a rule group decisions do not reach the quality of decision which can be achieved by the best participant if he or she decides alone (Reagan-Cirincione & Rohrbaugh, 1992). The best qualified participants must, therefore, be allowed to exert major influence on the decision if the quality of group decisions is to be improved (Libby, Trotman, & Zimmer, 1987). Regrettably, unqualified group members can influence the solution process negatively (Davis, 1982).

Groups decisions are often more extreme than the average of the decisions taken by individual group members. Myers (1982) explained this "polarization effect" by the fact that more extreme opinions are disclosed and exchanged in homogeneous groups than in heterogeneous groups. If persons who share similar opinions meet in a group, they disclose their secret wishes and intentions. A one-sided picture of the opinions held by the group can emerge which leads to more extreme decisions. In heterogeneous groups, it is more difficult to exchange opinions, and decisions are made in a more conservative and cautious way (Watson & Kumar, 1992). When homogeneous groups are dominated by an additional pressure of conformity exerted by a strong group leader, typical decision errors result: Alternative solutions to a problem are not fully considered, not all relevant characteristics of the alternatives are discussed, the consequences of the decision are not investigated, and commitments made early in the discussion are not further revised (Janis,

1982). This phenomenon was labeled "groupthink" and was shown to govern some influential political decision groups (Janis & Mann, 1977).

Berk (1976) recommends that the participants of decision groups should make their decisions privately in order to avoid unfavorable mutual influences of the group members. He advises that group members should not be confronted with the opinions of their colleagues and that they should not be required to announce any change in their personal opinion. It follows from these recommendations that members of decision committees should discuss data and arguments but not individual decisions. These decisions are better collected in secret ballots. The final decision should then be based on the majority of the votes. Keren (1992) recommends that detailed information on the stages and consequences of the decision process should be given to the judges in order to improve individual decision behavior. He argues that providing judges with information that helps to cognitively structure the whole decision process is more effective than providing quantitative information (statistical data) or recommendations on how to proceed.

The question of whether teachers and school administrators are able to make adequate classification decisions on students can be answered with a cautious "Yes" against the background of the research considered. Individual judgment and group decision are prone to numerous errors, but the persons responsible can make rational decisions if they weight the available information carefully and if they compare their opinions with the opinions of the other members in a reserved way. Two recommendations arise out of a closer inspection of the current state of the research: Firstly, more studies on the form and quality of identification decisions should be made in the area of gifted education, and secondly, in-service training should be provided for teachers and school administrators in which they are advised to reflect on and evaluate their own decision strategies.

Identifying the Gifted: State of the Art in Theory and Practice

An overview of the publications on the identification of gifted youth reveals a growing sensibility toward the substantial connection between identification and nurturing. The decision as to who is to be counted as gifted depends on the predominant definition of giftedness and on the demands which are put on the participants of the planned educational program. Effective educational differentiation requires selection. This cannot be avoided or replaced by a principle of pouring out education to everybody on the watering-can principle. However, identification procedures are only acceptable if they do not trigger unjustified labeling and if the assignments of individuals to categories can be revised easily. Classifying students or learners must be regarded only as an aid for fitting instruction to children in an appropriate way. The

system of categories must correspond to the categories of instruction which are or will be realized and should not be more detailed. The selection of gifted students for special education must be part of a general philosophy of education which deals with the learning needs of all children.

Explicit and appropriate statements about how to design a comprehensive and defensible identification procedure can be found in most relevant textbooks on gifted education. Numerous measurement instruments are available which are well suited to gain a reliable informational basis for the decisions to be made. The recommendations on how to design the selection often take very different forms (e.g., talent search vs the *Revolving Door Model*) but the underlying opinions regarding the function and the value of identification itself seem to follow a common pattern of reasoning. Even from an international perspective, the identification of gifted students seems to be a matter of discussion only when there is conflict between different general conceptions of how to nurture giftedness. So it seems that many insights arising out of decision theory (introduced in the second part of this chapter) are at least implicitly followed in many recommendations for practical identification.

However, when programs are evaluated it is regularly discovered that many of the selection instruments used deviate substantially from scientifically justifiable procedure. The use of restricted definitions of giftedness, the application of deficient measurement instruments, the careless combination of information, and discrepancies between the definition of giftedness, the selection procedure and the educational program are deficits which have been observed many times (Richert, 1991). The three different models of how to select gifted students which were presented earlier in this paper are not clearly distinguished in the discussions. Considerations of how to establish cut-off scores seldom follow the recommendations made in statistical literature.

To turn now to research, evaluations of currently used selection procedures are necessary, clarifying their deficits and making open recommendations for improvement. Furthermore, there should be investigations on how robust selection procedures are introduced by local school authorities to individual variations. This is necessary because it may happen that in spite of the use of insufficient sources of information and the faulty combination of data acceptable selection decisions are made. It is particularly important to investigate the subjective information processing of those responsible for selecting the gifted. From studies of this kind, indications of how to design in-service training courses which contribute to better decision behavior may be derived. Research on the efficiency of content-valid measurement instruments for selecting gifted students for domain specific educational programs must also be developed. If more emphasis was given to those measurement instruments

which meet the demands of criterion-referenced testing, the problems of labeling which often accompany ability related testing could be avoided. Furthermore, problems regarding the prognostic relevance of indicators, resulting from the orientation toward the later success of the individuals selected, would also be eliminated. Content-valid instruments should be individually designed to fit the program and student population concerned. Therefore, the college education and in-service training of teachers of gifted students should, among other goals (cf. Chapter 35 of this handbook), focus on competence in developing such instruments.

Identification of Gifted and Talented Youth for Educational Programs

JOHN F. FELDHUSEN AND FATHI A. JARWAN

Purdue University, West Lafayette, Indiana, U.S.A.

Introduction

Gifted and talented youth need differentiated educational services to sustain their academic, artistic, psychomotor, or social development. The curriculum must be modified and teaching methods adapted to the needs of these youth (Marjoram, 1990). However, educators are often unaware of these students' special abilities or in some cases are disbelieving or resistant to the diagnosis and the need for differentiated services (Garbers, 1987). Thus, special efforts are needed to identify gifted and talented youth, to diagnose their special talents and aptitudes, and to arrange optimal instruction for them.

For those educators who recognize gifts and talents in youth and the need for differentiated instruction there is a long standing tradition to regard the task initially as searching for "the gifted child" and as trying to avoid mistaken identification of students as gifted who are not "really or truly" gifted. The technical terminology is to avoid both false positives and false negatives. False positives are children identified as gifted who are not and false negatives are those who are mistakenly overlooked or rejected.

In early practice the term genius (Galton, 1869) was often used to denote people of very superior ability. Later usage, probably influenced by Terman and his genetic studies of genius, saw a gradual shift to the term "gifted". Terman began to use "gifted" in the alternative titles to the volumes reporting his longitudinal research, except for Volume 2 (Cox & Terman, 1926) which was titled "The Early Mental Traits of Three Hundred Geniuses".

Out of Terman's research and applications of his research from 1930 to 1970 and following a tradition of categorization and labeling in special education, the practice of identifying youth as "gifted" or "not gifted", based primarily on intellectual or academic abilities, became deeply entrenched in school practice. The practice persists to the present in spite of the frequent use of the terms "gifted" and "talented". In some cases "talented" or "academically talented" came to be used

as a lower level of giftedness, with the latter reserved for those of very special ability.

The publication of the Marland Report (1971) heralded a great surge of development of programs and services for gifted and talented youth in the United States. The report declared that:

Gifted and talented children are those identified by professionally qualified persons who by virtue of outstanding abilities are capable of high performance. These are children who require differentiated educational programs and services beyond those normally provided by the regular school program in order to realize their contribution to self and society (pp. I-3 to I-4).

The report further delineated six areas of giftedness:

- (1) General intellectual ability.
- (2) Specific academic aptitude.
- (3) Creative or productive thinking.
- (4) Leadership ability.
- (5) Visual and performing arts.
- (6) Psychomotor ability.

While the report had a great impact in the sense of stimulating development of programs for the gifted, identification practices moved in the direction of identifying all-purpose general giftedness, not specific talents or aptitudes. Equally pervasive in its influence on the field of gifted education was the "three-ring" model of giftedness promulgated by Renzulli in 1978 delineating (1) above average ability, (2) task commitment, and (3) creativity as basic components of the construct. The Renzulli model emphasized a search for "gifted behavior" as opposed to gifted status.

While these and other models (Sternberg & Davidson, 1986) continued to portray giftedness as a general condition or construct, other researchers had indeed been focusing their attention on special talents or aptitudes. DeHaan and Kough (1956) published the results of their work for the Quincy Illinois Youth Development Commission in which they had developed practices for identifying and nurturing talents and gifts in ten areas:

Intellectual ability; scientific ability; leadership ability; creative ability; artistic talent; writing talent; dramatic talent; musical talent; mechanical skills; physical skills.

From experiences in the Quincy Youth Development project DeHaan and Havighurst (1957) concluded that youth who are in the top 10% in a talent domain *may* be considered gifted and that talented youth may equal or exceed 20% of the school population.

Current practice in gifted education continues, however, to favor a general giftedness approach and the identification of all-purpose gifted youth, with far less attention to their special gifts and talents. In this paper we will review conceptions of giftedness in greater depth, discuss operational systems for identifying gifted and talented youth, examine concepts related to selection, and draw conclusions and guidelines for practitioners.

Conceptions of Giftedness and Talent

The history of the gifted education movement has witnessed extensive efforts in both theoretical and empirical areas to define the construct *giftedness*. Yet, there is little agreement among researchers and educators on a precise definition and measurement of giftedness (Horowitz & O'Brien, 1985; Janos & Robinson, 1985). The widespread disagreement is a result of varying and conflicting conceptions about the relationships among and definitions of giftedness, intelligence, and talent (Feldhusen & Hoover, 1986; Gagne, 1985). Hallahan and Kauffman (1982), however, argue that the reasons for disagreement are mainly due to differences of approaches regarding four issues: the range of skills and behaviors to which the term giftedness should be applied, the measurement of giftedness, the cutoff point above which a child is considered gifted, and the nature of the comparison group.

Identification of the gifted for academically oriented programs has become more complex and difficult as the focus of attention moves beyond traditional IQ definitions of giftedness to broader perspectives which view giftedness as a multifaceted process (Heller, 1991; Necka, 1991) including many talents and aptitudes as well as general ability (Feldhusen, 1986a, 1986b; Gardner, 1983; Getzels & Jackson, 1958; Guilford, 1967; Marland, 1971; Silverman, 1986; Treffinger & Renzulli, 1986; Tyerman, 1986; Wallace & Pierce, 1992).

Definitions of Giftedness

An explicit definition of giftedness is considered by many authors to be a keystone for the development of programs for the gifted. It is important because of the close link that must exist between the definition and the identification system (Feldhusen, Asher, &

Hoover, 1984; Hoge, 1988; Ward, 1983). It also is important because of its relationship with program goals and curriculum offerings (Feldhusen, 1982). Finally, the definition adopted or developed by a school will determine in general terms who will be selected and who will be excluded.

From a historical point of view, published definitions may be classified into six categories. They will be discussed next.

Psychometric Definitions

Psychometric definitions represent a quantitative approach in viewing giftedness in terms of cut off points on certain criteria such as IQ. This approach originated from the traditional psychometric research of Terman (1925) and Hollingworth (1929).

Terman and Hollingworth used intelligence as a basis for defining giftedness and operationally defined intellectual giftedness in terms of a line drawn at a score level on an intelligence scale (Terman & Oden, 1959; Hollingworth, 1929). In spite of using nine methods to collect data for the main experimental group of 643 subjects, an IQ of 140 on the complete Stanford-Binet scale was set by Terman as the provisional lower limit for inclusion in the case of children under 11 years. The ultimate goal, as indicated by Terman (1925), was to locate subjects in the top 1% of the school population.

Hollingworth (1929) also equated giftedness with high levels of intelligence as measured by standardized individual tests. She believed that "a mind must be judged by its product" and "the measurement of performance" is the "only approach to the measurement of mind" (p. 26). She defined intellectually gifted children as the most intelligent 1% of the population who are at or above 130 IQ.

Trait Definitions

Trait definitions are derived from psychological characteristics that are assumed to differentiate gifted children from others. At least one component of Renzulli's definition (1978), task commitment, is derived from this approach. Unusual curiosity, variety of interests, productive thinking, etc., are among the traits included in these definitions. Reynolds and Birch (1977) suggested that "The gifted student is likely to have: above average language development; persistence in attacking difficult mental tasks; the ability to generalize and see relationships; unusual curiosity; a wide variety of deep interests" (p. 216). Several of these characteristics may be viewed as traits.

Definitions Focused on Social Needs

This category refers to definitions that are based on social needs (Newland, 1976). In a comprehensive

historical review of public concern for the gifted during the period from 1950 to the present, Tannenbaum (1986) concluded that statistics of supply and demand in key professions, especially in science and technology, and racial balance were major factors in determining the direction and extent of concern about gifted education at all levels. The influence of politicians and economists in creating intense concern or lack of concern was always significant and consequently some researchers have concluded that “giftedness is societally defined” (Kirk & Gallagher, 1983; Sternberg & Davidson, 1985).

Educationally Oriented Definitions

Educational definitions focus on specific qualities of education or schooling that are important for the gifted. The federal definition (Marland 1971) represents this approach. Two conditions are essential: Demonstrated potential ability and a need for differentiated educational services. All definitions of giftedness that include a statement emphasizing the need for special provisions in the curriculum and/or instruction can be classified as educationally oriented definitions although some of them may be subsumed under two or more categories. Gallager’s definition (1975), for example, states that “These are children who require differentiated educational programs and services beyond those normally provided by the regular school program in order to realize their contribution to self and society” (p. 10).

Special Talent Definitions

The emphasis in the talent category is on particular aptitudes (von Ardenne, 1990; Balogh & Nagv, 1990; Howe & Sloboda, 1991). The term talented generally refers to students who are outstanding in a specific skill such as arts, music, mathematics, science, or any other esthetic or academic area (Davis & Rimm, 1985) that may or may not be matched by more general abilities (Kirk & Gallagher, 1983). Although it is common to use the words “gifted” and “talented” interchangeably, the relationship between the two concepts is somehow problematic.

Several theorists have attempted to clarify the concepts of gifts versus talents. Gagne (1985), for example, after reviewing related literature, presented a differentiated model in which he defined giftedness as above-average competence in one or more domains of human ability, and talent as above-average performance in one or more fields of human performance. Feldhusen (1992) proposed a new conception of the term talent as referring to superior aptitude or ability in any worthwhile line of human endeavor. He suggests that talent is a developmental phenomenon emerging out of general aptitudes and into specific career-oriented abilities.

Multidimensional Definitions

This category refers to recent definitions that integrate several factors and include more detail. Renzulli’s conceptual definition (1986) may be classified under the multidimensional, educational category:

Gifted behavior consists of behaviors that reflect an interaction among three basic clusters of human traits—these clusters being above average general and/or specific abilities, high levels of task commitment, and high levels of creativity (pp. 11–12).

Feldhusen and Hoover (1986) also presented a multidimensional conceptualization of giftedness as an interaction of superior general abilities (intelligence), focused talents, and a special conception of self. Motivation, according to their definition, is an outcome behavior resulting from self concept and self esteem which “impel an individual to work, to investigate, to learn, to solve problems, to strive, to achieve, to compete” (p. 141). Feldhusen (1986a) also stressed the role of a knowledge base, acquired through educational experiences, as another fundamental component of emerging giftedness.

DIFFERENCES AMONG THE DEFINITIONS

These definitions of giftedness differ in at least four fundamental ways:

(1) Degree of comprehensiveness or breadth: This dimension refers to the nature and number of variables included in the definition. At one extreme are definitions with a single variable and domain such as mathematical aptitude or creativity. At the other extreme are multivariate definitions that include a wide range of traits in addition to cognitive variables.

(2) Degree of superiority: This dimension ranges from conservative definitions such as Terman’s top one percent level in general ability as measured by the Stanford–Binet Intelligence Test to liberal definitions such as the multiple-talent viewpoint of Taylor, Allington, and Lloyd (1990) that considers almost every one to be gifted or talented in some way.

(3) Gifted versus potentially gifted focus: This dimension refers to an important aspect of the conceptualization of giftedness in terms of the extent to which definitions involve a static or dynamic view of components or characteristics of giftedness. According to Hoge (1989), the continuum ranges from definitions based on IQ tests to definitions that involve a set of potentialities that may or may not be developed.

(4) Terminology of giftedness: A variety of terms have been used in defining the giftedness construct. Some use the terms “giftedness” and “talent” synonymously, some distinguish between them, others associate them with the term “creativity”.

To sum up, there is much disagreement on the definition of giftedness. There is no one definition that will serve as the theoretical base for all programs and situations. Nevertheless, a definition is a central component of every organized program and should be conceptualized and stated with great care.

Developing Systems for Identification

For a sound identification system, there are a number of concerns to which personnel in charge of planning and developing identification systems must attend. These include (1) the rationale and goals, (2) defining the target population, (3) use of single or multiple criteria, (4) types of test instruments, (5) criteria for test selection, and (6) selection strategies.

Rationale and Goals of Program

The rationale and goals of a program for gifted and talented youth are of central importance in making informed decisions regarding the definition and identification of the target population (Borland, 1989). Advocates for gifted education combine individual and societal needs in their justification for programs (Tannenbaum, 1986; Ward, 1983). The assumption behind such a mixed rationale probably is that the *welfare of the individual* and the *welfare of the society* are congruent. In their discussion of the philosophy and objectives of special education for the gifted, Gowan and Demos (1964), for example, argued that the objectives should be determined by two factors, the needs of the individual and societal demands. Whether the concentration is on individual needs or on societal needs, there are important implications for the definition and identification of the gifted.

Nevertheless, it is widely accepted that the primary goal of programs for the gifted is to provide experiences that meet the needs of gifted learners which cannot be met in regular classrooms (Clark, 1992; Gold, 1980). A defensible goal for a special program should be to select and admit students who are most likely to benefit from the educational program and meet criteria of success as defined by program goals. This is no more than a frame of reference for the much more complicated task of working out specific, unambiguous objectives and activities. In addition to guiding all activities to be undertaken from the beginning, precisely stated objectives provide a solid foundation for any formal or informal attempt to monitor and evaluate (a) the degree to which objectives have been achieved, (b) the weaknesses and strengths of procedures and methods, and (c) the value of the objectives themselves. A key

question to be answered is: "With what objectives and under what conditions can the goals of the identification system and the program be achieved?" In the following sections some of the factors that can be brought to bear on this question are discussed.

Defining the Target Population

Defining the target population of students from which the selection is to be made is the first and perhaps the most important step in planning programs for the gifted (Borland, 1989). Almost all essential components of any well-structured program for the gifted are shaped by the definition of the target population. The Johns Hopkins accelerative model (Stanley, 1979), for instance, differs from the Triad model of Renzulli (1984) mainly because the target population for each model is defined and selected in a different way.

Sternberg and Davidson (1986) reviewed conceptions of *giftedness* and concluded that they have changed over the years from the psychometric conception that equated giftedness with high IQ (Terman, 1925) to a multidimensional conception (e.g., Marland, 1971; Renzulli, 1978; Tannenbaum, 1983) which includes intellectual and nonintellectual domains or factors and more domain-specific ones (Stanley, 1979). For practical purposes it is of great importance that the definition be reasonable to operationalize, that is, measurable. Otherwise, the theory-practice gap discussed by Yarborough and Johnson (1983) could not be closed. Defining the target population also requires accurate information about the student population in the grade level for which the program is intended. This is fundamental to informed planning for identification.

Special Populations

Identifying gifted students from special populations has posed a challenging problem for professionals and educators in the field of gifted education (Baum, 1986; Bragget, 1990; Feldhusen, Asher, & Hoover, 1984; Reid, 1989; Richert, 1985). Research in the past focused more on deficits rather than on strengths (Baldwin, 1985; Baum & Owen, 1988; Whitmore, 1981). However, gifts and talents among special populations exist in similar proportions as among the general population (Baldwin, 1985). Student civil rights to equal opportunity for special services means that an identification system should guarantee that no one who is qualified is overlooked.

The National Association for Gifted Children's Committee on Special Populations adopted a position statement relating to the definition and identification of special populations. The term is defined to include

“groups who differ from those who have been traditionally well represented in school programs for the gifted” and it “can be applied to children and young adults who are Black, Hispanic, Native American, Asian Pacific, rural, economically disadvantaged, handicapped, and female, as well as students whose gifts are in domains not traditionally recognized in school settings” (Jenkins-Friedman, Richert, & Feldhusen, 1991, pp. vi-vii). The statement also indicates that typical instruments and procedures used to identify gifted students for special programs may be inadequate and insensitive to the unique qualities and characteristics of special populations. Ignoring the needs and special problems associated with identifying gifted/talented students from special populations also leaves the field vulnerable to charges of elitism and racism (VanTassel-Baska, 1989).

Minority and Disadvantaged Gifted

The charge that minority groups are underrepresented in programs for the gifted and talented has been consistently supported by research findings (Skuy, Kaniel, & Tzurie, 1988). For example, representation of various ethnic groups in public schools compared to their representation in programs for the gifted is shown in the following table as presented by Zappia (1989):

TABLE 1

Ethnic group	Public school enrollment (1%)	Gifted programs enrollment (%)
Anglo-Americans	71.2	81.4
Blacks	16.2	8.4
Hispanics	9.1	4.7
Asians	2.5	5.0

The U.S. Office for Civil Rights (1987) also conducted a nationwide survey in the fall of 1986 to obtain data on the characteristics of students enrolled in public schools. According to the survey summary, 3% (372,421) of the total minority enrollment (12,199,456) were identified and served as gifted. The percent for whites was 5.35% (1,549,736) out of 29,956,580. The data indicated that minority students compose 29.6% of the total school enrollments but only 19.4% of the total population was identified and enrolled in special programs for the gifted.

In a national survey, including the fifty U.S. States, District of Columbia, and three territories, Patton, Prillaman, and VanTassel-Baska (1990) concluded that “Although states have been consistently positive in their philosophical orientation toward culturally diverse and low socioeconomic gifted students, they have lagged in incorporating these concerns for equality and pluralism into the definitional and funding structures of their gifted programs” (p. 94).

In another study, Colangelo and Kerr (1990) used data from the American College Test (ACT) Assessment Program’s Students Profile section to formulate and study profiles of the highest 5% and 1% of 729,606 high school juniors and seniors (334,126 male; 395,480 female) who took the American College Testing Assessment Program (English, Mathematics, Social Studies, or Natural Sciences) during the 1985/1986 academic year. A sample of perfect scorers (5,615) on at least one of the four sub-scales of ACT was selected. The results for perfect scorers by ethnicity indicated that all ethnic/minority groups of Blacks, Native American, Chicanos, and Hispanics were underrepresented. Whites were somewhat overrepresented and Asians were greatly overrepresented.

VanTassel-Baska and Willis (1987) conducted a three-year study to investigate the effects of low income on SAT scores among the academically able. The sample was composed of students who participated in the Midwest Talent Search Program in the years 1985, 1986, and 1987. Families of students with annual income of \$20,000 or below were considered “economically disadvantaged” based on U.S. Bureau of Labor statistics which indicated that the median family income in the United States in 1984 was \$28,623. Giftedness was defined as attaining a score of 95th percentile on an in-grade standardized achievement test in either math or verbal ability at the junior high level. Data analysis indicated that the participation rates of low income disadvantaged gifted students (in samples of 11,675, 14,486, and 16,425) were 13.2%, 13.8%, and 13.3% in 1985, 1986, and 1987, respectively.

Handicapped Gifted

The term “gifted handicapped” refers to children who have two sets of characteristics: giftedness and disability (Clark, 1992). They are impaired by one or more specific conditions that include: learning disabled, hearing impaired, visually impaired, neurologically impaired, emotionally disturbed, and motor impaired (Whitmore & Maker, 1985; Yewchuk, 1985). Obstacles to identifying disabled children as mentally gifted include: stereotypical expectations, developmental delays, incomplete information about the child, lack of challenge, and lack of appropriate tests or rating scales.

In the U.S. Human Civil Rights Office Survey of 1986, the total number reported for students having handicapping conditions other than mental retardation was 4,492,694. The estimated figure for gifted students among them ranges between 300,000 and 540,000 (Clark, 1992). The major problem in searching for gifts and talents among these handicapped students is that special teachers are more concerned about their handicaps than their abilities. For example, New York City schools provide full service for 60,000 handicapped students. According to Davis and Rimm (1985), a special program for the handicapped gifted was organized and

forms were sent to all schools serving those students asking for nominations to the program. The result of the survey indicated that none was nominated or referred to the special program from this large population.

Boodoo, Bradley, Frontera, Pitts, and Wright (1989) conducted a survey to investigate procedures used for identifying gifted learning disabled (GLD) children in all special education centers in Texas. The authors investigated whether any learning disabled children had been nominated, by whom, and what modifications were made in the criteria to allow such children into the gifted program. Responses from 180 special education centers and 143 gifted and talented programs were received. Analysis of the special education survey indicated that 91% of the districts (73% of which enroll less than 6,000 students) reported no GLD students, 6% had between 10 and 19, 1% had between 20 and 29, and one district had more than 50 GLD students. More than 90% of the districts did not respond to inquiries concerning aptitude, achievement, or behavioral characteristics of their GLD students.

Gifted Underachievers

"Gifted underachiever" is another category of special populations gifted. Whitmore (1980) defined "underachievement" as "performance judged either by grades or achievement test scores, or both, that is significantly below the student's measured or demonstrated potential for academic achievement" (p. 168). Although there are many different definitions (Seeley, 1989), the underlying concept is that there is a discrepancy between potential and actual performance (Mooij, 1992). The problem of gifted underachievers simply is that they often are not identified for any special services because they do not meet the criteria for selection which require high achievement or performance (Boyd, 1990). If the popular conception that many outstanding women and men were poor achievers or indifferent scholars as children is correct (Reynolds & Birch, 1977), and if the magnitude of the problem is huge as has been estimated (Whitmore, 1980), then identification of gifted underachievers should be one of the important concerns reflected in systems for identifying gifted students. Rimm (1986) has been a leader in efforts to identify and help gifted students who are underachieving in school. She offers a comprehensive set of guidelines for assessment of the underlying achievement problems and for corrective educational therapy.

Gifted Females

Gifted girls and women are listed as a "minority" group because of their underrepresentation in higher levels of schooling, professions, and achievement in mathematics and science (Gallagher, 1988). Sex differences on the Scholastic Aptitude Test, Mathematics, were found in

the first talent search of Johns Hopkins University (Stanley & Benbow, 1983). Fewer girls than boys scored at high levels of mathematical reasoning ability. At the high school level, the authors found sex differences favoring males in participation in mathematics courses, performance on the SAT-M, and taking of and performance on mathematics achievement and Advanced Placement Program Examinations. Also, in the Study of Mathematically Precocious Youth (SMPY), males performed better than females on achievement tests measuring knowledge and understanding of biology, chemistry, and physics.

Kerr and Colangelo (1988) in the same study discussed earlier also found increasing gender differences in American College Test (ACT) performance favoring boys. Girls who scored perfectly in English outnumbered boys at more than a 2:1 ratio. Boys scored perfectly in mathematics at more than a 3:1 ratio compared with girls. The authors concluded that at the highest extremes of academic ability, gender differences in performance are substantial.

Young (1988) presented "concerns and issues relating to the education of talented girls" from a New South Wales perspective. While the problems she delineated were derived from the Australian cultural context, the problems she discussed, underrepresentation of women in all professional fields, and the barriers confronting girls who aspire to higher level occupation—are relatively universal across world cultures. They represent major goals for leaders in gifted education in their efforts to bring about gender equality in programs for gifted and talented youth.

Alternative Identification Methods for Special Populations

Baska (1989) advocated using a quota system as one solution to ensure representation of all ethnic groups. Lowering the achievement criteria for admission of students from minority populations to increase their percentages in programs for the gifted is another solution (Maker, 1989). Frasier (1989) supports using "a culture-specific" assessment system that evaluates "the intelligence of each person in relation to others who come from similar socioeconomic backgrounds and who have had approximately the same opportunity to acquire the knowledge and skills needed to answer questions on an intelligence test designed for an Anglo-American society" (p. 219). She also recommends using standardized tests that allow for culturally different manifestations and interpretations of intellectual ability. While Frasier cited many references regarding the inappropriateness of traditional intelligence tests with Blacks, Kaufman and Harrison (1986) and Whitmore (1979) argued that intelligence tests are the only method appropriate for identifying gifted children who do not fit stereotypical patterns or who have undeveloped potentials or handicapping conditions. Whitmore argues

that the talents of underachievers and handicapped students are often not recognized before administering an intelligence test.

Maker (1989) synthesized different perspectives concerning identification of gifted children of cultural and ethnic minorities and made the following recommendations: use multiple assessment procedures, including objective data from a variety of sources; include culturally and linguistically appropriate instruments in the referral and testing processes; and use a case study approach, in which a variety of assessment data is interpreted in the context of a student's individual characteristics, and decisions are made by a team of qualified individuals (pp. 295-297).

From the review of literature on identification of gifted students from special populations we conclude that the problems associated with identifying and serving these gifted students are major concerns for both educators and policy makers. A defensible program for the gifted must deal with these problems proactively by using flexible, multiple criteria for identification. A variety of objective and subjective assessment data is better used and interpreted with reference to the diversity existing across and within populations and subpopulations of gifted children. In the nomination stage, the philosophy of "throwing a wide net" may be the best approach to discovering gifted students from special populations.

Developing Identification Systems

Multiple Criteria

In almost every program for the gifted there is a fixed number of openings and limited resources. The identification criteria are general conditions regarding eligibility for consideration or nomination. They function as a means of controlling the number of nominees or applications within a reasonable range.

A number of researchers and theorists have argued strongly and persuasively in support of multiple selection criteria (e.g., Howley, Howley, & Pendarvis, 1986; Richert, Alvino, & McDonnell, 1982; Witty, 1951). The use of multiple procedures for identification has been emphasized as a response to theories of human abilities which stress multiple factors (Gardner, 1983). It is important, however, to recognize that this approach does not necessarily guarantee making valid decisions. The quality and relevance of measures place limits on the reliability and validity of such decisions. The question to be raised, therefore, is not how many measures are used in the identification process, but rather what contribution each piece of information has to making valid decisions or to serving specific objectives. It is a waste of money, time, and effort to collect data that is not going to be used or that is not contributing to more valid and reliable decisions.

A variety of data sources are suggested in the literature for the identification of academically gifted and talented children for special services (Tuttle & Becker, 1983). The list includes standardized tests, school grades, rating scales, references, essay writing (Feldhusen & Baska, 1989), past accomplishments (Coleman, 1985), interviews, creativity tests (Torrance, 1984), and creativity inventories (Rimm, 1984). In a later section of this chapter we will present brief descriptions of instruments frequently used for identification, and criteria for test selection.

Phases of Identification

A sound identification system typically is carried out through a series of steps taken in the proper sequence and on time. The order and sequence of steps, clarity of objectives, purposefulness of each component, and the modifiability of the system are important foundations for a defensible identification system. The number of steps and the purpose of each step is dependent upon the nature of the program for the gifted. Is the program restricted to a school building? Is it a program serving a school district or a statewide population of students? Nevertheless, there are two common phases in most identification systems: screening and selection or placement.

Screening

Screening is probably the first major process in the identification system that requires translating theoretical foundations of the gifted program into real actions. It is the first level identification in Renzulli's (1984) revolving door identification model. Many activities are carried out during this process such as: Getting information from school records, collecting and categorizing information from nomination forms and referrals, testing, presenting and synthesizing information, and selecting candidates for further testing. The ultimate function of screening activities is to generate a pool of possible candidates for the next stage of identification. The following principles are suggested to guide planning to achieve this goal: (1) multiple criteria, (2) inservice training of staff on the identification procedures, and (3) using reliable and valid screening tests and rating scales.

Multiple criteria should be used to include as many promising candidates as possible. In addition to existing school records and group test scores, nominations from teachers, counselors, peers, parents, and the students themselves should be accepted. Setting cutoff points on some screening measures should not lead to ignoring strong evidence from other sources. The size and the quality of the target population from which the selection is to be done may be the most important guiding factor.

In school practice it is common to have 10–20% of the school population in the initial screening pool, especially if a broad definition of giftedness is used, including academic and artistic talent. Inclusion in the initial screening pool, not exclusion, is recommended by many researchers (e.g., Clark, 1992; Feldhusen, 1989). Borland (1989) suggested two practices to serve this purpose: (1) setting low cutoff points on screening measures, and (2) including every student who meets the cutoff score on any screening measure.

Effectiveness and subsequent efficiency of the screening process can be substantially improved by providing adequate training for all staff who participate in the screening process. An extensive review by Hoge and Cudmore (1986) of the literature on teacher accuracy in identifying gifted students concluded that the validity of teacher judgments or ratings can be improved through appropriate training. Such training should include clarification of the processes of screening and identification, communication of the overall goals of the program, and tryouts of all the forms and procedures.

Finally, the tests and rating scales should be of the highest quality obtainable. Evaluation information about tests is quite readily available in the *Mental Measurement Yearbooks*. Nomination forms and rating scales, however, are often locally produced with little or no attention to their validity or reliability. It is far preferable to use forms and scales that have been carefully developed and empirically tested in real practice.

Selection-Placement

In almost every program for the gifted there is a fixed number of openings and limited resources. Therefore, the ultimate goal of this phase is to select a limited number of students from the pool. Further testing may be required to make more valid decisions. Individual tests, group tests, essays, and interviews are possible sources of additional information that might be relevant to program services.

The task facing those who must make selection decisions is difficult and problematic. In order to assist the selection committee in its decision-making, several questions must be addressed. Some of these questions may be open-ended and have no absolute answers.

How should the data be synthesized?

How should the selection tests and criteria be weighted?

Where or at what level should the cutting lines for admission be drawn?

A plan for a comprehensive identification system should provide guidelines for those who must make decisions in both identification phases.

Selection Strategies

A special program for gifted or talented students should provide more advanced, rigorous curriculum experiences to satisfy intellectual needs which are not addressed in regular classes. Thus, selection strategies must be focused on finding those youth who need and can profit from the advanced learning experiences and excluding those who would not benefit from it or who would fail in the program. A straightforward objective strategy for selection thus is to rank order all qualified nominees based on a composite index (score), and to select from high to low until all openings are filled. Usually best available choices can be guaranteed using this strategy.

However, a problem may arise with this approach if the lowest scores selected are not qualified according to some minimal standards or abilities. Popham (1990) suggested that there are situations in education “where the decision revolves around not who is best or worse but rather who is qualified” (p. 35). Highly structured programs for the gifted can be included in those situations. An efficient identification system can play a role in providing the requirements for making selection decisions not only on the basis of “who is best” but also “who is qualified”. It is important for administrators of programs to be as clear as possible in adopting a selection strategy that assures that those who are selected meet minimum standards for success in the program. Decisions regarding minimum standards are influenced by the selection strategy and the orientation of the program. Empirical evidence and/or professional judgment can be used to make a sound decision.

There are two main approaches to making selection decisions: the statistical approach and the judgmental or clinical approach. The first approach requires the mechanical combination of different data sources using appropriate statistical methods, while the second approach depends on personal judgments. The statistical approach is generally superior to professional judgments in terms of predicting academic success (Sawyer, 1966). In addition, it is less costly since computer processing of the selection data can be used.

The final phase of the identification process is notification of students who are selected for the program that they have been selected and, if an application format was used, notifying those who were not selected and stating the reasons why they were not selected. For those who are not selected, an offer to reconsider the application is desirable. Generally, a review committee is formed to hear and reconsider those applicants who ask for a review.

The ultimate final stage of the identification process comes later when empirical tests of performance in the program are conducted to determine if those who are picked perform up to expectations and profit from program services. Procedures for such analyses will be presented later in this chapter.

Criteria for Test Selection

If a test is to be used for making selection decisions, it must demonstrate some standard technical properties. Following are major characteristics of tests that facilitate their use by professionals working with gifted students.

Relevance of Test

Identification techniques must be consistent with the stated goals of the educational program for the gifted. The initial step in selecting instruments for identification is to determine whether the purpose for which the instrument was designed matches the purpose for which the instruments are to be used. The test manual usually includes a description of the characteristics or behaviors measured. The best ways to judge the adequacy and appropriateness of the test's description of measured behavior for the intended purpose are to study the description in the test manual, examine the test itself, and read an evaluation of the test by a measurement expert as presented in the *Mental Measurement Yearbooks*.

Reliability

Reliability refers to the accuracy or precision of a test. It may be estimated in several ways: the degree of consistency among items (internal consistency), agreement between two alternative forms of the instrument (equivalency), or stability of results over time (test-retest). Internal consistency is assessed by finding the correlation of the test items with the total tests score. Equivalency and test-retest reliability are assessed by giving the test to a group and then repeating administration with an alternate form of the test or the same form some time later. In either event examinees' scores should be approximately the same from both testings. All of the forms of reliability should be examined in selecting an instrument for identification. Reliability estimates are reported in test manuals as correlation coefficients ranging from zero to one. The reliability coefficient is an index of the precision of the measurement. For example, a test reliability of 0.70 means that 70% of the difference between individuals taking the test will be explained by real differences, and 30% may be due to random or chance errors.

Another index related to reliability is needed to interpret individual scores; that is the standard error of measurement (S_e). The standard error of measurement is used to calculate confidence intervals around an individual's test score. The confidence interval states a range within which we are confident the true or correct score falls. The most common confidence estimates are 68%, 95%, and 99%. Suppose that we have two students with IQ scores of 115 and 120, and the standard

error of measurement of the test is 5. For the 68% confidence interval, the chances are 68 in 100 that if we retested these students, their true IQ scores would fall between 110–120 and 115–125 (plus and minus one S_e), respectively. For the 95% level, the ranges would be 105–125 and 110–130; for 90%, 100–130 and 105–135. The standard error and the confidence interval alert us, in the identification process, to the potential inaccuracies of the test scores.

Validity

Validity is the extent to which an instrument measures what it claims to measure. A test may have some validity for one purpose but be invalid for another. The questions to be asked about validity are these: What does the test measure? Is it measuring what we want to know? There are several common ways of estimating validity of a test: (1) prediction, (2) concurrent, (3) content, and (4) construct. For the purpose of identification or selection of gifted students the predictive validity of a test is usually the most important and most useful. Does the test select youth who will succeed in the program and go on to high level achievement? Concurrent validity refers simply to the correlation of a test with other established tests of the same characteristics. Content validity is used chiefly to judge the validity of achievement tests; does the test measure what we taught? Construct validity refers to theoretical efforts to understand psychologically what the test is measuring. Of these latter three types of validity, the third, content, may be of interest to coordinators of gifted programs when they use standardized achievement tests in selection or assessment of performance in the program. Again the question would be: Does the test measure student achievements that we regard as important indicators of learning?

Validity is a key evaluation concept in selecting and using tests in the identification process. It is imperative that the tests used in this awesome process of selecting youth for special educational opportunities measure abilities that are vital to success in the program. Students who lack the requisite abilities may suffer failure if the tests are invalid, and we do not want to miss students who should be in the program.

Normative Data

The quality and quantity of normative (comparative) data accompanying standardized tests is the key to interpreting test scores. Normative data (norms) allow the comparison and interpretation of an individual's score relative to groups of comparable students. If a student, for instance, has a percentile score of 80 on a test, this indicates that his/her score equaled or exceeded 80% of the examinees in the norm group. Information about the composition and selection procedures of norm groups is very important for meaningful interpretation of

scores. The norms of a test are based on performance of tested groups, and are reported in test manuals in many ways, such as standard scores, percentile ranks, stanines, or means. Therefore, the manual of a test should be studied carefully by gifted program coordinators to make sure that test scores are interpreted and used properly in the identification process.

Test Bias

A fifth criterion for evaluating a test for identification is the extent to which it is free from bias. Bias refers to aspects of a test that lead to lower test scores due to race, gender, social class, ethnic origin, religion, or age and that lead to inaccurate assessment of examinees. Bias is chiefly a problem of reliability of the assessment. Fairness, a closely related issue, is chiefly a validity issue. Is it culturally fair to use this particular test in the identification process if some examinees have never had an opportunity to develop this particular aptitude or ability?

Administrators and professionals involved in selecting instruments for identification of gifted students must be aware of problems of test bias and fairness with both scientific and ethical considerations in mind. Testing instruments should be reliable and valid for the youth being screened. Interpretation of test results should be based on accurate knowledge of the norm group's structure and the stated purposes of the test.

Ceiling Effect

Ceiling effect refers to the lack of an adequate range of difficulty of test items. A test with ceiling problems, when used for the identification of gifted students, will not reveal the full range of their abilities, especially the highly gifted. Real individual differences at the highest extreme cannot be assessed if the ceiling of the test is not high enough. Intelligence tests (Silverman, 1989) and grade-level standardized tests (Feldhusen & Baska, 1989) have serious ceiling limits. They are often not constructed and normed for use with gifted students. Ceiling effect is operating when the average score of a group is above 75% of the maximum score or when the distribution of scores is highly negatively skewed. The major approach to correction of ceiling effects is to use off-level testing (Feldhusen, 1991). This means that, if available, a higher and more difficult level of the test is used for a given age or grade level group. Thus, students in grades 4 and 5 are given the 7–8 grade form of the Stanford Achievement Test and similarly 7th and 8th graders are given the Scholastic Aptitude Test, ordinarily taken by graduating high school seniors. Interpretation of scores from off-level testing requires special attention, especially if percentile norms are used. The student's score from off-level testing may be lowered considerably but by attending to the norm

group the interpretation is that he/she has scored high, given the age and maturity of the new norm groups.

Test Instruments

A number of intelligence, aptitude, and achievement tests are commonly used in identifying gifted and talented youth. We will present brief descriptions of some of the most well known and widely used tests.

Intelligence Tests

Intelligence tests can be classified into four categories: individual, group, verbal, and nonverbal. An individual test is one that has been constructed so that only one person is tested at a time. A group test can be administered to a group of people at the same time. Individual tests allow examiners to observe behavior under standardized conditions and provide safeguards to maintain cooperation and motivation of the subject. Group tests are cost-efficient and typically more objective in scoring than individual tests. Verbal tests require reading or language skills while nonverbal tests do not require the use of language. Verbal intelligence tests predict academic success better than nonverbal tests (McLeod & Cropley, 1989). Nonverbal intelligence tests are more appropriate for individuals with limited verbal/language skill.

Despite criticisms about bias and limitations of intelligence tests (Snyderman & Rothman, 1988) they remain among the most useful (Borland, 1989), the strongest measures of intellectual ability (Gallagher, 1975; Snyderman & Rothman, 1988), and the most accurate method of identifying gifted children (Sattler, 1982). Individual intelligence tests are most useful for identifying gifted underachievers (Davis & Rimm, 1985; Whitmore, 1981), school-aged gifted youth (Robinson & Chamrad, 1986), gifted children with learning disabilities (Kaufman & Harrison, 1986), and for making decisions concerning early admission or grade advancement (Feldhusen & Baska, 1989).

The *Stanford–Binet Intelligence Scale* is a widely used individual intelligence test. It yields a single deviation IQ standard score that is comparable from one age level to another (i.e., has the same meaning or percentile standing). The fourth edition of this test (Thorndike, Hagen, & Sattler, 1986) includes 15 subtests and provides 20 scores measuring abilities in four broad areas: Verbal Reasoning (Vocabulary, Comprehension, Absurdities, Verbal Relations, Total), Abstract/Visual Reasoning (Pattern Analysis, Copying, Matrices, Paper Folding and Cutting, Total), Quantitative Reasoning (Quantitative, Number Series, Equation Building, Total), Short-Term Memory (Bead Memory, Memory for Sentences, Memory for Digits, Memory for Objects, Total).

Another widely used individual test of intelligence is the *Wechsler Intelligence Scale for Children (WISC-R)*. The WISC-R measures intelligence of children between the ages of 6 and 16 years and 11 months. Unlike the Stanford-Binet, the WISC-R provides three IQ scores: verbal IQ, performance IQ, and full-scale IQ. The WISC-R contains 12 subtests, two of which are supplementary. The verbal section includes information, comprehension, arithmetic, similarities, vocabulary, and digit span. The performance section includes picture completion, picture arrangement, block design, object assembly, coding, and mazes. A national survey of school psychologists in the United States indicated that the WISC-R is the overwhelming first choice as an assessment instrument in identifying gifted children, followed by the Stanford-Binet, with the Kaufman Assessment Battery for children as the third choice (Klausmeier, Mishra, & Maker, 1987). The *Wechsler Preschool and Primary Scale of Intelligence (WPPSI)* is a downward extension of the WISC-R for use with children from 4 to 6½ years old.

The *Kaufman Assessment Battery for Children (K-ABC)* is an individual ability test for children between 2½ and 12½ years of age. The K-ABC consists of 16 subtests grouped into five scales: sequential processing, simultaneous processing, mental processing composite (sequential and simultaneous combined), achievement, and nonverbal. Strengths of the K-ABC include its theoretical orientation, separated intelligence and achievement scores, the nonverbal score, limited oral instructions and limited verbal responding, colorful and interesting items, inclusion of sociocultural norms, and small racial differences (Kaplan & Saccuzzo, 1989).

The *Raven Progressive Matrices (RPM)* is a nonverbal group/individual intelligence test covering an age range from 5 to adult. The test is unlimited in time and requires minimal instructions. It consists of 60 matrices graded in difficulty. Each matrix contains a missing part, and the subject's task is to select from up to eight multiple-choice responses the appropriate design that completes the matrix pattern. It is especially valuable for evaluating minority and culturally different students who are limited in language skills.

Aptitude Tests

Aptitude tests are designed to measure specific abilities that develop over long periods of time or the potential for future achievement in specific areas or careers. Two aptitude batteries will be discussed, the *Differential Aptitude Tests (DAT)* and the *Scholastic Aptitude Test (SAT)*. The DAT is an aptitude battery that can be used with junior and senior high school students (Grades 7-12) and students in the upper elementary grades. The DAT measures verbal reasoning, numerical ability, abstract reasoning, perceptual speed and accuracy, mechanical reasoning, spelling, and language usage. The verbal reasoning and abstract reasoning may be used as

group intelligence tests. Stanley (1984) suggested using the battery as a screening method for intellectually talented students at the end of the seventh grade. Reliability and validity of the DAT are high and the test is viewed as an excellent measure of special abilities.

The *Scholastic Aptitude Test (SAT)* has been in use as a college entrance test since 1926. The Talent Search Programs in the United States (VanTassel-Baska, 1984) use the SAT as an off-level test for identifying precocious youth in mathematics and science at the 7th and 8th grade levels. It is also used as a criterion for admission in most state-supported residential schools of science and mathematics. The test is comprised of 85 verbal and 60 mathematical items. The SAT-V includes sentence completion, identification of opposites, use of analogies, and paragraph comprehension. The SAT-M includes items covering arithmetic, algebra, and geometry. The test is intended to measure reading comprehension, verbal reasoning and vocabulary, and quantitative reasoning. Separate verbal (SAT-V) and mathematical (SAT-M) scores are reported on a 200 to 800 scale. The SAT score is a transformed standard score with a mean of 500 and a standard deviation of 100. It is a highly reliable and valid test for the assessment of verbally and quantitatively precocious youth.

Achievement Tests

Standardized achievement tests are used to measure how much students have learned in a given subject matter content and especially to measure the high level achievement of gifted students. They can be group or individual tests. Group achievement tests are generally used as screening tools while individual tests are used for more precise assessment of a student's academic talent in a specific area. Standardized achievement tests usually provide national norms based on performance of a large sample. Because of the low ceiling of most grade-level achievement tests, we recommend using a higher level test for identification of gifted children. This can be done if the achievement test is in a multi-level form. Among the frequently used achievement tests in the United States are the *Metropolitan Achievement Test*, the *Sequential Tests of Educational Progress*, the *Screening Assessment for Gifted Elementary Students*, the *Wide Range Achievement Test*, and the *Peabody Individual Achievement Test*. They will be described next.

The *Metropolitan Achievement Test*, sixth edition, (MAT6) is a group multilevel battery measuring students' achievement in eight areas: vocabulary, reading, mathematics, spelling, language, science, social studies, and writing, K-12. The MAT6 is divided into a two-component system. The instructional (diagnostic) component has six levels, and is designed to provide specific information about students' performance in the curricular areas of language usage and mathematics at a given level. The survey tests component has eight levels,

and is designed to provide a global, overall assessment of student achievement (Rogers, 1989).

The *Sequential Tests of Educational Progress* (STEP III) are a multilevel test battery measuring achievement in the basic skills of reading, vocabulary, writing, and mathematics, and supplementary tests of science, social studies, study skills, and listening (Phillips, 1984). The tests include ten levels from pre-kindergarten through high school. The STEP III manual indicates that it can be used to diagnose students' competencies and as a selection device for special instructional programs. Separate locator tests are available to facilitate the use of a multilevel testing option in language and mathematics. The STEP III is a superior and well-designed achievement battery.

The *Screening Assessment for Gifted Elementary Students* (SAGES) was specifically designed to obtain information that is useful in identifying children for gifted programs that emphasize aptitude, achievement, and/or creativity (Johnsen & Corn, 1987). The three subtests of the SAGES, reasoning, school-acquired information, and divergent production, correspond to three areas of giftedness included in the federal definition, namely, general intellectual ability, specific academic achievement, and creative and productive thinking. Norms are available for average and gifted children. The reported research provides strong support for SAGES' reliability and validity.

The *Wide Range Achievement Test, Revised* (WRAT-R) is probably the most popular and widely used standardized individual achievement test. The WRAT-R measures the basic skills of reading, spelling, and arithmetic. It provides an estimate of grade level functioning in these areas. The test is not timed and easy to administer, with no certification requirements for administration. It has two levels, one for children from 5 to 12 and the other extends through adulthood. Estimates for internal consistency and test-retest reliability are adequate.

The *Peabody Individual Achievement Test* (PIAT) is an individually administered test designed by Dunn and Markwardt (1970) to measure scholastic achievement in five content areas: mathematics, reading recognition, reading comprehension, spelling, and general information. The PIAT is untimed and can be used with children from kindergarten through 12th grade as a wide-range screening measure (Williams & Vincent, 1985). The test is based on extensive reviews of the curriculum materials in the above five areas.

Rating Scales and Checklists

Rating scales are carefully developed instruments used in evaluating traits, attitudes, adjustment, abilities, personality or other characteristics of individuals. They are widely used to quantify observations, or to measure impressions in those instances where it is either unfeasible or illogical to attempt measurement in more

objective ways. Checklists are listings of behaviors, activities, or steps that have been noted by an observer. Items in a rating scale assess the degree or frequency with which a behavior occurs. Checklists assess behavior as observed or present.

Well-structured rating scales and checklists are useful instruments as part of a multi-identification system. They allow teachers, parents, peers, and other personnel to provide valuable information for use in the first stage of the identification process. Among the rating scales that have been developed through standardized methods are the Renzulli et al. (1976) Scales for Rating Behavioral Characteristics of Superior Students and the Purdue Academic Rating Scales (Feldhusen, Hoover, & Saylor, 1990). They will be described next.

The *Renzulli Scales for Rating the Behavioral Characteristics of Superior Students* (Renzulli et al., 1976) consist of ten rating scales that can be used by teachers in the identification of students with superior characteristics. The scales include learning, motivation, creativity, leadership, artistic, musical, dramatics, communication (precision), communication (expressiveness), and planning characteristics. Theoretical and empirical procedures were used to construct and develop these scales. Since no norms are available users are advised to develop norms locally.

The *Purdue Academic Rating Scales* (PARS) were designed and developed by Feldhusen et al. (1990) for teachers to assess students' observable behaviors associated with superior academic performance in English, mathematics, foreign language, science, and social studies at the secondary level. Each of the five instruments includes 15 items that are rated on a four-point scale (i.e., rarely, occasionally, frequently, always). A "Don't know" response option is also provided. Good reliability and validity of the scales has been reported by the developers. The Purdue Academic Rating Scales (PARS) provide a relevant and useful source of information for selecting students for advanced placement and honors classes and for other acceleration options.

While tests and rating scales might often have to be administered especially for identification purposes in a program for gifted and talented youth, students' cumulative school records may include recently administered test scores, grades in courses or subjects, teacher evaluations in narrative form, and teacher rating scale scores, all of which can also be valuable for use in the screening or the identification process.

Data Synthesis

An enormous number of research studies and writings have argued strongly and persuasively in support of using multiple selection criteria (Feldhusen, 1989; McLeod & Cropley, 1989; Monks, VanBoxtal, Roelofs, & Sanders, 1986; Richert, Alvino, & McDonnell, 1982; Sato, 1974).

But very few studies have discussed the emerging problems of (1) how to reduce and combine data in a defensible way that facilitates the final step of making selection decisions, and (2) what practical procedures need to be used in validating those decisions.

It is important to recognize that the use of multiple selection criteria does not necessarily guarantee making valid decisions. The quality of the identification measures and the manner in which the data are synthesized and interpreted is critical in making valid selection decisions. Therefore, the question to be raised is not how many measures are used in the identification system, but rather what contribution each measure makes to the validity and efficiency of the system. Five methods will be discussed:

- (1) matrix method
- (2) standard score method
- (3) multiple-cutoff method
- (4) holistic case study method
- (5) multiple regression method.

Matrix Method

Matrices have been widely used to gather and summarize data from the multiple sources used in the identification process. The Baldwin Identification Matrix is one example representing this method. According to Baldwin (1984), "it has been designed to include an array of assessment techniques which will help the planner get a complete profile of the child" (p. 7). The format of the matrix is organized to include six areas of giftedness: cognitive, psychosocial, psychomotor, creative products, motivation, and creative process. Each area has several components. The raw score for each component is transformed into a five-point scale. The points for each area are averaged and summed with other averages to give the total matrix score which cannot exceed 30 (5 points \times 6 areas). Feldhusen, Baska, and Womble, (1981) reviewed this matrix method and concluded that it is potentially inaccurate and combines data inappropriately. Initially reliable tests are reduced to less reliable scores in the matrix method of data synthesis.

Standard Score Method

The fundamental and appropriate metric of psychological measurement is the standard score system (Lauer & Asher, 1988). The use of the basic standard score scale (z-score) or any of its derivatives (e.g., T-scores) achieves comparability of means, dispersions, and the form of distribution (Guilford & Fruchter, 1973). Equality of units is an important characteristic of standard-score scales. A student's standing relative to his group on one test or more can be meaningfully expressed when raw scores, which have little meaning,

are converted into standard scores. The transformation of a raw score in a distribution to a z-score is done by subtracting the raw score from the mean of the distribution and dividing the result by its standard deviation. To avoid minus signs and decimals, the resultant z-score is often transformed to any of the common standard-score metrics by multiplying the z-score by a standard unit (e.g., 10 or 100) and then adding a constant (e.g., 50 or 500).

Feldhusen et al. (1981) suggested the use of standard T-scores to synthesize identification data. They demonstrated the advantages of using this method compared to the shortcomings of using the matrix method. The method requires converting raw scores to T-scores with a mean of 50 and standard deviation of 10. Then, T-scores can be added together to get a final selection index for each student. The group of applicants can be rank ordered and selection decisions can be made from high to low based on available spaces. Weighting of individual selection measures to increase their power or setting cutoff points is possible. Feldhusen et al. (1981) suggested that professional judgment might be used as a factor in determining selection in borderline cases.

This method has definite advantages over the previous methods, namely, (1) the use of a comparable common metric system, (2) allowing for compensation by using composite scores, (3) the simplicity of calculations, and (4) the flexibility of allowing for weighting variables and setting cutoff points.

The standard score metric can also be used to get a composite score for several identification measures within a theoretically circumscribed domain. For example, while it is indefensible to combine measures from mathematics, verbal ability, and artistic talent to select students for a program stressing science and technology, the standard score method can be used after selecting appropriate measures such as science achievement test scores, ratings by teachers of students' technological aptitude, and quantitative aptitude from a cognitive skills index. Here the measures may all have theoretical relevance to the program goals in science and technology.

Multiple-Cutoff Method

According to this method, a minimum score is set for each measure in the identification system. Students who have scores equal to or in excess of all the minimums are selected for the program. Any student who fails to meet the standard on any one measure is not selected. The rationale underlying this method is that high aptitude or ability in one area does not counterbalance low aptitude or ability in another area (Hills, 1971). The major problem with this method is that the cutoff points can be arbitrarily set without adequate evidence of the validity of the measures or without any reference to the criterion measure of success in the program. Also, as the measures become less reliable and highly correlated, the method becomes less and less defensible for selection

(Lord, 1962). In actual practice, the cutoff points are often established on the basis of external determinants, such as the number of applicants, the number to be selected, and the distribution of scores on one measure.

Rejection of an applicant who scores below the cutoff point on a single measure, as described by Guilford and Fruchter (1973), is "risky as compared with rejection on the basis of a composite score because of the fact that the reliability of a single test score is usually less than that of a composite" (p. 390). Also, the validity coefficient for a composite score derived from the combination of several related measures is likely to be higher than that of a single measure. Thus, the multiple-cutoff method does not maintain one of the significant advantages expected from using multiple selection measures, namely compensation.

Holistic Case Study Method

The main principle underlying this method is that an overall index of giftedness is better than the mechanical summation of individual scores on different identification measures. Obviously, the "holism" concept, originated from the Gestalt school of psychology, has a direct impact on this method. The concept simply means that the whole is different from the sum of its parts. Accordingly, by this method a holistic personal judgment or rating is made, not completely dictated by the data but rather guided by some broader framework for evaluation. In practice, this method may be implemented by a professional person or a selection committee. Candidates are rank ordered based on an overall score and selection is from the highest ranking applicants.

The problems with this method are two-fold. First, it is difficult to find scientific justification for the process of requantifying what is already presented in a standardized form such as IQ scores or SAT scores. A better alternative may be to restrict use of this method to evaluating the descriptive, qualitative portions of the criteria for identification (e.g., biographical data, recommendations). Second, this method does not consider the actual value or importance of each individual component in terms of its relationship with the criterion of success in the program.

Multiple Regression Method

The multiple regression method is based on the assumption that synthesis of the identification data should lead to a relatively accurate prediction of student success in the program. The assumption that an identification system is really selecting the right students with respect to the program goals cannot be taken for granted. The question of how effective and efficient the system is, needs to be carefully tested and validated against stated criteria of success in the program. The underlying

conception behind the use of measures in educational selection is that they have predictive validity (Cronbach, 1971; Feldhusen & Baska, 1989; Hoge, 1988), that is that they select students who will be able to meet the goals of the program and exclude students who would fail to achieve the goals. For such an assumption to stand, "data must be collected which indicate that the instruments used to identify students do indeed predict success in the gifted program" (Feldhusen, Asher, & Hoover, 1984, p. 151). This means that data are collected for predictor variables, tentative identification or selections are made, students enter the program and receive instruction, and at some end point they are tested for their achievements or learning. The scores from achievement tests then become the criterion measures for the regression analyses. Of course, other kinds of quantifiable outcomes or achievement measures reflecting program goals such as attitudes toward mathematics, metacognitive skills in solving mathematics problems, or mastery of basic mathematics operations might also be used as criterion measures.

Correlational and multiple regression analyses are appropriate means for dealing with the problems of synthesizing data and validating identification systems. Some of the advantages of this method are:

- (1) No other method has yielded more accurate predictions than the multiple regression method (Hills, 1971). Such predictions are not improved upon by using professional judgments as a method of combining data (Sawyers, 1966);

- (2) the use of multiple regression as a basis for synthesizing and validating the identification data implies a need for establishing solid relationships among the four major components of well-structured programs for the gifted and talented students: Program Objectives, Selection Measures (Predictors), Instruction, and Measures of Outcomes (Criteria).

- (3) The multiple regression method, according to Jensen (1980), also provides an unbiased selection strategy because instead of selecting on the basis of observed test scores, it selects on the basis of a predicted index that is a best-weighted linear combination of individual components with minimal error of prediction;

- (4) furthermore, the relative value of each measure or variable in the identification system can be determined by generating beta weights where all scores, ratings, and grades are converted into standard scores with means of zero and a standard deviation of one. Variables with low or zero weights can be dropped from the system, and the expense of the identification process can be reduced (Lauer & Asher, 1988).

- (5) The multiple regression method has an additional advantage over the multiple cutoff method, namely the compensation principle which allows a high score on one predictor measure to compensate for a low score on another.

- (6) The multiple correlation coefficient or the validity coefficient (R) is an accurate and clear indicator of the

degree of relationship between the composite predictor measures and the criterion measure.

(7) The flexibility in which the analysis is automatically done by computers is also one of the advantages of using correlational and multiple regression methods in combining and validating the identification data.

(8) In addition the major difficulty with multiple regression, namely finding reliable and valid measures of the criteria, can be a significant merit of the method in terms of forcing those making selections to think seriously and continuously about criterion measures as a critical component in a well-structured program.

(9) Multiple regression can handle both continuous and categorical variables. Some categorical variables such as sex or socioeconomic status may have to be considered in identification. In such cases, categorical variables are coded and analyzed along with continuous variables.

Conclusions and Recommendations

Finding gifted and talented youth who have potential for high level, creative achievement, performance, or productivity in adulthood is an inexact science. We know a great deal about finding bright students who are doing well in school but little about the additional factors that lead to superior achievement in the future. High intelligence and effective achievement oriented skills, however, are surely prerequisites for creative productivity in most fields of human endeavor. Thus, we can at least search for those youth who have high potential for creative productivity in the long run.

Evidence from recent research (Bloom, 1985; Feldhusen, 1992; Gagne, 1985) suggests that focusing on youth's special talents or aptitudes may be more productive than searching simply for generally gifted youth. Common practice in countries throughout the world is to search for the all purpose gifted child and then to provide general forms of educational enrichment. Our own research and analysis (Feldhusen, 1986a, 1986b; Feldhusen & Hoover, 1986) leads us to conclude that early in the assessment process diagnostic efforts should be used to identify the particular aptitudes, strengths or talents possessed by a child and that the results should be used to guide us in selecting appropriate educational services commensurate with the child's special abilities.

To a great extent, giftedness or superior talent reflect precocity in the development of special abilities. A child may be an early reader, show signs of musical talent at age four or five, exhibit greatly advanced skills in mathematics, reveal a vocabulary far larger than age peers, or reason with her/his parents at a nearly adult level of logical precision. All of these are precocious behaviors, signs that the child is out ahead of others and may remain so if educational or experiential services

continue to be available at appropriately advanced levels and pace.

There may be some value in communicating to a child and to his/her parents that the child is gifted but there are also liabilities in so doing. Labeling children "gifted" may generate undue or frustrating expectations from teachers, ridicule from peers, and puzzlement in parents. The term "gifted" also seems to carry high hereditary connotations. Robinson (1986) discussed the problems of labeling and urged that the negative effects be kept in mind by all who work with gifted children.

Over a period of years we have reviewed, analyzed, and critiqued identification processes in gifted education (Feldhusen, Baska, & Womble, 1981; Feldhusen, Asher, & Hoover, 1984; Feldhusen, 1991, 1992). Hoge (1988, 1989) has also carried out insightful critiques of practice and the literature on identification of the gifted. We agree with Hoge (1989) in concluding that there is a need to be explicit in defining the giftedness construct, the component traits and aptitudes, as a prelude to the use of the label. Further, definition should be derived from some theoretical formulation concerning human abilities in general and superior ability in particular. Then the specific identification or selection procedures should be derived directly from the definition and supporting theory. Finally, there should be substantial efforts to verify or validate the identification system empirically. In contrast to these suggestions, much of current practice in identification derives from practicality, judgment of questionable "experts", or tradition.

Our recommendations then are as follows:

(1) Identification processes in gifted education should be based on the best current conceptions and theories of human aptitude, talent, and abilities.

(2) Test instruments and rating scales with established reliability and validity should be selected for use in the identification process.

(3) Identification should be viewed as an ongoing process. One should not conclude that assessment at one point in time, even with multiple tests, finally and unequivocally identifies the gifted child. Giftedness is an emerging, developing set of abilities calling for repeated evaluation as the child matures.

(4) Labeling children as "gifted" should be avoided. It is preferable to regard the process as selecting children for programs or services.

(5) Identification should always be diagnostic in nature, identifying strengths, aptitudes, and talents as well as problems, weaknesses, and needs.

(6) Programs and services should be linked to the special talents, aptitudes, and abilities of gifted children as well as to their special problems and needs.

(7) Empirical validation should be used to verify that the identification-selection system is working as intended. Are the children selected doing well in the program? Are we missing children who should be in?

Are we selecting children who are achieving at high or superior levels in the long run?

(8) Efforts should be made to assure that all youth have equal opportunity to be identified for programs. Are we finding the gifted and talented among children of both genders, who are handicapped, among minority and culturally different children, and among those who may be underachieving and thus not revealing their gifts and talents? Instruments and procedures are now available to assure that all youth have equal opportunities to be identified and served in programs for gifted and talented youth.

The future of gifted education must be built upon the sound foundation of theory and research. Identification procedures lend themselves well to empirical validation and theory grows out of sound research. The two together can be used to identify and educate all youth who have special talents, aptitudes, or gifts.

Introduction

The study of giftedness has had a long and extensive history within the field of psychology. However, such study has focussed almost exclusively on giftedness in intelligence, as measured by the IQ test (Binet & Simon, 1916; Galton, 1883; Hollingsworth, 1942; Spearman, 1923; Sternberg, 1977; Terman, 1925). More recently, researchers have begun to investigate exceptional development in domains not measured by IQ tests, such as the arts (Bloom, 1985; Feldman with Goldsmith, 1986; Golomb, 1992; Pariser, 1991; Shuter-Dyson, 1986; Winner, 1982; Winner & Pariser, 1985). In this chapter, we consider what is known about exceptional development in two art forms: the visual arts, and music. As few large-scale psychometric studies of giftedness in the arts exist, our primary but not exclusive source of evidence will be case studies of individuals who have shown unusual giftedness in these domains.

A distinction is made here between ordinary giftedness and prodigiousness. Ordinary giftedness is a precocious ability in a particular domain: the gifted child advances more rapidly than his or her peers in a particular domain, and shows special aptitude in that domain. Prodigiousness is extreme precocity: the prodigy is a child who is able to perform at an adult level in a particular domain (Feldman with Goldsmith, 1986). Mozart is a prototypical example of a child prodigy. With one exception (the Chinese painting prodigy, Yani), our knowledge of prodigies in art and music is based on Western cases. In this chapter, we use the term "gifted" to refer inclusively both to the ordinary gifted child, and the child prodigy. However, wherever relevant, differences between these two kinds of children are pointed out.

We believe it makes no sense to talk about giftedness *per se*: one can only be gifted in a domain (although one can be gifted in more than one domain). By domain, we refer to a discipline or body of knowledge valued by a culture which is characterized

by a recognized set of steps that one must pass through to become proficient. Examples of domains valued today in many societies include chess, mathematics, music, and art, but not, for example, card games that rely on chance (as these would not satisfy the criterion of having steps towards expertise).

As Feldman with Goldsmith (1986) have pointed out, one only finds prodigies in domains which are both accessible and appealing to children. Hence, one finds prodigies in the visual arts and in music, but not, so far as we know, in law or finance. Feldman and Goldsmith also argued that prodigies are more likely to be found in domains whose knowledge base is highly organized formally. Perhaps for this reason, prodigies have been more readily found in the fields of music, chess, and mathematics than in literature and the visual arts.

We make two further distinctions in this chapter. First, we distinguish between individuals of normal or high intelligence who are gifted in a domain, and individuals who are gifted in one domain, but extremely retarded in all other areas. Such pathological individuals are typically referred to as *savants* (Miller, 1989; Treffert, 1988). We attempt to determine what distinguishes the gifted individual of normal or high intelligence from the gifted individual who is in all other respects low-functioning (either retarded or autistic).

Second, we distinguish between giftedness and *creativity*. By creativity, we refer to inventiveness within a domain. A creative individual revolutionizes a domain of knowledge. No child prodigies have ever, as children, effected a reorganization of a domain of knowledge; moreover, many who have effected such reorganizations were not themselves prodigies as children (Feldman with Goldsmith, 1986). Thus, there is no necessary link between giftedness and creativity. We focus here on childhood giftedness, and make no assumptions that early signs of giftedness are necessarily predictive of adult creativity.

Giftedness in the Visual Arts

There is an extensive body of research on the normal course of drawing development in the typical (usually Western) child (Arnheim, 1974; Cox, 1992; Eng, 1954; Freeman, 1980; Gardner, 1980; Golomb, 1992; Goodnow, 1977; Lowenfeld & Britain, 1970; Luquet, 1927; Winner, 1982). Children begin to scribble at about the age of 2; by the age of 3 or 4, they are making very simple but recognizable representations. Figures are formed by joining several geometric shapes. For instance, a person is drawn as a "tadpole:" a circle with lines extending from the circle for arms and legs. A cat is drawn as an oval (for the body), joined to a circle (for the head), with either lines or rectangles joined to the oval for the legs. These drawings are called schematic because they do not capture the contour of the object drawn, but rather represent the object through simplified, geometric shapes or schemes.

The normal course of drawing development has been described as U-shaped with respect to the development of esthetic properties (Gardner, 1980; Gardner & Winner, 1981; Winner, 1982). Prior to the age of about 7, children make drawings which have esthetic properties similar to those of adult artists' works. The strongest empirical evidence for this claim can be found in Davis (1991). Preschool drawings and paintings are striking, inventive, imaginative, expressive, and show little regard for the rules of realistic representation. Suns may be green, people may be the size of houses and may float all over the page, and hair may be purple. The child at this age is not striving for realism, but rather is playing with form and color. For this reason, this period is often considered the pre-conventional period.

Such flavorful, aesthetically appealing drawings give way in the middle childhood years to attempts to master the conventions of the drawing symbol system. During this conventional period, children become concerned with learning the rules of realistic representation: proportion, shading, perspective, etc. As a result, their drawings become wooden and labored. To put it succinctly, one might mistake the work of a 5-year-old for that of an adult abstract expressionist; one would never mistake the work of an ordinary 10-year-old for a master painter of any kind.

Most children never emerge from the literal stage. In late childhood and adolescence, children in our culture lose interest in drawing altogether, and the typical adult draws no differently from the typical adolescent.

Although considerably less is known about the development of exceptional talent in the visual arts, researchers have begun to study a range of gifted children over the past two decades. Our understanding of drawing development in gifted children comes from three quite different sources. (1) One source is children who have been identified as gifted in drawing by their parents and/or teachers (Cane, 1951; Gardner, 1980; Goldsmith, 1992; Goldsmith & Feldman, 1989; Golomb, 1992; Wilson & Wilson, 1976; Zhensun & Low, 1991). These

children may or may not go on to become artists: in many cases, the children have not yet grown up so it is too early to tell. What makes them a subject of study is that their drawings strike adults as in advance of those of their peers. (2) A second source is famous artists whose childhood drawings have been preserved (Gordon, 1987; Paine, 1987; Pariser, 1987, 1991; Richardson, 1991; Sloane & Sosniak, 1985; Vasari, 1979). We do not have an extensive body of juvenile artists, and most of the childhood works of artists that have been preserved were produced after the age of 9–10, leaving us with relatively little information on the very early drawings of artists. Nonetheless, such retrospective study provides perhaps the strongest evidence about the development of talent, since we know from the start that these children went on to become established artists. (3) A third source is a subset of autistic and/or retarded children whose drawings are nonetheless prodigious (Selfe, 1977, 1983; Morishima & Brown, 1977; Pariser, 1981; Park, 1978).

In what follows, the art work, personality characteristics, and environment of ordinary gifted and prodigiously gifted children is first described. Wherever possible, information on the childhood works of recognized artists is included in the discussion. The relation between artistic giftedness and other abilities is then considered, followed by a discussion of tests and other procedures used to identify artistically gifted children. Next, the phenomenon of exceptional artistic performance in nongifted children as a function of education is discussed by considering the striking results of Chinese art education. Finally, the phenomenon of artistic giftedness in nonpathological populations is compared to the puzzling phenomenon of savant artists. Here one finds the most extreme levels of giftedness in drawing operating independently of other forms of intelligence. Following our review of giftedness in the visual arts, we turn to a consideration of giftedness in music.

Early Signs of Artistic Giftedness

We do not know how common it is to find exceptional talent in the visual arts at a very young age (Golomb, 1992). Many art educators and researchers have become convinced that exceptional artistic talent at a very young age (e.g., 3 or 4) is rare, rarer than the frequency of such early talent in the domain of music (Feldman with Goldsmith, 1986; Goodenough, 1926; Hurwitz, 1983; Lark-Horowitz et al., 1973; Sloane & Sosniak, 1985). For example, Toulouse-Lautrec's drawings were simple, flat, and child-like until the age of 8 (Thomson, 1987). A survey of 18,000 drawings by children conducted by Lark-Horowitz et al. (1973) revealed no drawings produced by children under ten that showed exceptional talent. And Vasari (1979) describes Renaissance artists who were skilled draftsmen by 7 or 8, but not earlier.

As mentioned earlier, very young child prodigies may be less likely to show up in the visual arts than in music

because the domain of the visual arts is less formally organized than is the domain of music. Moreover, prodigies in music tend to be performers rather than composers. If we were to compare the incidence of prodigious ability in drawing and composition (both involve making rather than performing someone else's art), musical prodigies would be as rare as visual ones.

Realism

All researchers who have studied drawings by gifted children agree that these children pass through the same sequence of drawing stages as do normal children, but do so more rapidly (Gardner, 1980; Golomb, 1992; Lark Horowitz, Lewis, & Luca, 1973; Lowenfeld & Brittain, 1970). Children are singled out as gifted when they draw in advance of their peers on some dimension (usually realism), but these children do not skip any of the stages that their peers pass through. For example, as mentioned earlier, all children begin representational drawing by creating simple, schematic figures out of a few geometric shapes. Gifted children begin in this way as well, although they begin at a younger than average age and within a few months go on to draw in a more differentiated, realistic, non-schematic style.

The "core" indicator of giftedness in drawing is the ability to draw recognizable shapes at least one year in advance of the normal time of emergence of this skill. While typically children begin to draw recognizable

shapes representing objects in the world at around the age of 3 or 4 (Kellogg, 1969; Matthews, 1984), gifted children have been noted to begin to draw representationally at the age of 2. Figure 1 shows a striking contrast between the way in which a typical and an artistically gifted 2-year-old drew apples. The typical 2-year-old was asked to make an apple. He drew one slash. He was then asked to make another one. He obliged by making a second slash (Figure 1, TOP). This child made a slash for each apple because he had not yet acquired the understanding that lines on the page stand for the edges of objects. For him, a line simply stood for "thingness." The gifted 2-year-old drew one apple spontaneously, and added the second one effortlessly after his aunt asked him to draw another one (Figure 1, BOTTOM). This child had already grasped the concept of a line standing for an edge, and produced a fluid line describing the contour of each apple.

Soon after gifted children begin to draw recognizable forms, they also begin to draw in a realistic manner, capturing the precise shapes of objects, adding true-to-life details that typical children never would add (e.g., gas tanks on cars), and attempting to represent the illusion of volume and depth. In place of the simple, schematic, flat, charming, child-like forms typically found in child art, one finds remarkable adult-like, differentiated, complex images that suggest an effort to understand and master how objects are structured. Gifted children draw realistic images quickly and with ease. They do not labor and erase: their lines are sure and confident (Gordon, 1987; Paine, 1987; Pariser, 1987). The young Picasso, for example, could draw anything upon demand, and liked to start the figure from non-canonical places, for instance drawing a dog beginning with the ear (Richardson, 1991). A highly realistic pair of faces, copied by Millais at age 8 from an adult work is shown in Figure 2.

Numerous examples of children with precocious ability to draw realistically have been reported (Gardner, 1980; Golomb, 1992; Hurwitz, 1983; Kerschensteiner, 1905; Wilson & Wilson, 1976; Winner & Pariser, 1985). One of the most striking examples of early realism is found in the work of Eytan, an Israeli child described by Golomb (1992). Eytan's family did not remember whether he scribbled, but the family does have drawings that he produced at 2, an age when most children are just beginning to scribble. At 2, Eytan drew recognizable shapes: people, tractors, fish, cars, etc. Normal children make their first tadpole-like representation of a human at about age 3, and do not differentiate the head from the trunk until several years later. In contrast, Eytan began to draw humans with a differentiated head and trunk at 2½.

One way Eytan achieved realism was through the meticulous depiction of details, such as exhaust pipes on his vehicles. Another way that realism was achieved was through the depiction of volume and depth. Typically children in Western culture do not begin to try to depict the third dimension until the middle elementary school

FIGURE 2. Pencil copy of an adult work, drawn by John Everett Millais at age 8.

years. By the age of $2\frac{1}{2}$ Eytan was not content with drawing vehicles from their canonical side view, and invented ways to depict their volume, showing their sides receding into depth. He first used an orthographic projection system to show more than the front or side of a vehicle. By 3 he had abandoned this system and instead showed multiple sides of a vehicle by attaching the top and side faces to the front of a vehicle. After his third birthday, he used a mixture of three projection systems: horizontal and vertical oblique projection, isometric projection (in which the front view of a vehicle was its true rectangular shape, but the top and sides of his trucks were parallelograms); divergent perspective, in which lines diverge outwards to show the front, top, and both sides of a vehicle. By 4 he showed an understanding of the perspectival rule that objects receding in the distance are reduced in size, and he was beginning to experiment with foreshortening. Figure 3 shows an attempt at perspective by Eytan at age $3\frac{1}{2}$.

The ability to draw realistically at an earlier than average age also marks the childhoods of those who go on to become established artists. Gordon (1987) studied the childhood works of thirty-one Israeli artists and found that all stood out for their ability to draw realistically. The desire and ability to draw realistically at an early age also characterized the childhoods of those who go on to become sculptors: Sloane and Sosniak (1985) interviewed twenty sculptors about their childhoods, most of whom recalled drawing realistically at an early age. Numerous other well known artists' early drawings have been singled out for their advanced realism: e.g., Millais (Paine, 1987), Landseer (Goldsmith

& Feldman, 1989), Seargent (Cox, 1992), and Klee, Picasso, and Lautrec (Pariser, 1987, 1991).

Picasso provides a clear example of the ability to draw highly realistically at an early age. He claimed, perhaps apocryphally, that he bypassed the typical stage of early drawings in which children draw in a fanciful, playful, nonrealistic manner. "I have never done children's drawings. Never" (Richardson, 1991, p. 29). However, since we have no records of his works before the age of 9, it is not clear whether this is true. What is clear is that Picasso wanted to see himself as a prodigy. When he went to see a show of child art, he noted, "As a child, I would never have been able to participate in a show of this kind: at age 12 I drew like Raphael" (Richardson, 1991, p. 29). And he recalled specific examples of this adult-like style: "Even when I was very small, I remember one of my first drawings. I was perhaps six. . . . In my father's house there was a statue of Hercules with his club in the corridor, and I drew Hercules. But it wasn't a child's drawing. It was a real drawing, representing Hercules with his club" (Richardson, 1991, p. 29). At 11, Picasso enrolled in his father's academic drawing class, in which students had to make detailed renderings of plaster casts. While most students considered this drudgery, Picasso loved it, and produced technically skilled and precise drawings.

In their childhoods, artists not only draw realistically from life, but are also skilled at imitating the styles of other artists. Both Picasso and Lautrec were noted for their early ability to copy. Picasso could paint in the style of El Greco, Velasquez, and Goya at a young age; Lautrec was such a good imitator that

FIGURE 3. Drawing of a truck by Eytan at age 3½. From Claire Golomb, *The child's creation of a pictorial world*. Reprinted with permission of The Regents of the University of California, Copyright & Copy; 1992.

his teacher called him “a regular little ape” (Pariser, 1991).

Realism as an early indicator of giftedness in drawing may be culturally determined. In the West, at least from the Renaissance until the twentieth-century, artists have striven to capture the illusion of space, volume, and depth (Gombrich, 1960). While gifted children probably begin to draw realistically long before they have had much if any exposure to examples of Western fine art, they have certainly been exposed to realistic images on billboards, magazines, and picture books. The most well-known non-Western artistic prodigy is Yani, a Chinese child who painted in the Chinese brush and ink style at an adult-like level in the preschool years. Although like Western gifted children Yani's paintings do not look child-like, they cannot be described as naturalistic. They are painted in the allusionistic style of traditional Chinese painting, in which the goal is to capture the spirit of objects rather than their exact likeness. Thus, as Goldsmith and Feldman (1989) point out, the technical sophistication of her work reveals itself along dimensions different from those of Western gifted children.

It is interesting that the near adult-like level of skill displayed in Yani's paintings contrasts sharply with her child-like calligraphy (Goldsmith & Feldman, 1989). In an early study of the correlates of artistic aptitude, Manuel (1919) also found no relation between skill in drawing and handwriting. The technical graphic skill involved in drawing appears not to generalize to the domain of handwriting.

ESTHETIC PROPERTIES

Although almost all Western gifted children who have been identified in the literature stand out first and foremost for their ability to draw realistically, Golomb (1992) described two counter-examples. Varda and Amnon, two Israeli kibbutz children, were identified as gifted by age 5, and they both went on to pursue art training as adults. The works of these two children diverged from those of average children not by their verisimilitude, but by their sense of composition, form, and color. Lark Horowitz et al. (1973) also noted this alternative path of giftedness, in which children draw schematic, child-like drawings which are imbued with an order, clarity, and richness that renders them reminiscent of primitive art.

Similar cases have been described (Clark & Winner, cited in Winner & Pariser, 1985; Kerschensteiner, 1905). Hurwitz (1983) also has noted that artistically gifted children like to doodle, play with line and with negative space, and improvise. Thus, although an early ability to draw realistically may be the most typical and striking characteristic of gifted children, non-representational signs of giftedness such as skill in design, form, color, and composition should not be overlooked.

EXPLORATION OF A SINGLE THEME

Picasso viewed paintings as a logical sequence of explorations. “Paintings,” he said, “are but research and

experiment. I never do a painting as a work of art. All of them are researches. I search constantly and there is a logical sequence in all this research" (Lieberman, 1960, p. 33). Many gifted children seem to exemplify this approach. In their drawings, they explore a single theme, over and over again. For Eytan, for instance, the theme was vehicles, and these were drawn far in advance of his human figures. Yani painted only monkeys until the age of 7 (Goldsmith & Feldman, 1989). Kerschensteiner (1905) described G. J., who drew only horses. Gardner (1980) described Gabriel who focussed on portraits, and Stuart who focussed on comic book style figures.

Thus, the drawings of gifted children sometimes seem programmatic, each a further exploration of the same theme. Perhaps because of the continual practice with a particular subject matter, these children show far greater skill when drawing their favored themes than when drawing other subjects. It should be noted, however, that the drawings of ordinary children have also sometimes been described as having a thematic focus (Eng, 1954; Fein, 1984; Gardner, 1980). Thus, this characteristic may not be as clearly indicative of giftedness as is early realism.

THE INFLUENCE OF CARTOON IMAGES

Cartoon-style images exert a powerful influence on the drawings of those Western children who have access to such images. This influence appears to make itself felt in late childhood. Gifted drawers are often able to make comic strip images at an adult, professional level (Gardner, 1980). Cartoons are often produced in astonishing abundance: Anthony, a child studied by Wilson and Wilson (1976), drew about 10,000 comic strip figures in his school years. Gardner (1980), however, describes a gifted child who used cartooning as an escape route from a perceived inability to draw realistically: even the most illusionistic cartoon figures are more formulaic, and hence easier to draw, than are life studies.

THE INVENTION OF IMAGINARY WORLDS AND THE CONSTRUCTION OF NARRATIVES

Particularly in middle childhood and adolescence, artistically gifted children create imaginary settings and fantasy characters in their drawings, and their drawings depict episodes in the lives of these invented characters. This is the age when gifted children begin to create superheroes and science fiction characters modeled after the images they see in comic books. The Wilsons note that visual narrative need not be in the form of a series of frames, as in a comic strip. Each drawing functions as a shorthand for a complex plot. One episode may begin in one sketch book and then continue on disconnected pages. These fantasy worlds allow children an escape into a private world. One child studied by the Wilsons said, "Most people . . . just look at them and say "that's a pretty picture" without understanding what

the people are really like and the story behind them" (Wilson & Wilson, 1976, p. 46). The Wilsons note that gifted children are often much more interested in inventing imaginary worlds in their drawings than in experimenting with form and design. In the process, they produce countless drawings, and thus gain fluency and technical skill.

CAPACITY FOR SUSTAINED CONCENTRATION, AND INTRINSIC MOTIVATION TO DRAW

Artistically gifted children draw daily, for long periods of time at a stretch, often preferring the activity of drawing to play or TV. At the age of 2, Eytan was reported to spend 15–20 minutes at a time drawing (Golomb, 1992). The 2-year-old who drew the apples in Figure 1b often preferred to draw than to come to lunch (Sullivan, personal communication). Gardner (1980) describes a household in which Shula, an artistically gifted child, drew regularly for hours at a time.

The intensity with which these children draw results in a prolific body of work. Yani, for example, made 4000 paintings in the span of three years. Picasso recalled that he drew all the time as a child: while others played, he drew figures in the dirt. He not only drew constantly as a child, but also made skillful paper cut-outs of animals, flowers, and people (Richardson, 1991).

Artistically gifted children not only engage in continual drawing, but are also sometimes compulsive collectors of objects (Gardner, 1980). Artistically gifted children thus satisfy a hunger for visual stimulation by surrounding themselves with their own created images, and with objects whose shapes and colors they find appealing.

Such an intense need to draw suggests that for these children drawing is intrinsically rather than extrinsically motivating. These children are self-directed and self-disciplined (Hurwitz, 1983; Rosenblatt & Winner, 1988a). Often drawing serves as an escape into fantasy, or an escape from boredom, especially the boredom of school (Wilson & Wilson, 1976).

The Role of Family and Teachers

Artistically gifted children almost always seem to have parents or close relatives who are artists, or who are in fields related to the arts such as crafts or design (Feldman with Goldsmith, 1986; Goldsmith & Feldman, 1989; Gordon, 1987). The families of artistically gifted children tend to be very supportive and encouraging of their children's artistic inclinations. They make art materials available, and save and carefully date their children's drawings (Freeman, 1974; Gardner, 1980; Gordon, 1987). In some of these families, the craft of making art seems to be passed on much as in a guild.

Although only one of the parents of famous sculptors studied by Sloane and Sosniak (1985) was an artist, all were highly supportive of their children's artistic interests. One quarter of the sample revealed that their

families were not knowledgeable about the arts. One sculptor wrote, "[My mother] doesn't really understand art. She took us to museums. She did all the right things . . . She always supported culture in general terms. In the way a nineteenth-century woman would support culture, as one of the finer things in life" (p.95). However, most the families of famous sculptors were "artistically enthusiastic." Over half of the families visited museums and some parents participated in adult art classes. Other sculptors mentioned that a supportive parent or relative served as a role model for them.

Although most of the children who have been identified as artistically gifted have parents who are in the arts, or who value the arts, we do not know how many artistically gifted children go unrecognized because they lack such parents. If their parents do not notice, value, and encourage their ability, these children may simply lose interest unless they are discovered by someone outside the family. Kerschensteiner (1905) describes a child whose talent was discovered fortuitously by two artists who happened to see him copying an advertisement. He later went on to study art. Had he not been discovered, he probably never would have gone on to study art.

Gifted children typically are self-taught in early childhood. They guide their own graphic development, teaching themselves skills through constant practice. Although their parents are usually artists themselves, the parents at least claim to be supporters and encouragers rather than teachers. Thus, gifted children often have, in a parent, the kind of teacher that Bloom (1985) has argued is most important in the early years of a gifted child: someone who is warm, empathetic, and encouraging, rather than someone who gives lessons in skill development. (Yani, however, may be an exception. It seems likely that she received painting lessons from her ambitious father, although he denies teaching her.)

Artist parents may attempt to actively instruct their gifted children when they reach adolescence. However budding adolescent artists may actively reject offered instruction from their artist parents. One adolescent studied by Gardner (1980) insisted that he would rather solve visual problems on his own than be shown by his father how to solve them.

At least in the West, gifted children are often suspicious of formal art education, believing such tutelage to be unnecessary and potentially destructive of their talent (Gardner, 1980). The typical art class in elementary and high school does not serve to stimulate these children's art. It is a sad commentary on the way that art is typically taught in school that none of the sculptors studied by Sloane and Sosniak had anything good to say about their elementary or high school art classes. Winner and Pariser (1985) also noted this: the artists they interviewed reported that what crystallized their identity as young artists was some professional artist who noted their ability. Contemporary Chinese artists show the same negative attitude towards their elementary school arts instructors (Winner, 1989). Thus, family and community appear to be more important than schools in

the development of artistic ability. Not surprisingly, then, gifted children often make their best, most inventive work out of school (Hurwitz, 1983; Wilson & Wilson, 1976).

Correlations Between Artistic Giftedness and Other Abilities and Disabilities

Giftedness in the visual arts appears to be independent of intelligence as measured by the IQ test, but correlated with high imagery skills. In addition, there is some evidence that giftedness in the visual arts is correlated both with nonright-handedness (an index of anomalous brain dominance), and with verbal deficits.

RELATION BETWEEN ARTISTIC GIFTEDNESS AND INTELLIGENCE

Because of the temptation to assume that any kind of giftedness is a function of general intelligence, numerous attempts have been made to find a relationship between artistic talent and intelligence (e.g., Goodenough, 1926; Harris, 1963; Hollingsworth, 1942; Manuel, 1919; Terman, 1925; Thorndike, 1913). For example, Harris (1963) reviewed studies of drawings by retarded children and concluded that these drawings were behind those of normal children, leading to the conclusion that drawing development correlates with mental age. The assumption that drawing development is a function of general intelligence underlies the use of the Goodenough-Harris Draw-a-Person test as an IQ test. In this test, the number of details included in a drawing of a person is used as a measure of IQ.

However, the Draw-a-Person test correlates only modestly with standard IQ tests. And there is no evidence that children of high IQ draw particularly well (e.g., Hollingsworth, 1942; Terman, 1925). Moreover, there is no theoretical reason to expect such a relationship, as the skills deployed in drawing are visual and spatial skills, rather than the verbal, logical, and mathematical skills conventionally measured by IQ tests (Gardner, 1983). In short, there is no convincing test evidence that drawing ability and IQ are related.

The most striking evidence for the radical independence of intelligence and artistic giftedness comes from the drawings produced by autistic and retarded individuals with extremely low IQs, discussed later on in this chapter. There is also experimental evidence reviewed below demonstrating that children gifted in the visual arts have higher than average visual-spatial skills (they excel in recognition of hidden shapes and incomplete figures, and in visual memory), and that these skills operate independently of IQ.

RELATION BETWEEN ARTISTIC GIFTEDNESS AND VISUAL IMAGERY SKILLS

Artistically gifted children excel in their ability to recognize hidden geometric shapes in complex designs, and this ability is independent of IQ (O'Connor & Hermelin, 1983). Similarly, these children excel in visual imagination,

as measured by the ability to recognize incomplete figures in drawings. Artistically gifted children may excel on such a task because they can readily store and access an internal visual lexicon of images. Again, this ability is independent of IQ (Hermelin & O'Connor, 1986; O'Connor & Hermelin, 1983).

Artistically gifted children also excel in their visual memory. Vasari (1979) noted that Michaelangelo had such a good visual memory that he could remember every detail of a painting even if he had only seen it once (cited in Hermelin & O'Connor, 1986). And in his biography of Picasso, Richardson (1991) notes that Picasso prided himself on his ability to concentrate and remember visual details as a child. There is experimental evidence as well to demonstrate that artistically gifted children excel in both long- and short-term visual memory, and that this ability is not correlated with IQ.

An early study investigating visual memory in artistically talented children was conducted by Lark-Horowitz (1941, cited in Lark-Horowitz et al., 1973). Lark-Horowitz compared artistically gifted and average children's ability to draw a polar bear model immediately after viewing it, and once a year for three years after the model had initially been seen. The gifted children's drawings were far more accurate and detailed than those of the average children, and their drawings changed little over the course of the three years. However, because children in the average group may have recalled as much but have been unable to draw what they recalled, little can be concluded from this about visual memory. Later studies, however, have used measures independent of drawing to assess visual memory, and these studies have consistently shown that artistically gifted children excel in visual memory, and that this skill is not a function of intelligence.

For example, in a study by Hermelin and O'Connor (1986), children were asked to recall Persian letters. Artistically gifted children performed better than their IQ-matched controls, and better than a sample of mathematically gifted children with higher IQs. These results demonstrate the lack of relationship between IQ and the ability to store and/or access nonverbalizable shapes.

Children identified as gifted in drawing also have superior memory for properties of pictures. Rosenblatt and Winner (1988b) asked children identified as gifted in art by their teachers, and a control group of average drawers, to look at a series of pairs of pictures. Later, they were shown the same picture pairs again, but this time one of the pairs had been altered in color, form, composition, line quality, or content.

The gifted children outperformed the control group in identifying which picture had been altered, and in pointing out how each picture had been altered.

RELATION BETWEEN ARTISTIC GIFTEDNESS AND ANOMALOUS BRAIN DOMINANCE AS INDEXED THROUGH HANDEDNESS

It is well known that a disproportionate number of nonright-handers (both ambidextrous and left-handed)

turn up in spatial fields. This finding has been noted among mathematicians (Annett & Kilshaw, 1982; Benbow, 1988), architects (Peterson & Lansky, 1974, 1977), and athletes (McLean & Ciurczak, 1982). As are individuals in other spatial fields, visual artists (both adult artists, and artistically gifted children) are more likely to be left-handed than are individuals without a visual-spatial proclivity. Among adult art students one finds a higher proportion of left-handers than in the population at large (Mebert & Michel, 1980; Peterson, 1979); adults who rate themselves as having artistic talent are more likely to be left-handed than those who rate themselves as having verbal talent (Smith, Meyers, & Kline, 1989); and elementary school children identified by their teachers as gifted in art are more likely to be left-handed than children identified as simply average in art (Rosenblatt & Winner, 1988b).

The relation between artistic ability and handedness suggests that individuals with artistic gifts may have anomalous patterns of brain dominance (Geschwind, 1984; Geschwind & Galaburda, 1987). Geschwind (1984) has suggested that nonright-handedness may be an index of superior right-hemisphere brain development. Hence, one would expect to see a relationship between nonright-handedness and visual-spatial skills (since these are typically mediated by the right-hemisphere). This is precisely what one finds among artistically gifted individuals. As shown above, such individuals excel in a variety of visual-spatial skills besides drawing, and as shown here, they also have a higher than average tendency to be nonright-handed.

RELATION TO VERBAL DEFICITS

Geschwind (1984) went on to suggest that superiorities in the visual-spatial domain are often linked to pathologies in the verbal domains. For example, superior visual-spatial abilities have been found to be associated with autism (autistic children do not develop normal language) and dyslexia (Geschwind, 1984; Geschwind & Galaburda, 1987). Geschwind (1984) referred to the association between left-hemisphere disabilities and right-hemisphere talents as a "pathology of superiority."

If Geschwind's hypothesis is correct, one should find that artistically gifted individuals have a higher than average incidence of language problems. This hypothesis was supported by two studies. Adult art students report having more reading problems than did other college students (Winner, Casey, Da Silva, & Hayes, 1991). And they make more spelling errors than do other college students (Winner & Casey, in press). In addition, art students tend to make the kind of spelling errors associated with poor reading skills—nonphonetically based errors that do not preserve letter-sound relationships (Frith, 1980; Phillips, 1987). Nonphonetically based errors are ones in which wrong letters are included, correct ones are omitted, or letters are reversed (e.g., "physicain" for physician); in contrast, phonetically based errors are ones which, when

sounded out, sound correct (e.g., “phisician”). The tendency to make nonphonetically based errors obtained even when SAT performance was partialled out. It appears that artistically gifted individuals have problems specific to reading and spelling that are independent of the kinds of abilities assessed by the SAT.

These findings may shed some light on why artistically gifted children do or do not go on to become artists. Individuals may pursue art not only because of specific visual-spatial strengths, but also by default, because of verbal deficits. These verbal deficits may lead visually talented children to avoid fields which require extensive reading. By default, then, they may drift into the arts. Given that our culture places a higher value on linguistic than artistic skills, it would not be surprising to find individuals with both kinds of talents drawn to verbal fields.

Procedures for Identifying Artistically Gifted Children

School programs for the gifted and talented have for the most part focussed on academic giftedness, and have neglected giftedness in other domains such as the arts. It was not until 1972, for instance, that in the United States artistically talented children were identified as a subgroup of “gifted and talented” students. In 1978, the Gifted and Talented Children’s Education Act in the United States identified visual and performing arts as one of five areas of giftedness which should receive special services (Clark & Zimmerman, 1983). As a result, many public school programs for artistically gifted children were initiated in the United States.

Three kinds of procedures, varying in level of formality, have been used to identify artistically gifted children for special art programs (Clark & Zimmerman, 1987). The most formal assessment measure is the normed, standardized test, designed to be used uniformly in a wide range of classes. More informal tests or checklists have also been developed and used by particular programs for artistically gifted children. Finally, some programs have not relied on any tests, but rather on a combination of methods including nomination (by teacher, peers, or even the students themselves), portfolio review, interest inventories, and academic performance.

STANDARDIZED TESTS

A variety of tests were developed in the United States in the 1930s to identify artistically gifted children, but none of these tests are available today. These include the Meier-Seashore Art Judgment Test, the Graves Design Judgment Test, the Goodenough Drawing Scale, the Horn Art Aptitude Inventory, the McCarty Drawing Scale, the Kline-Carey Drawing Scale, the Lewerenz Test of Fundamental Abilities in the Visual Arts, the McAdory Art Test, and Munro’s Seven Drawing Test (Buros, 1972; Clark & Zimmerman, 1984).

Creativity tests such as the Torrance Test have also been used. Standardized tests to identify artistic talent have, however, been severely criticized (Clark & Zimmerman, 1992; Hamblen, 1988; Hausman, 1988; Munro, Lark-Horowitz, & Barnhardt, 1942), as there is no conclusive definition of talent in the visual arts. Moreover, students have gifts in different areas within the visual arts, and one test cannot detect ability in all possible specializations. Finally, there is no evidence that results on standardized art or general creativity tests predict success in art programs (Clark & Zimmerman, 1983, 1992). Thus, most researchers today argue against reliance on one purportedly all-purpose test of talent; instead they advocate the use of multiple criteria for identifying artistically talented students (Clark & Zimmerman, 1992).

INFORMAL INSTRUMENTS

Most programs today in the United States use a combination of at least two informal (i.e., non-standardized) methods for selecting students into special art programs (Clark & Zimmerman, 1992).

Nominations (by classroom or art teacher, self, peers, or parents) are the most widely used means of identification, and account for over half of the procedures used.

Non-standardized drawing tests are often developed for use by particular art programs. For example, the DeCordova Museum in Lincoln, Massachusetts used two tests designed by David Baker. In the Visual Narrative test, students are asked to tell a story by drawing a series of pictures; in the Memory Assessment, students see a painting by Van Gogh and then reproduce the painting from memory (Lazarus, 1982). Another example of a locally used assessment instrument is the Clark-Gareri Drawing Instrument used to identify students for the Iowa University Summer Arts Institute (Clark & Zimmerman, 1987). Students are asked to make three drawings in half an hour (a house seen from across the street, a person running fast, and a group of children playing). These locally-designed tests are scored on a variety of dimensions (e.g., composition, expression, technique), and the dimensions used, as well as the scoring guidelines, differ somewhat from test to test.

Portfolio reviews are used increasingly, because this method allows judges to review a wide range of work by each potential student. There is a current movement towards the inclusion in portfolios of drafts of work in progress and of student journal entries about the work (Wolf, 1989). In Australia, for instance, students must keep visual arts “process diaries” (New South Wales Department of School Education, 1988). The inclusion of drafts and written reflections makes it possible to assess students’ aptitude on a variety of dimensions, rather than on a single, global one. For an example of a detailed scoring system designed to assess students across the full range of ability, see Winner and Simmons (1992).

Behavioral and biographical checklists have been advocated as a means of identifying students whose art

work does not reflect their underlying potential (Clark & Zimmerman, 1987; Ellison, Abe, Fox, Coray, & Taylor, 1976; Khatena, 1982; Lazarus, 1982; Wilson & Wilson, 1992). Checklists allow children with potential in art to be identified because they spend their free time drawing, or because they take particular pleasure and pride in their drawings.

Academic performance as measured by grades or IQ scores are also sometimes used in conjunction with some of the above measures, because of the widespread belief that artistically talented children are also academically talented or have high intelligence (Clark & Zimmerman, 1992). However, as discussed earlier in this chapter, there is strong evidence that artistic talent is independent of IQ scores and hence of academic performance. Thus, the use of such measures is suspect.

There is no "tried and true" means of successfully identifying those students who will flourish in an art program, and Clark and Zimmerman point to the need for further research on appropriate identification tools.

High Drawing Ability in Ordinary Children as a Function of Instruction: The Case of China

If one spends time in China observing kindergarten and elementary school children drawing and painting, giftedness in the visual arts appears to be a cultural rather than an individual phenomenon. Chinese children do not make child-like drawings, but rather make drawings that seem to challenge theories of the developmental course of drawing skill. Instead of the charmingly simple, invented schemata produced by Western

children, one sees Chinese children producing highly differentiated, remarkably adult-like drawings and paintings (Gardner, 1989; Winner, 1989). Figure 4 shows a "Western-style" painting by a 6-year-old Chinese child; Figure 5 shows a "Chinese-style" painting by a 6-year-old Chinese child. These are the two styles in which Chinese children learn to paint. The Western style consists of cartoon-like figures in a multitude of positions; the Chinese style consists of watered-down versions of schemata developed over the centuries by Chinese masters.

Such adult-like paintings can be seen in endless supply in any good urban school in China. It is not just the gifted children who draw in this way. To be sure, the average Chinese child does not paint as well as Yani. However, while the artistically talented children excel, and while it is the talented children's pictures that are selected for international exhibitions, the paintings of the ordinary children are also strikingly higher in skill than those of Western children.

If one looks closely, the mystery of such mass talent can be resolved. From the age of 3, as soon as they enter kindergarten, Chinese children are *taught* to draw. In contrast, Western children are simply given art materials and allowed to explore. This difference in approach to early childhood education reflects very different views of childhood and learning: while in the West, progressive education is grounded in the belief that children learn best by doing, exploring, and discovering on their own (Dewey, 1934; Piaget & Inhelder, 1969), Chinese education is grounded in the belief that children learn best by imitating. Moreover, if adults know the solution to something, there is no point in letting children try to discover the solution on

FIGURE 4. Western-style painting by a 6-year-old Chinese child.

FIGURE 5. Traditional Chinese-style painting by a 6-year-old Chinese child.

their own. Such practice is simply a way of reinventing the wheel, for which no benefit is seen (Gardner, 1989; Winner, 1989).

The Chinese art teaching method consists of presenting the child with a set of very simple schematic formulae which are then gradually and additively made more complicated. The teacher and the textbook supply the models for these schemata, and the child copies the models in a step-by-step, stroke-by-stroke fashion, much as in the well-known drawing books by Ed Emberly (1972) and Mona Brookes (1986). This method is also used to teach calligraphy in China, and resembles the way penmanship was taught in the U.S. and elsewhere until recently. Thus, while to the naive eye Chinese children's drawings look non-schematic in their complexity, they are in fact based on schemata that the child has mastered bit by bit. This method of teaching is made possible in part because the domain of Chinese painting is itself quite formulaic: there are rules for how to paint birds, flowers, shrimp, goldfish, etc. The cartoon-like Western style that Chinese children learn is also equally formulaic.

The Chinese example demonstrates that it is possible to find near adult-level performance in drawing among average, non-gifted children, but only when the domain itself is highly formulaic, and when the method of teaching consists of copying adult models in an additive manner.

“Savant” Artists

A small proportion of children and adults with autism and/or retardation are able to produce drawings that are

unusually realistic. Such individuals, often referred to as “savants” (Miller, 1989; Treffert, 1989), are found in a variety of domains (e.g., mathematics, lightning calculation, calendar calculation, chess, mechanical ability, mnemonism, unusual sensory discrimination, music, and art) (see Feldman and Morelock, this volume). While the skills exhibited by savants depend on the domain in which their skill is found, all savants possess a phenomenal ability to recall things in vivid detail, and often possess eidetic imagery. The extreme level of skill displayed by these individuals, in the face of severe lack of skill in almost all other areas, is striking and not fully understood. The existence of such individuals in the domain of the visual arts (and music, as discussed later) provides incontrovertible evidence that drawing ability (and musical ability) can exist and operate at a very high level without the benefit of other, more “general” intellectual abilities.

Selfe (1983) reports in detail on a group of autistic children who show such anomalous drawing skill. These children all had prototypical autistic symptoms: delayed language, impaired social relationships, ritualistic behaviors, and severe learning difficulties (they were in the lowest 2% of the IQ range). All had poor gross motor coordination, as shown, for example, by late walking and difficulty in tying shoes and catching balls (cf. also Morgan, 1987). Along with their exceptional drawing ability, these children had good fine motor coordination (which helped them to wield a pencil with skill), and showed skills in perceptual matching, spatial imagery, and visual memory. In short, their drawing ability, visual-spatial skills and fine motor coordination were way in advance of all other abilities.

These children all showed an anomalous pattern of drawing development. While normally children begin to draw between the ages of 1½ and 3½ years, all six of Selfe's subjects began drawing somewhat later—between the ages of 2½ and 4. Normal children's first drawings are scribbles. Representational drawings (of recognizable objects) do not typically emerge until the age of 3 or 4. In contrast, these autistic children never scribbled. Their very first drawings were recognizable objects. Thus, these children appeared to bypass the scribbling stage (cf. also Morgan, 1987, for a similar claim).

While early representational drawings by normal children tend to depict a restricted range of rather predictable subjects (typically generic people and generic houses) (Lark Horowitz et al., 1973), these autistic children depicted a wide range of unusual subjects in their earliest drawings e.g., yachts, windows, cars, churches, hospitals and flowers. They repeatedly drew the same subjects with obsessional interests, and displayed their highest level of skill when drawing their favorite subjects. For example, Selfe's most famous and widely written-about subject, Nadia, drew horses constantly (see Figure 6); her few human figures were (with possibly one exception) drawn with a lower level of skill. A Japanese autistic child studied by Morishima and Brown (1977) drew insects with striking realism, but disliked and was quite poor at drawing humans (cf. also McGregor, 1990).

At the same age at which the young Toulouse-Lautrec or the young Picasso were making relatively child-like drawings, these autistic children are able to draw with adult-level realism. Typically these children show little interest in color or decoration. Their only interest appears to be naturalistic rendering. Their drawings show an extremely high ability to capture proportion, contour, occlusion, and depth through perspective and foreshortening.

The process of drawing appears to be more important to these children than the final product. While normal children typically talk about their drawings to others, and show them to their parents with pride, autistic children do not talk about or show their drawings, and

appear unaffected by praise of their work (Park, 1978; Selfe, 1983). They seem to draw for themselves only, and display no interest in others' reactions to what they produce. Moreover, while normal children distort the outline of an object to fit onto the paper (thus sacrificing realism to showing the complete object), autistic children with drawing talent frequently draw figures right off the page, truncating rather than squishing them, and sometimes make one drawing on top of another (Selfe, 1977).

These autistic children appear to possess excellent visual memories. They rarely copy directly, but instead draw from memory. While normal children complete a drawing object by object showing no sense of advance planning, these autistic children often draw details in various sections on the page and later connect these details with perfectly fitting larger lines, thus revealing that they are holding the finished product in mind as they draw (Selfe, 1983).

Autistic children with high drawing ability draw almost every day, producing many more drawings than do average children, and are often wedded to a particular drawing implement. Nadia, for example, drew with extremely high skill when using a fine ball point pen, but her drawing disintegrated when she was forced to use a thick crayon. David Downes, a child studied by Morgan (1987) also preferred implements that made a fine line, and rejected the use of wide brushes.

Drawings by the small subset of autistic children with drawing talent are not only unlike those of average children and of non-pathological talented children. They are also wholly unlike drawings by other atypical populations, such as children who are psychotic, deaf, or retarded. Psychotic children's drawings are bizarre and not highly realistic; drawings by deaf children are similar to those by normal children but somewhat behind developmentally (Winner, 1982) and drawings by non-autistic retarded children follow a normal, but delayed developmental sequence (Lark-Horowitz et al., 1973).

The drawings by Nadia and other autistic children with precocious drawing talent demonstrate an anomalous pattern of development. These children do not

FIGURE 6. Drawing of horses by Nadia before the age of 4.

pass through a regular series of stages, beginning with scribbling, and continuing on with schematic, simplified forms. Instead, these children begin to draw in a naturalistic style from the start. How can such extreme talent in the face of extreme retardation be explained?

One possible explanation rests on the fact that these children are linguistically impaired and thus socially isolated. Perhaps they turn to drawing as their only form of communication. However, children who are socially isolated because of retardation or psychosis do not draw like autistic children. Moreover, since these children do not talk about or show their drawings, and seem uninterested in the finished products, they do not appear to be using drawings as means of communication.

It might also be suggested that these children's skill results from the possession of eidetic imagery. However, if the possession of a completely accurate image is sufficient to capture that image realistically on paper, then all children should be able to draw realistically when looking at a model. Moreover, normal children with eidetic imagery do not show exceptional drawing skill (Haber & Haber, 1964).

In our view, the most satisfactory explanation is that the anomalous drawing ability of autistic children is directly tied to their inability to generalize, abstract, and classify (Arnheim, 1980; Pariser, 1979; Selfe, 1977). For example, Nadia was unable to match two pictures of the same object unless both were in the same orientation; and she could not match pictures of different types of chairs. The lack of ability to generalize and classify may be related to the ability to draw in a naturalistic fashion.

Normal children show their conceptual understanding of an object in their drawings, and their simple schemata are evidence of generalization and abstraction (Arnheim, 1974). The use of a circle for a head, for instance, is an abstraction: a circle is somewhat like all heads and overlooks the individual variations in head shape.

In contrast, the realistic drawings produced by autistic prodigies are not generalizations but are snapshot-like depictions of individual objects from particular vantage points, e.g., not a generic house, but a specific church seen from a particular angle. Thus, the high realism of autistic drawings may be a result of these children's inability to form visual concepts. These children may have no choice but to render every detail of a figure; they may be unable to grasp the general form of objects.

Selfe (1983) describes these children as using a visual-spatial modality without interference from language, "untrammelled by conceptual analysis and reorganization" (p. 202). Their conceptual deficiency leaves them free to record objects with a naked eye, without the interference of the schemata imposed by knowledge and understanding. Evidence that knowledge interferes with realistic rendering comes from studies showing that children draw more realistically when copying nonrepresentational designs than when drawing recognizable objects (Phillips, Hobbs, & Pratt, 1978),

and that people can copy pictures more faithfully when the models are unrecognizable because they are positioned upside down (Edwards, 1979).

Savants in the visual arts (as well as in music and other domains) may be an extreme example of what Geschwind and Galaburda (1987) refer to as the "pathology of superiority." Geschwind and Galaburda articulate a theory that can account for the frequent finding of superior right-hemisphere talents (visual-spatial skills, musical skills) with learning disorders (dyslexia, autism), an association that takes its most extreme form in savants. According to the theory, in savants there is a disruption of typical left-hemisphere brain functions resulting from prenatal influences, which leads to compensatory migration of neurons to the right, and to dominance of certain right-hemisphere functions. Left-hemisphere prenatal injury is more likely than right-sided injury because the left hemisphere develops more slowly than the right, and hence is more vulnerable. One influence on the prenatal brain is circulating testosterone, which can slow cortical growth in the left hemisphere (the more vulnerable hemisphere). Such slowing leads to compensatory neuronal migration to the right hemisphere.

This account is consistent with the fact that savants are disproportionately male (testosterone is a male hormone which is produced in greater quantities by the male fetus than the female fetus), and that the skills of the savant are right-hemisphere skills (spatial skills such as drawing, chess, mathematics, and music). This account is consistent with some evidence from CT scans of left-hemisphere damage in savants (Treffert, 1989). Geschwind and Galaburda's (1987) account is also consistent with the finding that a disproportionate number of savants were born prematurely (Treffert, 1989). There is massive brain cell death in humans just before birth, but when left-sided insult occurs in premature infants, before such massive cell death, there is still a large reservoir of right-brain neurons available to accommodate a neuronal shift to the right. This, Treffert argues, could well lead to the savant syndrome. Of course, though, premature birth could be only one of the associated factors, neither necessary nor sufficient: many savants were not premature, and most premature infants do not become savants.

Autistic drawing prodigies stand apart from nonpathological children with and without drawing talent. Nonautistic children who may go on to become artists do not typically display their precocity at as young an age as autistic children. While autistic prodigies share with the young Picassos and Lautrecs a strong inborn talent, their conceptual impairment allows them to do immediately what it takes most "normal" artists years to learn how to do—draw realistically, with minimal imposition of formulaic schemata (Gombrich, 1960). Drawings by autistic prodigies are thus a symptom of their autism. However, drawing talent is not a necessary symptom of autism, since prodigious drawing skill characterizes only a small subset of autistic children. Why some autistic

children possess this extreme talent while most do not is not known.

The Relation Between Artistic Giftedness and Creative Adult Artistry

The drawings of gifted children, like those of ordinary children, pass from a pre-conventional to a conventional stage, in which their drawings lose some of their early freedom and inventiveness. This has been noted by Clark and Winner (cited in Winner & Pariser, 1985), who found that two children they studied produced their most free and inventive work before the age of 7. In their high school years, their work became more constrained, and one of the children temporarily lost interest in art during adolescence.

An examination of the childhood and adolescent drawings of established artists shows that they too pass through a constrained, conventional stage at adolescence. In fact, they seem to pass through such a stage with a vengeance, insisting on drawing only in the most academic, realistic, dull style (Gardner, 1980). Picasso, Klee, and Lautrec all drew and painted realistically at adolescence, despite the fact that by this age they had had plenty of opportunity to view Impressionist and Post-Impressionist images. Pariser (1987) claims that these three artists all showed a “slump” in late childhood. He conjectures that this time “[reflects] the effects of a period of consolidation when old skills are changed to accommodate new demands” (p. 22). Klee’s early fluid, expressive, whimsical images gave way to banal and labored images in adolescence as he began to copy images from calendars and comic strips (Pariser, 1987). The 10-year-old Klee showed a “painful concern for accuracy and no trace of effort to be inventive or expressive,” notes Werkmeister (cited in Pariser, 1987, p. 10). But he did not lose his ability to draw playfully, as can be seen in free and humorous drawings done in the margins of his school notebooks (Pariser, 1987). Lautrec’s drawings lost their sense of movement in late childhood, and became more like drawings by ordinary children of the same age (Pariser, 1987). Picasso’s work between the ages of 10 and 14 has been characterized as “dull” (O’Brian, 1976; Pariser, 1987). Two of the Israeli artists studied by Gordon (1987) showed a similar decline, passing from assured, flowing lines to more tentative, faltering lines as they struggled to master the conventions or realism.

At adolescence, when ordinary children lose all interest in drawing, the individual who may become an artist emerges from this period of decline and begins to draw again with flow and self assurance (Gordon, 1987). Once they have mastered the conventions of the graphic symbol system, those gifted adolescents who continue to produce art go on to a post-conventional phase in which rules are willingly violated and realism is abandoned for other styles. It is at adolescence that future artists begin to find their own voice (Gardner, 1980).

It is noteworthy that children who go on to become artists pass through the same two-phase sequence as do normal children (pre-conventional and conventional) before going on to a third phase not attained by ordinary children (the post-conventional phase). Gifted children may well need an early pre-conventional period of freedom and exploration. They also need a period in which they conquer the rules of graphic symbolization valued in their culture—in the West, this means mastering realistic, illusionistic rendering. Gifted children arrive at this second stage earlier than do typical children, and they go much deeper into rule mastery, drawing much more illusionistically than does the average literal stage child. During this period, the gifted child’s drawings lose some of the whimsical charm of ones produced in the preschool years, just as those of the average child do. Since all artists seem to have passed through this literal stage, it is likely that this stage is a necessary prerequisite for later ability to violate conventions.

This broad three-phase sequence has been described by Alfred North Whitehead (1929) as characterizing expertise in all domains. First there is the period of romance, in which the child has the freedom to explore the domain. Following this is a period of precision, in which children learn the grammar of the domain, and gain technical mastery. Finally comes the period of generalization, in which the individual returns to the early romanticism with the added advantage of technical mastery. In his study of over two hundred talented individuals, Bloom (1985) found that these three stages characterized development in all of the domains he studied (including the sciences, the arts, and sports).

Not all artistically gifted children go on to become artists. Indeed, probably most do not. Why should this be so? One possible reason is that the arts are not highly and widely valued in our society. Thus, there are often pressures on artistically gifted adolescents to give up the arts in favor of more “useful,” conventional, or lucrative work (Getzels & Csikszentmihalyi, 1976).

Other historical and cultural factors may also play a role. There is a disjunction between the core ability of the artistically gifted or prodigious child, and the kinds of art that are valued by our culture today. The core talent of children who are gifted in the visual arts is the ability to capture the contours of objects faithfully, so that the resultant drawings look realistic rather than schematic. This ability is a visual-spatial and motor precocity: such children can guide a pencil so that the lines on the paper mirror the outlines of the object they are representing. Children with this ability produce drawings that are astonishing in their realism. This core ability is possessed by ordinary gifted children, by children who draw at a prodigious level, and by savant artists.

However, highly realistic drawings are very different from the kinds of art works produced by contemporary adult artists in our culture. What is valued in the West today is innovation and expressiveness, rather than faithful realism. As Richardson (1991) noted in his biography

of Picasso, no great painter has ever produced a work of "any serious interest" before adolescence. Presumably, this is because the technical accomplishments of the child drawing prodigy are a far cry from the expressive, innovative paintings we prize as significant adult works of art. Thus, one should not assume that there is any direct route from early signs of visual giftedness to adult creativity in the visual arts.

The case of China serves to underscore the historical and cultural determinants of who becomes an adult artist. In China, where traditional brush painting is still valued, gifted children's works (such as those of Yanli) do closely resemble the kinds of adult works that are prized by the culture today. Thus, there may be a more direct route from childhood prodigiousness to adult artistry in China today than in contemporary Western culture. And, as discussed below, in the domain of music, where early giftedness typically reveals itself in performance rather than composition, gifted children's performances also closely resemble the kinds of adult performances prized by the culture. Nonetheless, there is no direct route in music from childhood prodigiousness to adult artistry.

Giftedness in Music

Music has universal appeal, and all children show sensitivity to music. However, the differences among individuals in musical ability are extremely wide. Gesell and Ilg (1946) remarked that the area in which individual differences are most marked is the domain of music, noting that a child under 2 may sing songs with great accuracy while some adults (the present first author included) never attain this ability.

As is the case with the visual arts, a considerable amount is known about the normal course of musical development (Bamberger, 1991; Shuter-Dyson & Gabriel, 1981; Sloboda, 1985), and much less about the emergence and development of exceptional musical ability. As with the visual arts, our knowledge of childhood musical giftedness comes from three sources. (1) Children who have been identified as gifted or actually prodigious in music by their parents and/or teachers have been studied (Walters, Krechevsky, & Gardner, 1985; Feldman and Goldsmith, 1986). The most detailed study of the development of a musical child prodigy is the study of Erwin Nyiregyhazi (E. N.) carried out by Revesz (1925) when E. N. was between 7 and 12 years of age. (2) Biographical information about the emergence of talent in famous performers and composers exists, though on a somewhat anecdotal and disconnected basis (Scott & Moffett, 1977; Schonberg, 1970). (3) Finally, children who are classified as musical savants, who show extremely high levels of musical ability in the face of retardation and/or autism, have been studied (Miller, 1979). From these three groups of subjects, a consistent picture of early musical giftedness emerges. However, all studies of musically gifted children have

been of Western children, and all children studied have been gifted in Western classical music. We know little about the emergence of musical giftedness in cultures with non-Western music; and we know little about children who show musical giftedness with non-classical forms of music.

Early Signs of Musical Giftedness

The core ability of the visually gifted child was described above as a visual-spatial motor precocity which allows the child to capture the contour of three-dimensional objects on a two-dimensional surface. The core ability of the musically gifted child is a sensitivity to the structure of music: tonality, key, harmony, and rhythm. This sensitivity allows the child to remember music, and to play it back with ease, either in song or on an instrument. This sensitivity to structure also allows the gifted child to transpose a theme to a new key, to improvise on a given theme, and to invent melodies.

Signs of ordinary musical ability emerge very early in all children, usually during the preschool years. Musical giftedness also reveals itself very early. In fact, giftedness in music may appear earlier than giftedness in any other domain of skill (Stanley & Benbow, 1986).

Many well-known performers and composers have demonstrated musical giftedness as young as 1 or 2, and almost always before 6 (Scott & Moffett, 1977; Shuter-Dyson, 1986; Shuter-Dyson & Gabriel, 1981). For example, in a survey of forty-seven musicians, Scheinfeld (1956, cited in Shuter-Dyson & Gabriel) found that their ability had been detected on average at 4 1/2. Drake (1957, cited in Shuter-Dyson & Gabriel) found that 70% of the great violinists in Leahy's *Famous violinists* were prodigies as young children. Mozart composed a concerto for the harpsichord at 4 (Waterhouse, 1988). Mendelssohn was even more of a child prodigy than Mozart; and the violinist Yehudi Menuhin performed with symphony orchestras at the age of 7.

The strikingly early age at which giftedness often manifests itself in music may be because music is a domain that is both appealing and accessible. However, an early emergence of talent is not a necessary indicator of musical giftedness. Sloboda (1985) found that concert pianists are not necessarily recognized as musically gifted in early childhood.

INTEREST IN MUSICAL SOUNDS

Perhaps the earliest clue that a child is gifted in music is a strong interest and delight in musical sounds (Radford, 1990; Scott & Moffett, 1977; Sosniak, 1985). Stravinsky's first memories were of song (Gardner, in press, a). And Mozart's ear was so delicate that loud sounds made him physically ill (Schonberg, 1970). However, Sloboda (1985) points out that heightened attention to sounds *per se* is not in itself evidence of

musical sensitivity: a response to a sound may simply be due to the infant's natural heightened attentiveness to novelty.

Musical children respond more strongly to music than do average children, showing an intense interest in auditory information (Miller, 1989). Such children often have a strong sense of goodness of tone and timbre: e.g., both Rubinstein and Menuhin broke toy violins because the tone of these toys was so poor (Radford, 1990).

MUSICAL MEMORY

One of the earliest signs of musical giftedness is the ability to sing back heard songs with accuracy. This ability is made possible by exceptional musical memory, a skill that has been said to be the ability most central to musical talent (Judd, 1988).

While children typically begin to sing and talk at about the same age of 18 months (Sloboda, 1985), musically gifted children may begin to sing at a younger age, and often before they can speak (Shuter-Dyson, 1982). E. N., the 7-year-old Hungarian musical prodigy whom Revesz (1925) studied, did not speak until the age of 3, but before the age of 1 he began to try to sing back songs that he heard. Revesz reports that Handel also sang before he could speak.

In the normal course of development, children do not try to imitate heard songs until about 2–2½. Children are able to sing portions of these songs with accuracy at around 3, and can sing whole songs by about 4. However, intervals in these songs are only approximate, and children are not yet able to maintain the same tonality through a single song. It is not until about 5 that children can reproduce with accuracy the familiar tunes of their culture (Gardner, Davidson, & McKernon, 1981; Sloboda, 1985). Musically gifted children present a striking contrast: these children sing with great accuracy, demonstrating the ability to match pitches with precision by their second year (Revesz, 1925).

Musically gifted children can imitate a song after only one exposure, and familiar themes from TV are rapidly and effortlessly learned (Miller, 1989). Mozart began to pick out tunes on the piano at 3 (Schonberg, 1970). Pepito Areola, a child studied by Richet (1900), could play twenty pieces from memory by the age of 3½. At 3, the pianist Arthur Rubinstein listened to his older sister playing the piano and surprised his family by faultlessly playing the pieces she had been practicing (Winn, 1979). At the beginning of his fourth year, E. N. could reproduce with accuracy on the piano any tune that he overheard (Revesz, 1925); by 7 he could play complex Beethoven sonatas from memory. Mozart, at 14, was able to write down Alleferi's *Miserere*, a complex piece of music with nine parts, after listening to it only a few times (Henson, 1977).

A series of memory tests administered by Revesz showed the 7-year-old E. N. had a short-term musical memory almost equal to that of an adult musician tested. That is, E. N. performed as well as the musician when asked to listen to pieces of music, commit them to

memory, and play them back. Moreover, E. N. revealed a long-term memory which was far superior to that of the adult musician: both were asked to reproduce music heard 24 hours earlier, but only E. N. succeeded, and he did so effortlessly and flawlessly.

E. N.'s memory gave evidence of a tacit understanding of musical structure: he was better able to recall familiar structure, harmony, and rhythm than random harmonies, and had better recall for the music in the diatonic scale than for dissonant music built on the twelve tone chromatic scale. Thus, his memory was structure-preserving: it was somewhat dependent on familiar structure, and was thus not eidetic, mindless, or literal. Superior recall for familiar form indicates some at least unconscious representation of familiar form.

Bamberger (1986) notes that the extraordinary ability of musically gifted children to play back what they hear is nonreflective and tacit. Such children often say that they cannot imitate a piece if they think about it.

PERFECT PITCH

While one might predict that musically gifted children would show perfect pitch—the ability to name notes heard, and the ability to sing notes named—this is not the case. Some prodigies have shown perfect pitch. E. N., for example, at the age of 3 could instantly locate on the piano notes that were sung to him. He also had other, related acoustic skills: he could recognize intervals and the notes in a chord and analyze chords. In fact, his capacity for resolving multiple chords has hardly ever been equaled (Revesz, 1925). Mozart also had perfect pitch: he could tell when violins were a quarter out of tune by the age of 4 (Schonberg, 1970).

However, interviews with teachers of musically gifted children reveals that perfect pitch is not consistently associated with musical giftedness (Walters et al., 1985). Sergent and Roche (1973) argue that perfect pitch is a function of training. They surveyed one-thousand musicians, and found that the possession of perfect pitch was related to the age at which musical instruction was initiated. Of those who had begun instruction before age 4, 95% had perfect pitch; of those who had begun instruction at age 12, only 55% had perfect pitch. However, this evidence does not prove that perfect pitch is a function of training: perhaps children who begin instruction at a very early age are simply more gifted than those who begin later, and also tend to possess perfect pitch.

SIGHT-READING

As with the skill of perfect pitch, the ability to sight-read is also not consistently associated with giftedness in music (Walters et al., 1985). This is an ability possessed by some but not all musical prodigies. Mozart was one prodigy who did possess this skill. At the age of 8 he immediately could play a piece he had never seen before

(Scott & Moffett, 1977). E. N. also possessed this ability at the age of 7.

SKILL IN PERFORMING ON AN INSTRUMENT

While in contemporary Western culture artistically gifted children do not typically take art lessons, most musically gifted children begin formal instructions on an instrument in the early elementary school years. Musically gifted children thus get instruction from a young age, and weekly instruction is augmented by daily practice. Teachers report that they can easily tell whether they have a gifted student: gifted students play easily, learn rapidly, make quick self-corrections of their errors, and perform with confidence (Walters et al., 1985).

While musical instruction is necessary for the flowering of musical talent, training at any age will not do. The training of a future musician must be initiated at a very young age. Most great performers began taking lessons in their early years. "A string player," the violinist Alexander Schneider stated, "should begin at 5-years-old. Later is too late" (Winn, 1979, p. 40). However, there are some counter examples to this rule. Apparently the family of Leonard Bernstein did not acquire a piano until Bernstein was 10. And Shuter-Dyson & Gabriel (1981) note several other examples of famous musicians who did not take up an instrument until adolescence.

MUSICAL GENERATIVITY: ABILITY TO TRANSPOSE, IMPROVISE, AND COMPOSE

There is a clear distinction between the act of performing existing music, and the creation of new music. A further distinction exists between composing new music and two more constrained forms of creation: transposing a given piece to a new key, and improvising from a given musical theme. The transposer takes a given piece and shifts it to a new key. The improviser takes a given musical theme and improvises from this theme, without changing the essential style and structure of the already existing piece.

All children begin to produce their own, spontaneous songs at around 18 months. During this time, they are experimenting with intervals. Their spontaneous songs grow in length and internal organization between 2 and 3. However, by 5, spontaneous singing declines in frequency, as the child becomes concerned with making mistakes, and shows an interest in imitating heard songs with accuracy (Sloboda, 1985). Thus, the ordinary child, at least in Western culture, stops generating music by the end of the preschool years. This decline in playful experimentation with song has its parallel in the decline of flavorful, pre-conventional drawings of the preschooler, and the concern for literalness in drawing discussed earlier in this chapter.

Once again, musically gifted children tell a different story. Most musically gifted children learn to play an

instrument, and soon after they begin to play an instrument, they show "musical generativity." This generativity first takes the form of the ability to transpose tunes to new keys, and to improvise on themes. E. N. could transpose pieces to new keys at 7. By 10 he could accurately transpose complex pieces at first sight into any key without difficulty.

E. N. could improvise at the beginning of his fourth year, and until 7 he improvised more than he composed. He was able to improvise on his own themes as well as on those of others. When he had just turned 6, for example, he was given a pastoral theme and asked to improvise a funeral march on it, which he did with great skill. He was then asked to improvise a children's song on the same theme, which he again effortlessly carried out. These improvisations showed remarkable spontaneity and musical imagination.

A musician studied by Walters et al. (1985) reported being "one of those kids who would play the piano, play it wrong and keep playing it wrong, fooling around with the themes. At a young age, I would pick things off the radio by ear, and then change them and rearrange them." Similarly, Pepito Aereola could, given a few bars, continue a melody in the same style (Richet, 1900). And Mozart improvised at 4 (Scott & Moffett, 1977; Schonberg, 1970).

The ability to compose music in early childhood is much rarer than the ability to interpret music (by singing or playing an instrument in an advanced manner). Musically gifted children typically first reveal their talent by early, accurate singing, and early ability on an instrument, and only later on do a minority of these begin to compose. Revesz (1925) argued that a gift for composition is rarely seen before late childhood. J. S. Bach, Handel, Beethoven, Mendelssohn and Brahms are examples of great musicians reported by Revesz who were performing virtuosi in early childhood, but who did not begin to compose until at least early adolescence, if not early adulthood. E. N. is one of the rare cases of children who began to compose music at an early age, composing melodies with accompaniments at 3½. Haydn, Mozart, Chopin, Mahler, Meyerbeer, Saint-Saens, and Strauss also produced their first compositions before the age of 10 (Revesz, 1925; Radford, 1990). Mozart started composing at 4, and by the age of 8 he had already written six sonatas for piano and violin, and three symphonies for small orchestra. However, the biographies of great composers show that the ability to compose at an early age is much rarer than the ability to interpret (i.e., perform) music at an early age.

A comparison with the domain of the visual arts is instructive here. As was pointed out earlier in this chapter, the incidence of very young child prodigies in the visual arts is lower than the incidence in music. However, what is usually meant by this is that prodigies in the visual arts are rarer than prodigies in music *performance*. Drawing is more analogous to composition of music than to performance. If we compare the frequency of prodigious composers to the frequency of prodigious

drawers, we may find that musical prodigies are just as rare as are visual arts prodigies.

CAPACITY FOR MULTIPLE REPRESENTATION OF MUSICAL RELATIONS

Musically gifted children have an unusual capacity for representing musical relations in multiple ways (Bamberger, 1986). These children move freely among four ways of attending to a piece of music, shifting their focus of attention among the instrument and the actions performed on it, the score, the sound, and the music's structure.

When one focuses on the instrument, the music is represented as a felt path, a sequence of actions performed on one's instrument. For instance, one might think of a pitch on a violin as the third finger on the E string. The musical score is a very different kind of representation, and students must connect the kinesthetic representation to the notational one. The imagined sound towards which the performer is striving is yet another representation. When thinking of the music in terms of sound, one listens to one's own playing to keep it in tune, or one matches one's sound to remembered models of others playing. And finally, there is the level of musical structure, in which one attends to the organization of a piece, and the relations among its parts.

From studying conversations between music teachers and their musically gifted students, Bamberger (1986) noted that the teachers shift continually among comments which highlight music as a felt path, as a set of notations, as sound, and as structure. The children shift their attention readily with the teacher. Bamberger argues that such easy shifts from one mode of representation to another is a significant aspect of musical giftedness.

An experimental task administered by Bamberger (1986) to gifted children revealed this ability to entertain multiple representations of music. Four groups of individuals were given a set of Montessori bells, all of which looked alike, but each of which had a different pitch when struck with a mallet. The four groups were: gifted children, musically untrained children, musically untrained adults, and musically trained adults. Thus, musically gifted children could be compared to nongifted children, and to nongifted adults with and without training. Subjects were given all of the pitches of the C major scale plus three matched pairs: two Cs, two Gs, and two Es. The bells were laid out in arbitrary order.

Children were asked to do three tasks: (1) construct "Twinkle Twinkle Little Star;" (2) notate the song in any way they wanted; and (3) arrange the bells so that a notation different from theirs would make the same tune. The tasks were designed to tease apart multiple representations of music. For instance, the construction task was meant to disturb the familiar structure of the instrument field, because the bells were arbitrarily

arranged. Thus, the felt path of pitch relations (low to high) was violated.

Some pitches in "Twinkle" are identical but have a different function. For instance, when performed in the key of C, the note G occurs on "twinkle" and again on "star", but the second time it occurs at the end of a phrase and thus has a different structural function from the first G. Some people hear these Gs as the same, some hear them as different. If one responds to the context, the two notes sound different; but if one can focus on the single dimension of pitch, the two notes sound the same.

The gifted children shifted strategy during the construction task, and with each shift, they attended to different dimensions, as detailed below. In contrast, the nongifted subjects maintained a single, consistent strategy during the entire task, including the trained adults who were students at a prestigious American university and had had at least five years of music instruction.

The children and adults with no musical training always added new bells to the bell path in their order of occurrence in the tune, never moving backwards to hit the same note a second time. The result was a row of bells, one for each pitch. Thus, they needed to use two different bells for the two Gs. Each was heard as a different event. These nongifted and nontrained subjects were using what Bamberger (1986) calls a "figural" strategy, because they were focusing on the shape, or figure of the tune, and hearing individual notes within the context of the shape of the tune. Doing so leads to the two Gs being heard as different events because of their different functions within the tune.

The nongifted but trained adults used a "formal" strategy. They built a C major scale out of the bells, and played the tune on the scale, moving back and forth as needed. Unlike the untrained individuals, these people focused on the tune as it relates to the formal structure of the C major scale.

The gifted children switched strategies as they went about the task. At first, they looked like the untrained subjects. They began with a figural strategy by searching for each pitch, lining them up from left to right. But when they got to "star," they switched to a formal strategy: they moved backwards to hit the G already used for "twinkle." Thus, they recognized the two Gs as the same. The first part of the piece (Twinkle twinkle little star) was thus played on bells lined up as C-G-A. But they then faced a dilemma when they got to the F for the first note of "How I wonder what you are." If they followed their initial figural strategy of lining up bells in order of occurrence, they would have to put G to the right of A. But this move would not represent the downward pitch from G to F; and such a move would not yield a purely figural strategy since it would require skipping from G over the A to F. If on the other hand they followed their new formal strategy, the F would have to go to the left of the previous G since it is lower. But the C bell was already to the left of G, because of

the initial figural strategy of placing the bells in order of occurrence.

The gifted children felt this conflict between figural and formal strategies, and made different choices at this point. For instance, one child responded to the fact that F is lower than G. Thus, he moved left. But the bells were not ordered from low to high, so he realized that he had to search for the F bell. He then recognized that the F had a double meaning: it was next in the tune, but also lower than G and higher than C. So, he pushed the C to the left, and inserted F between C and G. The added notes beginning with "star" were placed in order of occurrence (backward) but also classified according to a low-high series (D E F). Thus, for the gifted children, multiple dimensions came into conflict. During the construction task, all of the gifted children made multiple representations of the tune as they constructed it.

When asked to notate the song so someone else could play it, none of the gifted children used standard notation, although they all knew such notation well. Instead, they invented their own way of notating the task. When asked to make sense of another form of notation different from what they had constructed, no one in the nongifted group, whether trained or not, could make sense of notations other than their own. It was as if the internal representation and the notation were locked into one another. In contrast, all but one of the gifted children could easily grasp the alternative notation and were able to rearrange their bells so that the new notation would play the same tune. For instance, those who had used numbers as names for positions were able to make sense of notations in which numbers referred to order of occurrence in the tune.

Thus, musically gifted children have multiple internal representations for the same piece of music. They can move freely from one kind to another, and can easily see one as the other. In contrast, nongifted individuals, irrespective of age and musical training, use a single strategy, and focus consistently on a limited set of musical dimensions.

CAPACITY FOR SUSTAINED CONCENTRATION: SELF-DISCIPLINE AND COMPLIANCE

Discipline from an adult mentor is not all that is necessary for the maturation of early talent. A certain personality structure may also be important (Winn, 1979). Children who are rebellious and independent often react negatively to pressure and refuse to practice. Without regular practice, one does not go on to become a great performer, or indeed, composer. Thus, a certain degree of compliance as a child may be one of the ingredients necessary for musical talent to come to fruition.

Self-discipline and drive are also critical. Musical prodigies are often as hard on themselves as are their parents and teachers. There are anecdotal reports of such children refusing to go to sleep until they have

mastered the passage they have set for themselves that day (Marshall, 1981). Like prodigies in all domains, musical prodigies have an exceptional ability to concentrate in their field of endeavor, and to persist and work hard (Feldman with Goldsmith, 1986). These children usually have an extraordinary amount of energy: one mother of a prodigy recalled that as a baby, her child never needed a nap (Marshall, 1981). Mendelssohn is reported to have thrived on a strict schedule set by his parents which began at 5 a.m., when he and his sister began their studies of music, history, Greek, Latin, science, literature, and drawing (Schonberg, 1970).

Thus, extensive work in childhood seems to one of the necessary ingredients to becoming a great adult musician. Louise Behrend, a music teacher, suggested that this might be why so many great musicians have been Asian or have emerged from the early twentieth-century Jewish population of Odessa, in Russia. Both of these cultural groups are extremely disciplined (Winn, 1979). It is likely that there are children with exceptional giftedness who never develop their talent because they lack this personality factor (whether inborn or a product of culture) of persistence and drive.

THE MUSICAL PRODIGY'S "MIDLIFE CRISIS"

The conflicts induced by Bamberger's (1988) laboratory tasks, described above, are in some ways analogous to the disequilibrium that occurs spontaneously during the adolescence of musical prodigies. At adolescence, musicians become increasingly reflective about their music. One result is that once seamlessly connected dimensions become separated, and effortless performance seems to fall apart. One of Bamberger's (1988) subjects, a 16-year-old performer, said, "It's easy to feel like your playing has gotten worse because now we're listening and hearing so much more" (p. 410).

Bamberger (1982) refers to this crisis as a "midlife" crisis which results, for many prodigies, in the giving up of music. These adolescents go through a period when their musical abilities as performers break down. They report that in childhood they were able to make music spontaneously, but that they have now become self-conscious and have lost the ability to play with the ease of their childhood. Adolescent prodigies' need to reflect about their previously spontaneous music making results in chaos.

The adolescent midlife crisis for the performer is a period of cognitive reorganization. Adolescents cannot return to the nonreflective, spontaneous intuitions of childhood, and must invent new ways of understanding the music they are performing. It is at this point that some prodigies stop making music altogether. These individuals carry with them a strong feeling of having failed, no matter how much success they achieve in other fields in their lifetime (Bamberger, 1982).

The Role of Family and Teachers

While musical giftedness typically displays itself very early, this gift does not mature without strong discipline and formal training. Almost all music prodigies come from musical families (Judd, 1988; Radford, 1990; Scott & Moffett, 1977).

Scheinfeld (1956) found that 75% of fathers, and 50% of the mothers of a group of musicians he studied had some musical talent. A musical environment in the home may be particularly crucial for the development of musical talent. Freeman (1979) presented evidence that the home was more important than the school for musically gifted children: without a supportive home environment, such children often give up a musical instrument.

Music prodigies who continue to perform and compose as adults are nurtured and even pushed by their parents and teachers. The gift is never fully developed when first observed, and must be nourished through daily training. Those who continue with music as adults all report having had at least one parent or teacher who cared deeply about their talent, and who worked with them daily, sitting with them as they practiced and establishing a structure of discipline. Thus, parents play a much more active, interventionist role in the nurturance of musical compared to artistic talent.

The musician studied by Sosniak (1985), for example, had a mother who worked with him twice a day for 15 minutes. Practice was a daily event, rarely forced, but simply expected. The violinist Isaac Stern remarked, "There *has* to be someone pushing, a parent or a teacher. Every one of the kids I've guided has someone like that in their lives, pushing them, sometimes gently, sometimes horribly, sometimes, unfortunately, to the point of driving the child away from music. It's the quality of parental pushing that helps determine the eventual outcome of the prodigy" (Winn, 1979, p. 40).

Correlations Between Musical Ability and Other Abilities

RELATION BETWEEN MUSICAL GIFTEDNESS AND INTELLIGENCE

As with artistic giftedness, musical giftedness appears to have no necessary link to intelligence. Attempts to correlate musical aptitude with measures of general intelligence have yielded positive but low correlations. It appears that once an IQ of about 90 is attained, intelligence is not predictive of musical ability (Shuter-Dyson, 1982).

To be sure, there are many reports of musical individuals possessing a high IQ. E. N. was intellectually advanced for his age. Most of the prodigies studied by Feldman with Goldsmith (1986) showed above average musical skill. And students at the Yehudi Menuhin school of music were shown to have IQs averaging 130, a level well above the average of 100 for the population at large. However, the student at this school with the

lowest IQ, who was quite deficient in both reading and mathematics, was given an award for musicianship (Shuter-Dyson, 1986). Moreover, as in the case of the visual arts, the existence of musical savants with pathologically low IQs demonstrates that high musical aptitude can flourish in the context of a very low IQ.

RELATION BETWEEN MUSICAL GIFTEDNESS AND VISUAL PERCEPTUAL SKILLS

As discussed earlier, artistic giftedness seems to be accompanied by superior visual imagery abilities. These abilities allow skilled manipulation of visual information, whether or not that information is related to the domain of the visual arts. Parallel research on musically gifted children has not been carried out. Thus, for example, it is not known whether such children have superior memory for nonmusical auditory information, suggesting an enhanced general auditory processing skill, rather than one limited to music. However, the fact that superior auditory discrimination skills as measured by the Seashore music tests are not necessarily predictive of musical giftedness (Sloboda, 1985, discussed below) suggests that the auditory processing skills of the musically gifted child may be confined to the domain of music.

Some research has examined the relation of musical ability and visual-spatial perceptual skills. Both adults and children with musical talent have been shown to have enhanced visual-spatial abilities, as measured by such tasks as finding hidden patterns, or combining apparently disconnected visual stimuli into a single image (Barrett & Barker, 1973; Karma, 1979; Hassler, 1990; Hassler, Birbaumer, & Feil, 1985, 1987). These findings suggest that musical and spatial abilities are both made possible by an enhanced right hemisphere. Hassler (1990) also makes the interesting observation that these findings are consistent with a hypothesis put forth by Waterhouse (1988) that special abilities of all kinds involve prodigious ability to store, generate, and manipulate precise visual and auditory images, and to generate and recognize patterns in these images. Waterhouse (1988) notes that musicians, painters and writers have been reported (anecdotally) to possess prodigious memory for both visual and auditory patterns. The extent to which musical and artistic giftedness is supported by an ability to operate on *both* auditory and visual imagery is a fascinating question which calls out for further experimental research.

RELATION BETWEEN MUSICAL GIFTEDNESS AND ANOMALOUS BRAIN DOMINANCE AS INDEXED THROUGH HANDEDNESS

In most people, tonality and pitch are processed in the right hemisphere, although the left hemisphere may be dominant for the processing of rhythm (Gardner, Winner, & Rehak, 1991). Thus, if left-handedness is an index (however crude) of superior right-hemisphere development (Geschwind & Galaburda, 1987), one

might expect a disproportionate number of left-handers among musicians. Such a finding would mirror the findings on handedness and artistic giftedness discussed above.

The picture is complicated in the case of music by evidence that the left hemisphere plays a larger role in musical processing in the case of musically gifted and/or trained individuals (Bever & Chiarello, 1974; Mazziota, Phelps, & Halgran, 1983; Shanon, 1980). However, the evidence is conflicting: Gordon (1970, 1980) found a stronger right-hemisphere advantage for musicians than for non-musicians. Moreover, it is not clear whether the stronger role of the left hemisphere that has been reported is a function of giftedness (and hence is present at birth), or is a function of training, or both. If, as is likely, the left hemisphere takes over as a function of training (as students become more analytic about music), then one might still expect a higher incidence of left-handers among musicians.

Unlike artistic giftedness, musical giftedness does not appear to be correlated with anomalous dominance as indexed through handedness. Oldfield (1971) found that the incidence of mixed- and left-handedness was no higher in musicians than in the population at large. This finding was replicated by Byrne (1974) for left-handedness, but not for mixed-handedness: among a group of instrumentalists, there was a disproportionate number of mixed-handers. However, Byrne (1974) found no difference in musical ability as a function of handedness.

Given that musical performance requires rapid movement and skilled coordination of both hands, it is possible that musicians develop their left hands through constant practice, leading to the finding of a high number of mixed-handers among instrumentalists. Such learning would be consistent with the fact that musicians do not seem to have a tendency to be left-handed, and would suggest no difference in cerebral organization in musicians and non-musicians.

However, there is some intriguing evidence that musicians do indeed have anomalous dominance in the form of more symmetric brains, as predicted by Geschwind and Galaburda (1987). Hassler (1990) found greater right hemisphere involvement in processing of linguistic material in male musicians than in male nonmusicians. Just the opposite result was reported for female musicians, however. Clearly, more research on the relation between musical giftedness, sex, and cerebral organization is needed.

Procedures for Identifying Musically Gifted Children

As in the case of the visual arts, numerous standardized tests of musical aptitude have been developed. These have been used to identify musically gifted children for special programs in music, and for research purposes, to try to identify the components of musical aptitude. These tests are described in detail by Shuter-Dyson and Gabriel (1981).

All of the tests require children to listen and to respond to music, but not to perform music. Each test is made up of subtests which assess particular components of musical ability. The tests differ primarily in terms of which subtests are used, and the age group for which it is appropriate. The two most frequently used tests are the Seashore Measures of Musical Talents (Seashore, 1938; Seashore, Lewis, & Saetvit, 1960) and the Wing Standardized Tests of Musical Intelligence (Wing, 1962). A full discussion of these tests can be found in Sloboda (1985). These tests are designed for children no younger than 8.

In any of the music aptitude tests, subjects typically hear a pair of sounds (e.g., two notes, two chords, two simple melodies), and the task is to indicate whether the two are the same or different, whether one is higher or lower, louder or softer, better or worse, etc. Sloboda (1985) reports that the most common subtest in all the music assessment measures requires subjects to listen to two melodies which differ by one note. The task is to determine whether the two melodies are the same or different, and, if different, to indicate where the different note is.

Tests reflect particular conceptions of musical ability. For instance, the Seashore tests contains a subtest of pitch discrimination and of loudness discrimination which may require finer discriminations than even professional musicians can make. The inclusion of such measures reflected Seashore's (1938) view that such sensory skills were central to musical ability. However, this view has been often challenged, and one might argue that musical expertise has more to do with grasping structure than with making extremely fine discriminations (Sloboda, 1985). For this reason, the Wing test has been argued to be more valid than the Seashore test (Shuter-Dyson & Gabriel, 1981; Sloboda, 1985).

Tests of musical ability, like tests of artistic ability, have never been as widely used as have academic and intelligence tests, probably because there has simply been less teacher demand for such tests. Sloboda (1985) points out that for this reason, there has been much less research into the development of these tests. Hence test results should be used with caution. Moreover, these standardized tests should not be used alone. Indeed, they were designed only as supplements to other records of achievement. When used in this way, these tests can be of some use in detecting musical giftedness at least in the school years, and in selecting students for special music programs. However, as in the case of the visual arts, many teachers admit that the tests are rarely necessary: one can detect a musically gifted child immediately, simply by observing the kinds of signs of musical giftedness detailed earlier in this chapter. For older children, the most commonly used means of identification is not the standardized aptitude test, but the extended audition (a kind of achievement test), combined with an interview (Shuter-Dyson, 1985).

High Musical Ability in Average Children as a Function of Instruction: The Example of Suzuki

The view that only the talented few can benefit from extensive training to become great as adults has been challenged by the Japanese violinist Shinichi Suzuki (1969). Through a carefully designed method, Suzuki has taught thousands of ordinary Japanese children to play the violin in a manner comparable to that of child prodigies. Suzuki's pupils begin their training as early as the age of 2. The first stage of training involves the mothers more than the children. All mothers are given violin lessons, and they practice the violin daily in the presence of the children. The violin is treated as a special object that the children are not yet ready to use or even to touch. As a result, the children naturally begin to yearn to play the violin themselves.

Once it is clear that the children are motivated to begin to play, they are given a small violin and are allowed to begin lessons. Suzuki-trained children are not exposed initially to musical notation, but are taught to play entirely by ear. Constantly exposed to violin music (they carry tape cassettes in their knapsacks), these children learn to play back what they hear on the violin, learning by exposure and imitation, and this only after they have been seduced into wanting to learn.

The results of this training are as astonishing as are the results of the typical Chinese drawing regimen described earlier in this chapter. Suzuki-trained children play complex pieces with exceptional skill at very young ages. Suzuki thus demonstrated that by rigorous training beginning at an early age, average children can perform skillfully in music. But just as most Chinese children trained to draw well do not go on to become artists, so also most Suzuki-trained children do not go on to become musicians. This need not be seen as a failing of the Suzuki method, however. Suzuki feels that the goal of his method is character building through steady work, rather than the creation of future musicians.

"Savant" Musicians

The "savant syndrome," is just as striking in the domain of music as in the visual arts, and provides the strongest evidence for the independence of musical ability from other cognitive and even perceptual skills (Charness, Clifton, & MacDonald, 1988; Hermelin, O'Connor, & Lee, 1987; Lafontaine, 1968; Miller, 1989; Sloboda, Hermelin, & O'Connor, 1985; Treffert, 1989).

Treffert (1989) and Miller (1989) argue that musical savants may be even more common than previously supposed. As is the case with prodigies, the domain in which savants have most frequently been noted is music (Rimland & Hill, 1984). Musical savants are typically retarded and blind, and less typically autistic. Like savants in the visual arts and in all other domains, they also are disproportionately male. However, as Miller (1989) points out, we know nothing about the role of

culture in musical savantism. For example, we do not know whether musical savants emerge in cultures with non-Western scale structures, and if so, whether their pattern of abilities resemble those in Western savants. Thus, the following discussion makes reference only to savants in the Western musical culture.

As with drawing prodigies and savants, musical prodigies and savants resemble each other in their pattern of skills. Like music prodigies, musical savants display signs in early childhood of musical giftedness. In fact, there are no known cases of musical savants whose talent has emerged after early childhood (Miller, 1989). The early signs of talent displayed by savants are identical to the signs shown by musical prodigies. Parents of autistic musical savants have noted that at the age of 1 or 2 their children could sing in perfect pitch and rhythm, and could sing many long and complex songs. These children show an intense interest in and emotional reaction to music at an early age. One child sat rapt, at the age of 3, through a 3 hour opera on TV, yet was unable to sit through one program of Sesame Street, showing extraordinary attentional abilities limited to the domain of music (Rimland, 1978). Another child was unresponsive to his environment but was drawn to music and, like Mozart, was easily disturbed by loud noises (Miller, 1989). These children have been reported to play many songs on the piano in any key by 3, and to pick out melodies on the piano from sonatas they had heard by the age of 4 (Rimland, 1978).

Like musical prodigies, musical savants all possess a phenomenal memory, able to play back faithfully anything they hear. Like artistic savants, musical savants produce works that are highly faithful to the physical stimulus (Rimland & Fein, 1988). The artist savant makes drawings that capture all of the details of the object represented; the music savant reproduces music from memory without missing a note.

Blind Tom, a famous example of a retarded musical savant, possessed a repertoire in memory of over 3000 pieces (Miller, 1989). Also, like musical prodigies (at least E. N.), savants have a memory that is not literal, but is sensitive to the structure of music (Miller, 1989). N. P., a 23-year-old autistic musical savant, was studied by Sloboda et al. (1985) and compared to E. N. and to a professional musician who had not been a prodigy. Like E. N., N. P. recalled familiar, diatonic music better than atonal music, and outperformed the professional musician in recall. However, when the piece was atonal, the professional musician showed better recall than the savant, presumably because he was more familiar with the structure of atonal music. This study provides evidence that the savant's memory for music is not mindless and eidetic: if it were, the savant should have shown superiority of recall regardless of the structure of the music. Musical savants appear to have the same kind of structure-preserving, structure-understanding memory for music as did E. N.

Musical savants more closely resemble their non-pathological counterparts than do savants in other

domains. For example, Miller (1989) contrasts musical savants, who have intact musical skill, to savants in calendar calculation and hyperlexia. Such savants have splinter rather than intact skills: calendar calculators cannot calculate outside of the calendar, and hyperlexics can decode print but cannot extract meaning from large units of texts. It is for this reason that one would not ever consider a calendar calculator to be a mathematician, nor a hyperlexic to be a superior reader (Miller, 1989). And savants in the visual arts are also quite different from their nonpathological counterparts in their lack of interest in the finished product. There are no obvious gaps in what musical savants can do with music. Hence, Miller argues that their music making is essentially indistinguishable from that of prodigies, especially from those with absolute pitch.

However, researchers including Miller (1989) have also pointed out ways in which musical savants differ from prodigies. First of all, unlike musical prodigies, most savants do not come from musical environments (Miller, 1989), suggesting little or no role for an environment which supports and nurtures musical talent.

Second, unlike musical prodigies, all musical savants have displayed their talent through the piano (Miller, 1989). Perhaps this is because the piano is in fact easier to play than wind or string instruments. The piano keyboard maps sound to keys digitally in one to one correspondence, so that one need not learn the subtleties of bowing and fingering required by string and wind instruments.

Third, unlike prodigies, savants all appear to possess perfect pitch (Treffert, 1989). Perhaps perfect pitch is what allows the savant, who lacks other conceptual skills, to grasp musical structure.

Fourth, the creativity of savants is more often limited to transposition and improvisation than to composition (Treffert, 1989), although some instances of genuine musical generativity have been reported by Hermelin et al. (1986). These researchers compared five savants to six children who were proficient on the piano, testing them for musical inventiveness (e.g., composing a new song, creating an accompaniment). On all tests, the savants were superior to the comparison groups. Thus, musical savants are not just extraordinary performers and imitators: they can also generate music, even if they have no "meta-cognitive" awareness of how they compose (Treffert, 1989). Hermelin et al. (1987) argue that, like savant artists who can access a representational store of images, savant musicians can access a representational system of musical rules and structures which enables them to invent music conforming to familiar structures. However, Hermelin et al. (1987) also admit that the musical savant's creativity is more limited than is that of the musical prodigy. Whether this is because creativity is constrained by IQ, or because savants do not experience the world in the same way as "normal" individuals and thus do not experience the full range and subtlety of human emotions, is not known. Certainly it is true that there are no world-class performers or composers who

are savants, suggesting that genuine creative artistry depends on more than an isolated island of skill, no matter how spectacular the skill within that island.

Fifth, it has been argued that savants play in a rigid manner devoid of expression and subtlety (Judd, 1988; Treffert, 1989). Such a position would be consistent with the early view that savants are incapable of abstraction, and are pathologically concrete (Scheerer, Rothman, & Goldstein, 1945). Their music has been called colorless, stereotyped, and mechanical. However, Miller (1989) strongly rejects the claim that savant musical performance is rote and without interpretation or comprehension. Instead, he argues that savants have much in common with normal musicians: they have strong emotional reactions to the music they play, they take delight in playing, and they have clear preferences for certain types of music over others. Finally, savants also differ from prodigies in that they do not reflect about their music (although Miller (1989) cautions that this could be due to limited language skills). Nonetheless, savant music has a nonreflective character to it, as shown in the speed of their responses to experimental tasks (Miller, 1989).

As in the case of savants in the visual arts, the existence of musical savants can be accounted for by Geschwind and Galaburda's (1987) theory of the pathology of superiority. As discussed earlier, research on normal subjects has shown that music is processed in the right hemisphere in musically naive individuals but that musically trained people, who use analytic strategies, may also use their left hemisphere for music (Bever & Chiarello, 1974; Mazziotta et al., 1983). Treffert argues that musical savants are probably using a nonanalytic, and hence right-hemisphere strategy when they play music. They typically play by ear, and are nonreflective about their music.

The fact that so many musical savants are blind is intriguing. One suggestion put forth by Treffert (1989) is that blindness may leave neurons to be recruited for other talents (much as deafness frees cells for visual purposes) (Neville, 1991). Such a suggestion would be entirely compatible with the pathology of superiority explanation. However, although the association of blindness, retardation, and savantism is too regular not to be causally connected, we do not yet know what the underlying cause is.

Children trained to draw in China, and Suzuki-trained violinists, can be seen as the mirror image of artistic and musical savants. On the surface, all three groups of children demonstrate exceptionally high ability. But for the Chinese-trained child artists and the Suzuki-trained child violinists, the ability displayed is simply the result of rigorous and early training which emerges despite lack of exceptional inborn talent. For the savants, the ability displayed is the result of exceptional inborn talent which emerges *despite* lack of training. In neither the "average-highly-trained" group, nor the savant group, do we find a population of future geniuses who will transform their respective fields. These are not the

children who become Picassos and Mozarts. Perhaps the genius of an adult Picasso or Mozart is the result of a blend of the inborn giftedness of the savant *without* the savant's pathology, along with the rigorous training of the Chinese drawers and Suzuki violinists.

Relation Between Early Musical Giftedness and Adult Musicianship

Great music is of course not only formally complex but also emotionally expressive. In this way, music and the visual arts stand apart from the two other domains in which one finds child prodigies: mathematics and chess. Because the domain of music is so complex and formally structured, the danger for child prodigies in music is that they may acquire skill without emotional depth. Emotional depth can only come with experience, and thus cannot be found in even the most prodigious child genius. The violin teacher, Dorothy Delay, demythologized the child prodigy by insisting: "Children are *never that good*. No matter what you say, a child can never play the way a 45-year-old musician can" (Winn, 1979, p. 41). Nonetheless, Revesz (1925) insisted that E. N. was not just a technical virtuoso as a child, but also played with expression and interpretation, and was able to criticize others' performances in terms of the performer's interpretation of the music played. Radford (1990, p. 102) notes the performance of Corey Cerovsek who at 14 was described by his conductor, Rudolf Barshai in these words: "His imagination is like an adult's. His style is that of an experienced artist." But, as Radford (1990) points out, it is deemed unusual for a prodigy to show such depth of feeling and understanding of the music he/she performs.

Children who go on to become adult musicians typically begin to connect to music in an emotional way during late childhood. If this does not happen, the child may stop playing. Isaac Stern explained, "The child must become possessed by music . . . It can happen at any time between the ages of 10 or so and 14. Suddenly the child begins to sense something happening and he really begins to work . . . At this point the prodigy begins to flower. It happened to me when I was 11." And the violinist Nathan Milstein stated, "I didn't like to play the violin when I was a child. I didn't love music. Few children do. But suddenly I changed because I started to love what I play, not just the playing" (Winn, 1979, pp. 40-41).

This deep emotional involvement in music seems to emerge around adolescence. At this age, musical prodigies go through a period of transition, a shift from precocity to more mature artistry. Here, according to Menuhin, is where many flounder, unable to make the bridge between sheer mechanical skill and personal, expressive style (Winn, 1979). It is at this age that Bamberger (1982) notes that a "midlife" crisis occurs (as discussed above), as adolescent prodigies begin to ask themselves why they are so involved in music,

whether they are simply fulfilling their parents' dreams, or whether this is what they themselves want to do.

This same adolescent transition from precocity to mature artistry was also discussed above in relation to the visual arts, when children begin to find their own personal voice (Gardner, 1980; Gordon, 1987). It is not until adolescence that children are able to express deep emotions in their art or music.

Conclusions

Children who are gifted in art or music do not necessarily become adult artists, musicians, or composers. In fact, most probably do not. When discussing artistically gifted children, the art historian Hartlaub commented that the promise of these "over-potential years of childhood is almost never fulfilled in adulthood" (Lark Horowitz et al., 1973, p. 190). As Bamberger (1982) points out, prodigies experience a "midlife" crisis at adolescence, at which point many give up working in their domain of gift altogether.

Even among those who weather this crisis and do not drop out, most do not become known as creative geniuses. This is not surprising, as there is no direct route from precocity to inventiveness. But of course a few prodigies do go on to change their respective domains. These are the ones who earn the epithet "creative" or even "creative genius." These are the individuals who, at adolescence or early adulthood, take a new stance. They begin to take risks; they challenge the establishment (Gardner, 1993).

In a study of seven creative geniuses, Gardner (1993) suggests that a certain degree of tension, or "asynchrony" is required for a prodigy to grow into an adult artist or musician/composer who would be classified as creative, or even as a genius. Gardner (in press) argues that creative geniuses differ from prodigies in how well the individual synchronizes with his or her domain as it currently operates within the society. The prodigy typically exhibits talents that fit well with a domain that is recognized by the society as important, and the skills of the prodigy are thus instantly recognized. In contrast, the creative genius often initially exhibits talents that do not fully fit within the domain in which the individual works, and which do not fit with the established tastes of the field (e.g., critics, gallery owners, conductors).

Of course, some individuals, such as Mozart, are initially child prodigies and later go on to become adults who transform their fields. As a prodigy, Mozart pleased the establishment. But it is only because of his later behavior, when he began to write music that was considered shocking, and which broke with established convention, that we now consider him to be a creative genius. The creative artist/musician takes risks, and breaks with conventions. The gifted child, or the child prodigy, does not. As Hurwitz (1983) points

out, gifted children have invested a great deal of energy in mastering a set of skills, and are often unwilling, or even unable, to experiment in the way that one must do in order to be creative.

Gardner's (1993) notion of "fruitful asynchrony" is compatible with Getzels and Csikszentmihalyi's (1976) notion of problem finding. In a study of art students, Getzels and Csikszentmihalyi (1976) found that the art students who went on to become recognized as creative artists did not differ from their art student peers in technical skill. Where they stood out was in their tendency and ability to find challenging problems. This problem finding mentality is reminiscent of Picasso, who delighted in posing difficulties for himself which he could then go on to solve (Richardson, 1991). Even as a child, he fought against what came naturally, insisting on setting up difficult drawing challenges for himself such as beginning a drawing from an odd starting point, or drawing a profile facing right when the opposite orientation is more natural for a right-hander (Richardson, 1991).

Sheer hard work also plays a role in determining whether a prodigy becomes a creative adult artist or musician or composer. The personality characteristics associated with success in any field may be drive, tenacity, and the willingness to overcome obstacles (Gardner, 1980, 1993). "I believe in nothing but work," said Picasso, who had tremendous energy and drive (Richardson, 1991, p.48).

Finally, historical and socio-cultural factors determine who becomes classified as an adult creator or genius. No individual or artistic work is inherently creative or not. Instead, creativity is an emergent property formed by an interaction among the individual's gift, the state of the domain at the time when the individual begins to exhibit talent, and the tastes and judgments of the field (e.g., critics, curators, publishers) (Csikszentmihalyi, 1988; Gardner, 1993 in press; Gardner & Wolf, 1988). There is a fair amount of serendipity involved in determining whether giftedness grows into creative genius. One needs, quite simply, to be born at the right time, at a time when the field is ready to recognize one's talents.

Introduction

Approaches to Identifying Early Indicators of High Ability

One of the first complex studies designed to determine indicators of intellectual giftedness was carried out by Terman (1925) and his colleagues. The longitudinal investigation beginning in 1920 included 1528 school children having an IQ of 135 or above. Although one may criticize the Terman study for its lack of a control group, the selection procedure, and other reasons (e.g., Rost, 1993), the researchers did determine—retrospectively—several differences between their more gifted and less gifted children. The more gifted children were able to walk about one month earlier and their language development began about 3.5 months earlier than the less gifted children. In addition, approximately 50% of the children studied could read before entering school. Parental interviews suggested that these children could be characterized by rapid comprehension, insatiable curiosity, familiarity with things, excellent memories, large vocabularies, and an unusual interest in numerical relationships (Terman & Oden, 1947).

Following in the footsteps of Terman, giftedness researchers attempted to identify indicators which predict excellent performance in school or even in later life. In considering the promise of development, researchers have primarily worked on the following areas: sleep, habituation, memory, concentration or attention, information processing, and accelerated development in individual areas, etc. Most of the research was done in a retrospective way, i.e., questionnaires with possible indicators were given to the parents of gifted children and youth asking about interesting aspects of the (early) development. On the basis of these,

behavioral checklists (e.g., Renzulli & Hartman, 1971) were then constructed for early identification of gifted or promising children. This retrospective approach seems very problematic to us. A second unsatisfactory aspect is that the samples were frequently recruited in counseling centers.

When faced with the problem of identifying and fostering infant or early development of high ability today, it is apparent that the traditional approach of identification has become increasingly questionable. Tannenbaum (1992), for example, compared different studies of child prodigies. He demonstrated that the hope placed in such children by researchers, teachers, and/or parents was frequently misplaced. Feldman (1986) reported that six infant prodigies he had selected for their talents in chess, music, mathematics, painting, and omnibus abilities disappointed his expectations as early as school age. Only one of the six prodigies developed in a more or less continuous way. There is little evidence that an early unfolding of intellectual potential will lead to extreme giftedness in one or more areas as adults. In truth, the little research available on infant prodigies raises more questions than it answers.

As far as possible, this contribution will emphasize a developmental or prospective perspective. It will not take a retrospective approach about the developmental relevancy of cognitive abilities and personality traits of infant prodigies. Crook and Eliot (1980) showed that predictions of this sort are often faulty. A more fruitful approach is to prospectively examine indicators which can be used to predict the developmental course of gifted individuals. As Nancy Robinson (Chapter 27 in this volume) so aptly points out, however, the emphasis in literature on early development has been on central trends or on children with developmental problems. Therefore we have to include cross-sectional studies, too.

We will attempt to provide a concrete practical orientation in this chapter, focusing on indicators of high ability. We will begin with definitions of high ability as a theoretical framework for the chapter. Following the description of three approaches to defining high ability, we will focus on selected sets of indicators which are frequently cited in the literature: general psychometric measures, more or less stable components of the cognitive apparatus, including motivational characteristics, and also early expertise in selected fields of achievement. Following a discussion of psychometric instruments used with young gifted children, the following components of high ability will be reviewed: attention and habituation, memory capacity and durability, memory efficiency, sleep, knowledge base and strategies, strategy use, metacognition and executive control, causal attribution, and curiosity and interests. Later, indicators to do with specific areas of achievement such as language, numerical/mathematical expertise, or (precocious) reading and writing will be summarized. Finally, socialization variables influencing development of high ability will be discussed, primarily the question how certain social conditions, especially caretaker-child interactions can effect a child, fostering exceptional learning and cognitive abilities. Finally, the practical applications of the findings, as well as ages and domains where they are appropriate will be discussed. Related problems in the interaction of promise of development and its fulfillment will also be addressed.

The careful reader may notice that the majority of the research cited in this chapter stems from English-speaking countries or at least from research published in English. Obviously it is difficult to review books and journals from countries where you do not understand the language. But another reason for this is the lack of empirical research or at least the lack of data-based publications on early indicators of giftedness in wide parts of the world. The Soviet researcher Leites (1990), for example, does not refer to empirical research. The Munich-Moscow Study of Giftedness, conducted in 1990-1993, is the first empirical giftedness study in Russia which covers different areas of giftedness and achievement (Averina, Scheblanova, & Perleth, 1991). The German authors Stapf and Stapf (1988) or Urban (1992) do not provide the reader with evidence from empirical data (empirical data for German gifted children are available from the Munich Longitudinal Study of Giftedness conducted by Heller and associates, the Marburg Study of Giftedness conducted by Rost and coworkers, or Trost's study; none of these studies, however, cover the preschool age; see Heller, 1991b; Perleth & Heller, 1993; Rost, 1993; Trost, Chapter 17 in this volume). A Chinese group from the Institute of Psychology of the Academia Sinica conducted studies in gifted children including preschoolers. However, a Chinese publication from this group (Zha, 1990) does not include statistical results on the quality of early indicators of giftedness apart from the finding that the

gifted children outperform average ones in cognitive variables.

Early Identification and Early Nurturance of Highly Able Children

When considering early identification of children with intellectual gifts and talents, one question should always be asked: Is it necessary to identify such children before school age, or as some research (e.g. habituation and sleep studies) indicates as early as infancy? Here we are faced with a general problem of diagnosis. We must consider our objectives when determining and defining indicators of high ability. Obviously, during the preschool years, the primary goal should be the guarantee of optimal child development. Decisions about the nurturance of giftedness should be based on adequate diagnostic information about the status and prediction of personality development. Otherwise, talent development in a broader sense is unfeasible. Early developmental predictions are indispensable for educators dealing with preschool children as well as aiding the child psychologist. Some researchers (e.g., Clarke, 1984) assert that predictions about development made prior to the age of 4 are too unreliable and should not be made. However, the predictive potential also depends upon the level at which the ability was assessed (cf. Casey & Quisenberry, 1982; Sattler, 1988). In prospective longitudinal studies (Crook & Eliot, 1980), children rated as mentally retarded frequently showed spontaneous remissions or positive developmental trends. On the other hand, there is also evidence for unvarying problematic developmental courses (Weinert, 1984), supporting the position that reliable indicators are hard to find at an early age. In contrast, predictions of higher intellectual functioning of groups of children are more reliable and stable (Humphreys & Davey, 1988) although this finding is somehow trivial from the statistical point of view.

Clearly, however, the identification of high ability should be linked to specific suggestions for creating optimal learning conditions. By steadily enriching knowledge, nurturing strategies, and motivation in social interactions, we can hope to aid in making "temporary" developmental advantages permanent.

Models of High Ability

In this chapter, our understanding of high ability or giftedness are those capacities and competencies found in the infant and child which are relevant for academic learning processes. We, therefore, do not subsume constructs such as musical or psychomotor giftedness under the term high ability, but view this, as Campione, Brown, and Ferrara (1982) expressed, as: "the ability to perform well in schoollike and testlike situations"

(p. 392). In the following, we will therefore only deal with a segment of that which makes up modern conceptions of giftedness (e.g., Tannenbaum, 1983; Gardner, 1983; Perleth, Sierwald, & Heller, 1993).

Traditional Psychometric Approaches

Traditional approaches to intelligence and giftedness continue to play the most important role in the research about and fostering of gifted children. These include psychometric measures, especially intelligence tests, which are the most often employed instruments for identifying gifted children in research and everyday practice. The most widespread tests are—with very few exceptions, e.g. the German Rasch-scaled test for “Adaptive Intelligence Diagnosis” by Kubinger and Wurst (1988)—based on formulae of classical test theory (e.g., Lord & Novick, 1974).

The background of these aptitude tests are Spearman’s (1904, 1927) theory of general intelligence, Thurstone’s (1931, 1938) theory of multiple intelligence factors, or Cattell’s (1957, 1963, 1965) two-factor theory of intelligence. Broadly applied tests related more or less to these theories (in many cases no explicit reference to a special theory of intelligence is made) are the Stanford-Binet (Thorndike, Hagen, & Sattler, 1986), the Wechsler tests (WPPSI and WISC; Wechsler, 1974, 1989), Raven’s Progressive Matrices (1983, 1986), etc. The Cognitive Abilities Test by Thorndike and Hagen (1987) is an example related to the theory of multiple intelligence. In addition, tests of specific abilities such as the Peabody Picture Vocabulary Test (Dunn & Dunn, 1981) are in use, and, in very young infants, developmental tests like the Bayley Scales of Infant Development (Bayley, 1969) are employed for the assessment of aspects of (cognitive) development.

Information Processing Approaches

In the framework of psychometric intelligence theories, primarily the relationship of various dimensions of intelligence as well as the concurrent and predictive validity of the tests is important. On the other hand, information processing or cognitive approaches aim at identifying and analyzing the components and processes which interact when cognitive tasks are solved (Pellegrino & Glaser, 1979; Waldmann & Weinert, 1990).

Frequently cited cognitive or information processing models of intelligence are those of Sternberg (see Chapters 8 and 12 of this volume) and Campione and Brown (1978; see also Borkowski & Peck, 1986) or Campione et al. (1982). Whereas Sternberg’s model certainly initiated fruitful research in the area of giftedness (Shore & Dover, 1987), the Campione and Brown model seems useful for classifying some often cited early indicators of giftedness, despite the fact that this model was originally derived from research with retarded children.

In the Campione and Brown model (1978; see also Campione et al., 1982; Borkowski & Peck, 1986) the “architectural” level, i.e., the “hardware” of the cognitive apparatus, comprises a three-storage space memory model (sensory register, short-term memory STM, long-term memory LTM; for summary see Wessells, 1984). The characteristics of these entities, i.e., their capacity, duration, and efficiency, do not underlay developmental processes. Therefore, they are neither changeable nor trainable. Under the term capacity, Campione and Brown (1978) understand the number of entities that can be stored in the STM or LTM.

The speed of information processing and retrieval represents the operative efficiency of the system. While capacity and duration are—according to the authors—not related to intelligence, the efficiency is regarded by Campione et al. (1982) as a determinant of intelligent behavior. Other authors (e.g., Jensen, 1969) put this speed of information processing in the center of their theoretical conceptions of intelligence. These and similar conceptions of intelligence refer directly to the unchangeable hardware properties of the cognitive apparatus.

The higher “executive” system in Campione and Brown (1978) is made up of the following components: (a) The knowledge base in which the whole world knowledge of the child is organized and represented, whereby the knowledge can be regarded both as a symptom and as a determinant of extraordinary achievement. Further components represent (b) rules and strategies and (c) metacognition/metamemory (knowledge about strategies, knowledge about the task, knowledge about characteristics of one’s own cognitive apparatus) and executive metacognitive control processes. The latter are used as metacognitive components in the regulation in memory tasks (see also Borkowski & Peck, 1986), processes of comprehension, or in problem solving. These components of the executive level which are considered, for example, to strongly influence memory performance, underlay “dramatic development” processes (Campione & Brown, 1978, p. 284), and can also be improved by training measures.

Borkowski (1985) modified Campione and Brown’s (1978) classification of the components of the executive system. He distinguishes (a) the knowledge base which contains the (declarative) world knowledge as well as (procedural) strategies, (b) schemas in the sense of Piaget, (c) control processes in the sense of Brown (1978, 1984), and (d) metacognitive knowledge in the sense of Flavell and Wellman (1977) or Flavell (1984). In many studies, however, the differentiation between metacognitive knowledge and control processes is problematic; the latter is very difficult to assess in any case.

Training was put in the center of the discussion by Campione and Brown (1978) or Campione et al. (1982). According to these authors, intelligence can be simply defined “in terms of speed of learning and/or breadth of transfer” (Campione et al., 1982, p. 436). In this context, concepts such as the learning potential (e.g., Feuerstein,

1980) or the zone of proximal development in the sense of Vygotsky (e.g., Day, 1983) have to be discussed (see also Guthke, 1974, 1992).

A second information processing model which seems to us to be appropriate for promoting research in gifted children is the comprehensive "Good Strategy User Model" (e.g., Pressley, Borkowski, & Schneider, 1987; Schneider & Pressley, 1989). In this model, task-specific and task-related strategies make up a fundamental part (for example, memory strategies like clustering, rehearsal, or the use of mnemonics). Good strategy users have huge metacognitive knowledge reserves about the rules of these specific strategies. In comparison with average learners, good strategy users also know about general strategies which support the efficient use of cognitive strategies. By this, the authors mean, for example, processes for directing one's attention, processes for examining how successful a strategy was in task solving, or simply the knowledge that strategy use is profitable and one must exert oneself in order to be successful.

The non-strategic knowledge base which includes the child's whole world knowledge is regarded as an element of major importance in the Good Strategy User Model. Along the lines of Pressley et al. (1987), broad world knowledge, in particular, enables the child to detect similarities between different tasks; this can be regarded as an essential prerequisite for strategy transfer to new task contexts (Schneider, 1989). Other determining parts of the Good Strategy User Model are work styles (reflexivity, impulsivity, anxiety) and motivational variables (self-concept, causal attribution). All these components interact with each other.

Achievement Oriented Approaches

A third approach for investigating gifted children is represented by the expert–novice approach (see Schneider, Chapter 16, this volume, who summarizes theories of acquisition of expertise and reports on experimental findings). In this research paradigm, the special abilities or skills of young experts, prodigies, or precocious children are investigated. Fields of interest for research on the gifted are early reading/writing, mathematics, music and arts (see Winner, Chapter 14, this volume), and so on. As many areas of infant and child expertise are covered by other chapters in this volume, we will concentrate on the promise of early reading and writing, precocious language development, as well as of extraordinary mathematical skills.

Methodologically, research using this approach compares young experts in a specific domain with average children who do not possess the skills under investigation, or to a lesser extent. One research question is to analyze what precocious children do when solving tasks, so that aspects of the cognitive component and the cognitive correlates approach are touched upon. The other question is whether intellectually precocious

children will maintain their advantage in later school years so that these extraordinary skills can be used as early indicators of high ability.

Identifying Young Gifted Using Psychometric Methods

Psychometric instruments for the assessment of high ability or rather intelligence are broadly used in research and practical attempts at identifying and nurturing gifted children. Nevertheless the psychometric approach in identifying the young gifted is crucial: We know from research with "normal" samples that we cannot assume either high reliability of intelligence tests nor stability of measured traits in preschool children (see Sattler, 1988, for a comprehensive review). The following short descriptions of different tests focus on test properties which are most important for identification of gifted children: above all reliability, norms, and predictive validity. Especially with regard to the latter, we have to face the fact that nearly no longitudinal studies have been conducted which followed preschool and early elementary school children for a minimum of several years to analyze possible indicators and determinants of giftedness and achievement. The volume by Subotnik and Arnold (1993) on newer longitudinal studies of giftedness, for example, lists only three projects which investigated the development of giftedness in young children (younger than 8 or 9 years); one of these is limited to the musical domain, a second to the evaluation of a gifted program, and only the third one covered a broad area of giftedness factors and achievement areas (Perleth & Heller, 1993).

Tests of "General" Intelligence

Although newer conceptions of giftedness or intelligence more frequently make use of multidimensional models, the tests generally used in the identification of gifted children represent measures of general intelligence subsuming verbal, mathematical, figural, memory, and other tasks in one or few global scores. While such a procedure can be criticized when applied to youth and adolescents, it can be considered less problematic in young children because factor analytic research seems to show that the structure of intelligence becomes more differentiated with increasing age. Therefore, multidimensional tests such as the Cognitive Abilities Test series (Thorndike & Hagen, 1987; German version: Heller & Geisler, 1983) also offer only a global intelligence score for young children. In the following we provide an overview of the intelligence tests most frequently used with young gifted children including information available on their reliability and predictive validity in this population. See Sattler (1988) for a comprehensive critical overview of intelligence tests

available in English-speaking countries (also Feldhusen & Jarwan, Chapter 13, this volume).

STANFORD-BINET INTELLIGENCE SCALE

The Stanford-Binet Intelligence Scale: Fourth Edition (SB:FE) by Thorndike et al. (1986) is the current version of the Stanford-Binet intelligence test originally developed by Terman on the basis of Binet and Simon's scale (see Binet, 1905). The SB:FE is the successor of the 1960 Stanford-Binet: Form L-M (SB:L-M) for which new norms were published in 1973 by Thorndike. These 1973 norms were used for much of the research reported in this chapter. According to the very informative manual by Thorndike et al. (1986), the new SB:FE provides the examiner with an overall score for general intelligence which is composed of three dimensions measuring crystallized abilities, fluid abilities, and short-term memory. The crystallized abilities contain two scales for verbal and quantitative reasoning, while fluid abilities are made up of items of abstract/visual reasoning. The test can be used with children from the age of 2 years.

Since Terman (1925) used the Stanford-Binet (SB) in his classical giftedness study, the SB is still very popular in the field of giftedness research and practice. Many authors stress that the SB differentiates better in the extremely high range of intelligence. This additional advantage could be concluded from the fact that the norm tables provide values up to IQ 170 (e.g., Freeman, 1979). In our view, this is too optimistic for the following reasons. First, the standard deviation (*SD*) of the SB is 16 so that in comparison with the "normal" IQ-scale (mean: $M = 100$, $SD = 15$) the SB provides slightly higher values. A SB-IQ of 130, for example, is equivalent to an IQ of 128 measured by a Wechsler test (see next paragraph). Second, the standardization samples of the older version SB:L-M as well as the current SB:FE are much too small to calculate IQ scores above 130 (see below).

To judge the predictive validity of the SB for gifted children, the classical study by Terman and Oden (1959) is often cited. These authors discovered a good concordance between childhood and adult IQ scores. Interpreting this, however, you must take into account that Terman (1925) did not begin his study solely with young children but with 4- to 14-year-olds (median between 9 and 10). Kangas and Bradway (1971) report for the preschoolers of the 1937 standardization sample of the SB correlations of $r = .59$ and $r = .41$ with SB-scores measured 25 ($N = 109$) and 38 years ($N = 48$) later.

Willerman and Fiedler (1974, 1977) analyzed children from the Collaborative Perinatal Study in which Boston children born between 1958 and 1966 were included. These children were given the Bayley Scales of Mental Development at age of 8 months, the SB at 4 years, and the WISC (see below) at age of 7. In Willerman and Fiedler's (1977) sample of gifted children only a correlation of $r = .33$ was found between the SB and the

WISC full scale, and even lower relationships between the SB at 4 years and the scores of an achievement test at age of 7. The general decrease in the intelligence scores from age 4 to 7 can be explained by the non-equivalent norms of the SB L-M and the WISC. Interpreting the low correlations, one should remember that Willerman and Fiedler (1977) did their research on a sample with gifted children only. Thus, the reduced variances of tests and criterion variables might be regarded as one cause for the weak relationship.

Robinson (1987) reported a retest correlation of $r = .75$ for gifted preschoolers assessed at age 2 and 6 ($N = 16$), $r = .59$ between children of age 3 and 6 ($N = 117$), $r = .61$ between age 4 and 6 ($N = 74$), and $r = .71$ between age 5 and 6 ($N = 25$). Although Robinson (1987) judges these results as "relatively low" (p. 162), they show in our opinion that intelligence as measured by the SB is a relatively stable trait even in the preschool age.

Shapiro, Palmer, Antell, Bilker, Ross, and Capute (1989) tried to predict WISC-R IQs measured at age 7½ (a sample of 200 children containing 36 gifted) with developmental indicators assessed at 7–12 months and SB:L-M scores evaluated at 3 years. While the correlation between the SB-scores and the WISC-R were medium at least for the WISC-R full-scale ($r = .53$), it was not possible to predict giftedness at age of 7½ with the SB in a discriminant analysis. The results were not better for the other indicators in the study. The authors conclude that "the expectation for precocious infants to become precocious children, while appealing, is not supportable" (Shapiro et al., 1989, p. 209).

Sometimes short-form versions of the SB as, for example, the Slosson Intelligence Test (Slosson, 1961, 1981; the test also includes some items from other tests) are used. In some studies these forms turned out to perhaps be appropriate for screening purposes (e.g., Tomsik & Rankin, 1985, who compared selection effects of the 1961 and 1981 restandardized versions; McCallum & Karnes, 1990, who found good concordance between the complete and brief form of the SB:FE) while other authors judge the Slosson as improper for that purpose (e.g., Bondy, Constantino, Norcross, & Sheslow, 1984). Hagen (1989) argued that it is, especially in primary school children, preferable to use a standardized group test for screening instead of short versions of individual tests with unknown statistical properties (although Thorndike et al., 1986, recommend several brief forms in the SB:FE manual).

WECHSLER INTELLIGENCE SCALE

The Wechsler Preschool and Primary Scale of Intelligence (WPPSI) (Wechsler, 1967; the revised WPPSI-R was published in 1989) and the Wechsler Intelligence Scale for Children—revised (WISC—R) (Wechsler, 1974) are the second most widely used intelligence tests in gifted children following the Stanford-Binet. The tests measure "the aggregate or global capacity of the individual to act purposefully, to think rationally

and to deal effectively with his environment" (Wechsler, 1958, p. 7). In consequence, the most frequently used indicators derived from the tests are the total score and the global scores for the verbal and performance scale. Although there have been some studies of the factor structure of the test (see Sattler, 1988, for a comprehensive overview), alternative scores or the profile are seldomly used for scientific or practical purposes.

As in the Stanford-Binet, the Wechsler scales have been shown to be sufficiently reliable and valid for the assessment of general intelligence. A problem, however, might be the fact that the norms of the WISC-R and the old WPPSI (about 200 children in each age group) are rather old, although the mean IQ scores of the new SB:FE composite IQ scores is only a little lower than those of the WPPSI full scale (difference: 5 points; verbal scales of both tests differ only by 0.5 points) or those of the WISC-R full scale (difference: 2.8 points; verbal scales of both tests differ only by 1.6 points) (Thorndike et al., 1986). Schneider and Gervais (1991) argue that the WPPSI-R is more realistic in identifying gifted children than the WPPSI.

A major problem in using the Wechsler test for studying gifted young children occurs when longitudinal research is planned. The WPPSI(-R) covers an age range from about 4-6;6 years while the WISC(-R) is constructed for 6-16;6-year-olds. As the WPPSI(-R) does not contain all subtests of the WISC(-R) and the two tests overlap only for the 6-month period between 6 and 6;6 years, it is problematic to switch between the two tests. Sattler (1988) questions the general interchangeability of both scales. In addition, over ten years lay between the gathering of the norms of the WISC-R and the WPPSI-R.

Hawthorne, Speer, and Buccellato (1983) judge the WPPSI as not appropriate for the identification of gifted children because of ceiling effects in nearly all subtests. In half of the subtests, the criterion to discontinue the test was not reached at all for two-thirds of the children with an IQ above 120. Woo-Sam and Zimmerman (1973) remarked that the WPPSI should not be abbreviated because the individual differences between full-scale score and short form are too large, although abbreviation formulae might work properly for group means.

As mentioned above, Schneider and Gervais (1991) examined the possibility of identifying gifted kindergarten children with the WPPSI-R as an individual test following two short screening tests. The results of the study indicate, as interpreted by the authors, that this procedure is useful as a part of a multimethod identification approach but that it should not be the only method for identifying young gifted children.

From their factor analytical findings, Schneider and Gervais (1991) conclude that the verbal and nonverbal part of the WPPSI-R should be considered separately. A similar suggestion is made by Brown and Yakimowski (1987) for the WISC-R although their method of using

the factor analyzed WISC-R results for the definition of the giftedness groups are highly problematic.

Tests of Specific Abilities

MCCARTHY SCALES OF CHILDREN'S ABILITIES

The McCarthy Scales of Children's Abilities (McCarthy, 1972) are individually administered intelligence tests for children from 2;6 to 8;6. They provide information about verbal abilities, nonverbal reasoning abilities, number aptitude, short-term memory, and coordination. Norms for a composite score as a measure for the so-called General Cognitive Index of the test person are also available. The fact that the standardization samples of the age groups contain only 100 children each, however, limits the differentiating power of the test in the upper (and lower) range of intelligence, although reliability and validity of the test can be judged positively.

KAUFMAN ASSESSMENT BATTERY FOR CHILDREN

The Kaufman Assessment Battery for Children (K-ABC) (Kaufman & Kaufman, 1983) can be used with children from 2;6 to 12;6. The four scales available give information on the sequential and simultaneous information processing, the child's factual knowledge and skills (so-called Achievement Scale), and nonverbal reasoning abilities (score composed of subtests from the sequential and simultaneous processing scales). The K-ABC was normed with 200-300 children for each age group. The reliability of the test is as sufficient as those for the SB or WPPSI/WISC-R, the validity with regard to the underlying information processing model of intelligence seems unclear (see Sattler, 1988, for a critical review of the test).

Swanson, Brandenburg-Ayres, and Wallace (1989) investigated the construct validity of the K-ABC in children from gifted classes ($N = 169$). They found a factor structure of the test which differs from the one reported for normal children in the manual. In the sample of Swanson et al. (1989) a hierarchical model was established by exploratory factor analysis. The model subsumed a verbal memory, nonverbal memory and nonverbal reasoning factor under a (weak) factor of general intelligence. Therefore, the usual K-ABC factor structure supporting the model of simultaneous and sequential processing was not confirmed for gifted children. From the methodological point of view, however, it has to be stated that the intercorrelations between the K-ABC subtests were very low (with the exception of one correlation all coefficients were between $-.18$ and $.22$).

With respect to the test fairness of the K-ABC, Nolan, Watlington, and Willson (1989) could not find indications of a systematic bias in the K-ABC items against

gender and race (black and white children) in gifted and nongifted children (using the standardization sample of the test). This confirms the results of McCallum, Karnes, and Edwards (1984) who found hints that the K-ABC is more suited for the identification of minority children than the WISC-R or the SB.

TESTS OF NONVERBAL REASONING ABILITIES

The Progressive Matrices (Raven, Court, & Raven, 1983, 1986) measure nonverbal reasoning abilities (inductive reasoning) without verbal, quantitative, or memory aspects. Therefore they are sometimes classified as tests for general intelligence in the sense of Spearman (Heller & Perleth, 1991). The Colored and Standard Progressive Matrices are available for the purpose of assessing intelligence in gifted young children. They cover an age range of 5–11 and 6–17 years, respectively. The fact that there are no verbal items makes the tests attractive for the assessment of children from minority groups or risk groups (e.g., foreign children, children from underprivileged families and so on). Götzlü (1986) showed that for Turkish children living in Germany, the language of instruction, the language of the test instruction (German and Turkish), and the children's knowledge of each of the languages do not produce significant interaction effects on the test scores in this type of test.

PEABODY PICTURE VOCABULARY TEST

The Peabody Picture Vocabulary Test—revised (Dunn & Dunn, 1981) is—in spite of its exclusively verbal character—sometimes used as a screening test for the selection of gifted children (see Hayes & Martin, 1986). Norms (based on 200 children in each age group) are available from 2½ years on to adulthood. Sattler (1988) judges the reliability and validity as sufficient, but warns, however, against the use of the PPVT-R as a “screening device for measuring intellectual level of functioning” (p. 350). Bracken, Prasse, and McCallum (1984) give an overview of research available on the PPVT-R.

Similar to Hayes and Martin (1986), Tarnowski and Kelly (1987) doubt the effectiveness of the PPVT-R as a screening instrument with the SB as the criterion for intelligence. In both articles the authors state that there are many misclassifications especially in the upper range of intelligence. Whereas we would warn against using the PPVT-R as a (screening) instrument for identifying gifted children, we would not do this on the basis of the data from the two studies (as the norms of the SB L-M provide inflated IQ-scores), but we would deduce this from the exclusively verbal character of the test.

Developmental Tests

As the intelligence scales described above are not available for very young infants, developmental scales such as the Bayley Scales of Infant Development (Bayley, 1969)

are sometimes used for the estimation of the cognitive level of gifted children. The Bayley Scales, from which an index for mental development can be derived, for example, can be applied from 2 months to 2½ years of age. In this age, however, the course of development is inter- and intraindividually very unstable—and thus the use of these scales is questionable for the detection of early signs of giftedness.

Willerman and Fiedler (1974) found no significant and substantial correlations between Bayley results gained with 8-month-old children and the SB-IQ assessed when the children were 4 years old. Following the sample further on, Willerman and Fiedler (1977) report that the Bayley results, in consequence, did not show any relationship to WISC-IQ scores measured in the children of the sample when they were 7 years old.

The above-cited longitudinal study of Shapiro et al. (1989) started with recording of developmental milestones in newborn children. At 13 months of age, children were administered the Bayley test. As mentioned above, the SB L-M was given at 3 years of age, although WISC-R results were collected when the children were 7½ years old. While the Bayley scale index for mental development correlated modestly but significantly ($r = .29$) with the WISC-IQ, the Bayley scores were not successful in predicting later giftedness in discriminant analysis.

Thus, the results of the prospective studies reported here indicate that developmental indicators of early infancy are not appropriate for prognosis of later intelligence or ability in gifted children. The overview by McCall (1979) for normal children shows that higher correlations could be obtained with children older than 18 months because in the first month the developmental tests assess sensorimotor more than cognitive functioning (Sattler, 1988; Shapiro et al., 1989).

Comparison of Different Measures and Problems Related to the Psychometric Approach

Nearly all studies in gifted young children employ tests of cognitive functioning. The results of these tests are, on the one hand used as indicators of intelligence, high abilities, or giftedness itself, on the other hand, if an alternative definition of giftedness is used, intelligence or abilities tests are used as reference variables, e.g., to make the samples of different studies comparable. There are several problems to be regarded if the psychometric approach is used in giftedness research.

As was mentioned above, many practitioners and researchers look for tests which provide them with differentiated norms in the upper extreme. Concerning the SB, the SB L-M is therefore sometimes preferred to the newer SB:FE because of better discrimination in gifted children (Kitano & DeLeon, 1988). A similar argument was, for example, expressed against the K-ABC by Roberson (1988, cited by Storfer, 1990). In our opinion, this seems to be an unrealistic expectation.

The 1973 standardization of the SB was done on the basis of about 2100 testees, the one of the SB:FE on the basis of about 5000. This means that, on the average, the norms for each age group were computed on the basis of only 100 or 300 persons. In samples of that size, you find on the average 2 or 6 persons with an IQ higher than 2 standard deviations (*SD*) from the mean (*M*), and you probably find no person with an IQ higher than $M+3SD$ (i.e., SB-IQ > 148). To be sure that a sample contains 10 gifted persons with an IQ over $M+2SD$ (SB-IQ > 132) you have to collect a representative sample of $N = 438$. In order to find a single person with an IQ higher than $M+3SD$ (SB-IQ > 148), respectively $M+4SD$ (SB-IQ > 164) on the basis of the deviation IQ you need a sample of 741 and 31,546 persons respectively. These examples show that it is not at all realistic to gain valid IQ-scores that are able to finely differentiate between persons with an IQ higher than $M+2SD$ (SB-IQ > 132, Wechsler-IQ > 130). Thus, norm tables that provide you with such extreme values are constructed on the basis of random extrapolation and smoothing but not on the basis of empirical data of representative samples.

The preference of many giftedness researchers to be able to differentiate in the IQ range over $M+2SD$ (SB-IQ > 132) seems to be a relict of the former ratio-IQ concept when IQs were computed by the formula $IQ = (\text{mental age MA})/(\text{chronological age CA}) \times 100$. This way a 5-year-old child (MA = 5) that was able to solve problems which an average 8-years-old could solve (CA = 8) scored an IQ of $8/5 \times 100 = 160$. But this ratio-IQ has statistically nothing in common with the modern deviation IQ, which is primarily defined by the mean and standard deviation of the standardization sample and which is used by all important well-constructed intelligence tests presently available.

As a consequence, profile analysis with gifted children is in most cases very difficult or even impossible as these children may score beyond the ceiling of the subtests. Reynolds and Clark (1986) propose a procedure with the help of which the subtest scores can be restandardized intraindividually using the norms of older children or those from higher grades and thus making profile analysis possible. Prerequisite for this is that age or grade norms of the test are available and the reliabilities and the structure of the subtests across age or grade are the same.

There is a great deal of evidence that there has been a shift in the mean IQs of children and adults. Flynn (1987; see also Storfer, 1990) reviewed research available for fourteen nations and reported massive IQ gains for countries all over the world. Analyzing data gathered from the thirties to seventies, Flynn (1987) found IQ shifts between 5 and 25 points within one generation. This means that a performance which would have been enough to get into a sample of gifted in the past would not be sufficient 10 or 20 years later or today. With current norms of a test, an objectively higher knowledge or ability is needed to be included in a gifted sample today.

There was a shift in the IQs from the SB L-M of about 10 points from the 1960 to the 1973 norms (see e.g., Roedell et al., 1989). As can be read in the SB:FE manual (Thorndike et al., 1986), a sample of gifted individuals which was administered the SB L-M and the SB:FE scored 13.5 points higher on the 1973 SB L-M than on the 1986 SB:FE (similar results are reported by Robinson, Dale, & Landesman, 1990). With respect to the other tests, the SB:FE manual contains information that children classified as gifted by their schools reached a mean composite IQ of 123.2. In comparison with the WISC-R full scale score, the SB composite score turned out to be slightly lower (1.4 points), while children scored even lower in the K-ABC composite score than in the SB:FE (4.7 points). As can be seen from Thorndike et al. (1986), the differences are smaller for samples of individuals with average ability.

The findings from Thorndike et al. (1986) on mean differences between the SB L-M, the SB:FE, the WISC-R, and the K-ABC were confirmed by McCallum et al. (1984) who reported that gifted children score lower on the K-ABC than on the WISC-R or the SB L-M. With respect to the PPVT, Knoff and Blednick (1986) found a difference of more than 10 points between the older PPVT and the newer PPVT-R, while in a study by Bondy et al. (1984) gifted children scored 8–20 IQ points higher in the Slosson test than in the McCarthy test.

Results of such studies are of major importance for giftedness practice and research as severe consequences for recruited samples of gifted children are related to the question of which test and which norms were used. If the IQ shift between the SB L-M and the SB:FE is 13 points in the upper extreme, a gifted sample gathered using IQ > 132 using the old SB L-M in 1985 does not contain the top 2% of the population but the best 10%.

Apart from the problem of the test norms, comparing samples recruited by different measures of intelligence requires "comparable" instruments. The question of concurrent construct validity, however, is difficult to solve for gifted children. For average, heterogeneous samples, Thorndike et al. (1986) reported high correlations between the SB:FE and the WISC-R ($r = .83$), the WPPSI ($r = .80$), as well as the K-ABC ($r = .89$). This is even higher than the correlation between the SB:FE and the SB L-M which is $r = .81$, these correlations are necessarily lower with gifted samples because of the reduced variance in such samples (Perleth & Sierwald, 1992). McCallum et al. (1984), for example, reported a correlation of $r = .5$ between the WISC-R and the K-ABC for gifted samples. For a sample of 82 gifted primary school students, Thorndike et al. (1986) found a correlation of only $r = .26$ between the SB L-M and the SB:FE which has to be explained by reduced variances and invalid IQ scores in the extreme upper range of the SB L-M.

Modern approaches in constructing measures of cognitive functioning—apart from the further development of traditional, well-accepted tests—can be described by at least three important trends (see also Heller, Chapter

3 in this volume). First, the results of the information processing approaches are used to establish measures for components of intelligence. The K-ABC may be given as a first illustration of this, (other examples are presented by Sternberg or Ruppell, see Sternberg, 1991; Ruppell, 1992). These are, however, more concerned with older children and adults and less with young children.

The second trend refers to the placing of training and transfer in the center of theories of intelligence. Using a pretest-treatment-posttest design, Guthke (1974, 1992) began in the sixties to develop so-called learning tests which assess the "learning potential" of the child in the sense of Vygotsky's theory of zone of proximal development. Later, a similar test-teach-test approach was developed independently in the Anglo-American countries under labels such as dynamic assessment or learning potential assessment device (Feuerstein, 1980; see also Campione et al., 1982; Day & Hall, 1987). The ideas common to both the German and the American tradition is the assessment of the level a child can achieve given ideal teaching or the advancements than can be obtained through training. Although tests of this type were used as standard measures of intelligence since the late seventies, this approach, however, has produced no instrument which can be employed in the assessment of intelligence in gifted children. Some applications, however, especially in underprivileged, very young, or extremely anxious children, seem to be on the verge of a breakthrough (Guthke, 1992).

A third trend is the development of adaptive or tailored tests. If tests of this kind are given to children, the children work only on these items that are best suited to measuring their ability. This means that gifted children only complete rather difficult items whereas retarded children are given the easier items. This normally necessitates computer-aided testing. With the help of probabilistic test theory, ability parameters for each child are available and comparable, even if completely different subsets of items are administered to every child (Weiss, 1983; Embretson, 1985). For German-speaking countries, Kubinger and Wurst (1988) presented a paper and pencil test for adaptive intelligence diagnosis (AID) which is already widely used. In this test, it is not the single items but blocks of items which are tailored according to the ability of the child (principle of branched testing). Following a concept similar to the WISC-R, the AID enables the measurement of intelligence in gifted primary school children with good precision.

With regard to the question of the extent to which later (superior) performance can be predicted on the basis of tests administered during preschool and early school years, we have to state that no precise answer can be given based on the presently available (or rather lack of) empirical evidence. There are too few prospective studies or at least combined longitudinal-cross-sectional studies which could provide practitioners and researchers with respective data.

In general, the abilities measured by intelligence tests

are quite unstable in preschoolers. While Sattler (1988) found a correlation of $r = .5$ from 7 to 8 years of age with youth and adult intelligence and achievements, the same author states: "The older the child is when first tested and the shorter the interval is between tests, the greater the constancy of the IQ" (p. 73). Thus, IQ scores measured prior to 5 years of age must be interpreted cautiously. Fluctuations of as much as 20 IQ points are possible, even if the oscillation of the IQ for the majority of children is lower after age 5 (Sattler, 1988). The same holds true for the relationship between intelligence and achievement (which can be moderated, for example, by external factors).

In view of this state of the art, further evaluation of relatively well-known tests in samples of gifted children are preferable to the construction of new instruments for identifying young gifted children. As the example of Mardell-Czudnowski and Goldenberg (1990) shows, even theoretically well-founded systematic measures can fail to show any (predictive) validity with respect to achievement measures.

It is our opinion that practitioners and researchers should be skeptical of too much optimism about the possibility of predicting high ability and high achievement from early age. According to Howe's (1990) critical summary on research which investigated the predictive validity of intelligence tests (in most studies administered to older children and youth) for real life achievement, prognoses must be made with extreme caution. Also considering the results from the Terman study, Howe (1990) concludes that "such tests are especially ineffective at making predictions that concern the achievements of individuals who are highly able" (p. 202).

Information Processing of the Young Gifted

The subsequent section follows the outlined information processing model of intelligence presented above. Since parameters of information processing in newborn and infants are measured primarily in habituation studies, we have included a subsection on this. We have also included a section on sleeping behavior under the topic architectural level as this is frequently reported as an important early indicator of giftedness, especially in German-speaking countries. Possible links of sleep parameters to giftedness have to be on this "hardware" level. With concern to the higher order components, we summarize knowledge base and strategies as declarative and procedural knowledge on the one hand and strategy use, metacognition, and executive control on the other hand.

Architectural Level

ATTENTION AND HABITUATION

As infant intelligent tests have little predictive validity, researchers have turned to other areas promising better

results. Indeed it would seem that cognitive functioning makes great developmental leaps during the first two years of life. In habituation studies, a stimulus (generally a visual one) is repeatedly presented until the subject ceases to attend to it. In the literature there is a discussion in progress about how such habituation phenomena should be interpreted. The length of time the subject spends on the stimulus could diminish because the processing of information has been completed or because interest in the stimulus decreases due to ineffective information processing.

Typically, infants placed in otherwise homogenous environments will orient and attend to a novel stimulus. This attention will diminish if the stimulus is presented continuously or repeatedly. Bornstein (1988) explains habituation using a two-component process. The infant develops a mental image of the stimulus and continually compares the mental image to the stimulus presented. A representational match will not hold the baby's attention, but mismatches maintain it.

From our point of view, it is important that habituation studies have linked intelligence or cognitive functioning to early habituation results. Lewis and Brooks-Gunn (1981) view habituation to redundant information and recovery when stimulus is changed as perceptual-cognitive ability or information processing. These are abilities which can be examined even in very young infants. The developmental theory upon which their research is based assumes that different skills develop at different ages and "those central to a specific age group are most likely to be predictive of the next major skill, even though the next skill might be quite different from the preceding one" (Lewis & Brooks-Gunn, 1981, p. 132).

To put it briefly, cognitive ability is a transformation of skills from one age level to another. The research of Lewis and Brooks-Gunn (1981) did, in fact, provide a better prediction of intellectual functioning at 24 months (Bayley scores) from 3-month habituation/recovery than 3-month (Bayley scales) global intelligence or object permanence scores. Their research results are also supported by Bornstein and Sigman (1986), who showed that attention focusing at 6 months may be used as a predictor of subject's IQs between 2 and 8 years of age, and Rose and Wallace (1985), Fagan and McGrath (1981), and Fagan and Singer (1983) also discovered a relationship between preference for novel stimuli and mental abilities.

Rose, Slater, and Perry (1986) investigated retest-reliability and predictive validity of different parameters for habituation. Although the results seem to be encouraging (e.g., some medium correlations between single habituation values in infancy and 4½ years of age) some facts should be considered when interpreting the data: First, the sample was rather small ($N = 16$) and second, the measures of habituation outperformed the indicators for novelty responses in contradiction to, for example, the Fagan and Krahe McGrath (1981) or Lewis and Brooks-Gunn (1981) studies. Bornstein's (1989)

review across ten reports indicates that measures of habituation are psychometrically acceptable and show a moderate median predictive correlation of $r = .49$ mainly with measure of intelligence and verbal abilities.

The relationship of habituation to later intellectual abilities was also shown for higher IQs, at 24 months in the Lewis and Brooks-Gunn study. In their discussion, these researchers suggest that attention ability may be one of the earliest components of intellectual ability with predictive validity for a later age. Bornstein and Sigman (1986) explain the early habituation and the later intelligence as both reflecting effectiveness in encoding information. Thus, more intelligent infants encode everything of interest or perhaps they more quickly match it to their mental representation.

Lécuyer (1989), however, judges these correlations as less substantial. Analyzing the correlations reported in the Bornstein and Sigman (1986) article, he found a correlation of $r = -.61$ between the sample size and the observed correlations of the studies cited by Bornstein and Sigman (1986). Lécuyer (1989) also points at the "0.05 syndrome" (p. 149) which might suppress the publication of lower correlations or studies in which no relationships between habituation and later cognitive indicators were found. All in all, Lécuyer (1989) links the habituation findings not to the speed of effectiveness of information processing (as for example Deary, 1988, does) but to the capacity in sustaining attention.

Of course, as Tannenbaum (1992), points out, neither habituation nor response to novelty actually requires reasoning or logic, but rather are viewed as being measures of efficiency in information processing. That is, they are a means of predicting later intellectual functioning without explaining the relationship between habituation and IQ.

MEMORY CAPACITY AND DURABILITY

Although it has often been shown that gifted children's memory performance is better than that of average children, these results are generally not interpreted as meaning higher memory capacity or memory durability in gifted children. Memory capacity here means the number of "slots" of the working and long-term memory rather than measures of the memory span where the number of recalled words or numbers can be increased, for example, by using appropriate strategies. On the contrary, there is much evidence that there are hardly differences in the capacity and durability of the short-term or working memory as well as the long-term memory of children and adults of different level of giftedness and of different ages (Howe, 1990).

All differences in memory performance reported in the literature have to be attributed to differences in speed of information processing (memory or cognitive efficiency) or in higher order components as knowledge, metamemory, and executive control which lead to a more efficient use of the limited capacities of the short-term memory (see the surveys of Campione et al.,

1982; Jackson & Butterfield, 1986; Borkowski & Peck, 1986; Brewer, 1987; Torgesen, Kistner, & Morgan, 1987). In addition, Schneider and Pressley (1989) argue that intraindividual development changes in memory performance cannot be linked either to changes in capacity or to speed of information processing.

MEMORY EFFICIENCY

Although Schneider and Pressley (1989) deny a causal relationship between intraindividual development of memory performance and speed of information processing, the efficiency of the memory system is considered to be the main cause on the architectural level of interindividual differences in the achievement of gifted, average, and retarded children (Campione et al., 1982; Jackson & Butterfield, 1986; Borkowski & Peck, 1986; Brewer, 1987; Torgesen et al., 1987). Memory or cognitive efficiency refers primarily to the speed of information processing. This includes properties of the sensory system and the short-term memory and, in consequence, the speed of registering, identifying, and analyzing incoming information, the speed of storing new information in long-term memory as well as the speed of retrieving information from memory, the speed with which information in the working memory is processed etc. All in all, cognitive efficiency enables one to make better use of the limited capacities of the working memory. Memory efficiency increases as cognitive processes become more and more automatic. Automation frees capacity of the working memory and at the same time attention for more complex problems. Thus, the superiority of gifted children may be attributed to higher cognitive efficiency, i.e., to a higher basic speed of information processing and a higher level of automation.

While aspects of attention, memory, and cognitive efficiency are regularly included in checklists for the early identification of gifted children, there is not much empirical evidence for the concurrent and predictive validity of these indicators in young children. In our opinion this is a consequence of the methods employed. Information processing in infants up to 1 year is measured using the habituation paradigm (see above); for a methodological discussion see Daehler & Greco, 1985) while recognition tasks, reaction time tasks and so on have normally been applied in children older than 9 or 10 years. Thus, there are few studies with gifted children under 8 or 9 years of age investigating cognitive efficiency. On the other hand, there are many more studies dealing with retarded or learning disabled children. Possible relations between cognitive efficiency and later achievements were demonstrated, for example, by Jackson and Myers (1982) who could show for 37- to 66-month-old preschoolers that rapid letter naming and backward digit span was a predictor of reading skills six months later while no relationship could be found for measures of IQ (e.g., Stanford-Binet, WPPSI-subscores).

Transferring respective results from one age group to another or interpolating results comparing retarded and average to gifted children, however, might be misleading. Although, for example, memory scanning differences between gifted and average were found in 9-year-olds, these differences were not observable in 17-year-old adolescents after practice (Keating & Bobbit, 1978). There is also some evidence that memory efficiency concerning retrieval processes cannot be associated uniquely with differences in the basic speed of information processing (Brewer, 1987). The superiority of the gifted in cognitive efficiency may be caused by a faster speed of information processing, enhanced attention processes, a superior organization of the knowledge base, more effective strategies, a better motivational structure, longer and more intensive practice, or the complex interaction of all these and other components. All in all, Brewer (1987) concludes that "more research is needed before firm conclusions can be drawn" (p. 43). Jackson and Butterfield (1986) state that none of the studies cited in their review "suggest any qualitative difference in the basic short- and long-term memory processes of gifted and average children" (p. 164).

SLEEP

Occasionally, descriptions of young gifted children include the idea that the gifted child sleeps less than other children and/or has sleep problems (see Freeman, 1979; also Louis & Lewis, 1992). Frequently, behavioral checklists, especially ones for the hands of parents and teachers, include an item such as the following from Geuß and Urban (1982): Needs comparatively little sleep and this irregularly (p. 94, checklist for early identification of giftedness). This continues to be reported by parents, practitioners, and is reflected to a certain extent in the literature. As a consequence of this reduced need of sleep and irregular sleeping times of gifted newborns and infants—according to respective literature—the parents of the gifted may be under considerable strain (e.g., Webb, Meckstroth, & Tolan, 1985; Heinbokel, 1988; Stapf & Stapf, 1988).

The empirical evidence for these indicators is rather poor. Despart (1949, cited along Busby & Pivik, 1983), for example, reported shorter sleep periods of the gifted but did not present any statistical or polygraphical evidence for this statement. On the contrary, Terman (1925) stated that his sample of gifted children (age 7–14) slept even longer than normal children. In accordance with this result, Freeman (1979) reports that in her study no differences were found concerning sleep behavior and sleep problems between gifted controls and non-gifted control children. Only the parents of the children of the so-called "target group" which consisted of gifted children whose parents were members of the English National Association for Gifted Children reported a lower amount of sleep and more sleeping problems for their children. In a similar way, the sample of Stapf and Stapf (1988), who also report a low sleep need

for young gifted children, was collected in a counseling center. Browder (1993), on the other hand, could not find a difference in the sleep length between gifted and average children, using reports of the parents who did not know that their children were gifted.

Freeman (1983) suggests that sleep problems tend to be more an indication of parental attitudes. The parents of the gifted children tend to be middle class, and at the same time expect their children to sleep more than working class parents. Thus they put their children to bed earlier. "Quantity of sleep depends on what parents expect and on the children's psychological adjustment" (Freeman, 1983, p. 30) and, therefore, in her opinion cannot be regarded to be an indicator of giftedness.

This view is confirmed by a look at the general sleeping behavior of infants and toddlers. As Wolke (1993) points out, the variance of sleeping behavior is intra- and interindividually, as well as interculturally, extremely high. Between 20 and 38% of all parents, for example, consider night-waking a mild or serious problem for their families' life; about 6–10% of all toddlers wake more than twice per night.

A major problem in the research on the sleeping behavior of gifted infants is the retrospective way in which the indicators were collected. To our knowledge, there are no prospective studies investigating the relationship between sleeping behavior of newborn or young infants which turned out to be gifted in later childhood or in primary school. On the other hand, there are some longitudinal studies on representative samples or on children at risk which can provide some information about the correlation between sleep behavior and intelligence and other indicators of cognitive capacity in school time.

Pollock (1992), for example, recently published results of the British Birth Survey, in which 98% of the births occurring in the week 5–11 April 1970 throughout the United Kingdom could be included and studied in early infancy (17,196 children). The parents of 86% of these children ($N = 13,961$, Northern Ireland was excluded) were given questionnaires in a follow-up 5 years later, and in 1980 93% of this original sample ($N = 14,906$) were administered a battery of tests and questionnaires. Although the emphasis in Pollock's (1992) study was on identifying factors that lead to sleeping problems, it is interesting that in spite of the huge sample size "this study has failed to show any association" (p. 165) between sleeping behavior at early infancy and intellectual abilities at age 10, only a slight superiority of the children with sleeping problems in a vocabulary test at the age of 5 and a reading test at age 10 was found.

Unfortunately Pollock (1992) prepared his data for analysis by dichotomizing most of the variables. Thus, he investigated only above and below average groups but no groups of gifted children in a narrow sense. It would be interesting to use this and similar data for further secondary analyses of possible early indicators of giftedness.

Researchers who compared not sleeping behavior

but sleep patterns and sleep variables of mentally retarded and normal children were a little more successful. From such research it seems to be obvious that the REM latencies are longer, the REM sleep is shorter, and the eye movement density during REM sleep is less in the mentally retarded (Busby & Pivik, 1983; Grubar, 1985b). Studying normal children alone, however, Borrow, Adam, Chapman, Idzekowski, and Oswald (1980) could not find any association between these parameters and intellectual ability. In general, however, the reliability and validity of such research is critical as the recording of physiological functions is stressful and often unacceptable in infants and young children so that their ecological validity has to be questioned (Wolke, 1993).

In consequence, sleep studies with gifted children under the age of 8 years are—to our knowledge—not available. Busby and Pivik (1983) compared six gifted and five average children ranging in age from 8 to 12 in several sleep parameters. The authors found that the gifted slept 20 min longer, and that their eye movement density during REM sleep was lower which was a surprising result. The authors interpret this finding as a more efficient level of information processing during waking and REM sleep of the gifted. As an alternative explanation in the sense of homeostatic-recovery theories, the authors take into account the possibility that the high cognitive activity of the gifted during waking makes a reduced activity during sleep possible.

While Busby and Pivik (1983) could not confirm significant differences between the gifted and average in REM sleep duration—although the REM sleep during the first REM cycle of the gifted was longer—Grubar (1985a,b) reported a higher proportion of REM sleep and also more REM cycles for five gifted children of a mean age of 10;8. Moreover the latency of the first REM sleep phase was shorter in the gifted, while Grubar (1985b) could not find any differences concerning total sleep time. In contrast to Busby and Pivik (1983), Grubar (1985b) found a significantly higher eye movement density during REM sleep in the gifted. The author interprets this finding by "a superior ability to organize information, and thus an advanced maturity of processing" (p. 154), referring to theories that interpret REM sleep as phases of the consolidation of newly learned material (Wolke, 1993).

All in all, the evidence from the sleep studies of Busby and Pivik (1983) and Grubar (1985b) is small and contradictory. Considerably more efforts have to be undertaken to clarify the sleep characteristics of gifted infants or children. At the present state of research, sleep variables cannot be taken as early indicators of giftedness, even if Grubar (1985a) hopes that the measurement of sleep variables may enable a new way of assessment of intellectual potential. In consequence, corresponding items in checklists reflect myths or more or less subjective impressions of the staff in counseling centers rather than empirical findings.

Higher Order Components

KNOWLEDGE BASE AND STRATEGIES

The knowledge base is frequently regarded as an important component of giftedness (e.g., Chi, 1984). Muir-Broadbent and Bjorklund (1990) see differences between gifted and average children not so much in the use of strategies or executive processes but in non-strategic aspects, above all the knowledge base. The authors report that their research results show that "typicalness" evaluation of concepts with regard to their categories of more intelligent 10- to 14-year-old children are similar to those of adults. In comparison with average children, this adult-like knowledge base can be observed primarily in the reproduction time of words of different categories, while no differences between giftedness groups could be found concerning words of the same category. On the other hand, with regard to clustering behavior, Muir-Broadbent and Bjorklund (1990) found no significant differences between the groups, whereby a trend in favor of the average students had to be reported.

The following chapter by Schneider deals with processes of knowledge acquisition and expertise and reviews the respective research in detail. In his chapter, however, Schneider reports mostly research conducted along the expertise–novice paradigm, generally with older children and adolescents. Concerning aspects of the knowledge base in gifted children, apart from a few studies with older children (e.g., Davidson & Sternberg, 1984), the complaint of a lack of research has to be made. McFarland and Wiebe (1987) state that "there is a certain irony here: the complexity and methodological sophistication used to study mentally retarded children clearly surpasses that used to study cognitively superior children" (p. 109).

STRATEGY USE, METACOGNITION AND EXECUTIVE CONTROL

In the tradition of Flavell and Wellman (Flavell, 1971; Flavell & Wellman, 1977; Flavell, 1978, 1984), we use the term metamemory or metacognition, on the one hand, to refer to the knowledge about the capacity/efficiency and about the function of one's memory or the whole cognitive set-up. Seen from an alternative theoretical point of view (e.g., Brown, 1978, 1984), metacognition means the cognitive processes which—referring to the respective demands—plan cognitive processes, which choose adequate cognitive strategies, which execute and control them in reference to their efficiency.

As demonstrated above, metacognitive knowledge and metacognitive control processes play an eminent role in newer theories of intelligence and giftedness (Sternberg, 1985, 1991; Campione & Brown, 1978). Quite surprisingly, however, there are only a handful of studies on metamemory or metacognition in younger gifted children, although some research has

been conducted in metacognition in (educable) mentally retarded or learning disabled pupils (see Borkowski & Day, 1987; Sperber, McCauley, & Brooks, 1984, or Ceci, 1987, for overviews in the mentally retarded and learning disabled). Studies with gifted pupils have been carried out mainly with adolescents older than 10 or 11 years.

One of the reasons for this might be the fact that research in metacognition—especially if one focusses on knowledge aspects—calls for a certain reflection ability which emerges only gradually during the course of childhood development. On the other hand there are a number of studies with average children (e.g., Sodian, Schneider, & Perlmutter, 1986; Schneider & Sodian, 1991; Sodian, 1990) that show that research in metacognitive knowledge can be carried out with preschoolers. This would indicate that it should be even easier with gifted children whose language might be more elaborate.

Some research, however, has been conducted in young children investigating metacognitive control processes. Here the way children cope with a problem, whether they adopt a trial-and-error strategy or whether they switch to systematically checking and comparing different possibilities, or whether they reflect on the problem-solving processes are aspects of metacognitive control with direct relations to success in the respective task. Such control activities are acquired in interaction with parents or other persons while the child is brought up (Karnes, Shwedel, & Steinberg, 1982; Kontos, 1983; Browder, 1993).

In order to increase our understanding of how the antecedents of metacognition are structured, we must deal closely with the caregiver–child interaction, in which metacognitive directions are provided as verbal or non-verbal aids. They help the child wake up to his/her own storage capacities. Gifted children eagerly seize on such metacognitive directions provided by a caretaker (information about task and strategy characteristics, and about the child's personality characteristics that interfere with the problem-solving process). Without subjecting them to much experimentation, gifted children use directives to expand their repertoires of verification procedures (Lehwald, 1992).

Moss (1990) and Moss and Strayer (1990) investigated the problem-solving behavior of 3- to 4-year-old gifted and average nursery school children of a (upper) middle class area in Montreal. They examined their play with blocks when the problem was solved in the presence and with the help of the mothers. As a result, Moss and Strayer (1990) determined that the mothers of the gifted focussed the attention of their children on important relations between problem aspects while the mothers of the average gave more hints about concrete solutions. All in all, the mothers of the gifted provided their children with a more favorable environment for the formation of metacognitive competencies. The gifted children used metacognitive strategies after the modeling of their mothers, but also more and more

spontaneously during the task (see also Browder, 1993). This way, the mothers of the gifted operationalize to some extent the principles of Brown and Palincsar's (1987) reciprocal teaching ("expert scaffolding" and "fading out").

Investigating primary school children, Geis and Corriher (1977; cited according to Waldmann & Weinert, 1990) hardly found differences between gifted and average children with respect to metamemory, although the more gifted children profited in higher memory performance from the more consistent use of a memory strategy. Similar results are reported by Robinson and Kingsley (1977) who moreover—although independent of the ability level—determined a qualitative difference between second and fourth graders with regard to the employment of preferred strategies: While the younger children employed a word-related strategy, the older ones made use of a clustering strategy.

Kontos, Swanson, and Frazer (1984) found in their small sample of 13-year-olds (14 average, 13 gifted) no superiority of the highly gifted in aspects of metamemory; however, these children were more aware of the role of effort. In a more recent study, Swanson (1990) was also unable to find a relationship between general intelligence and metacognition. Metacognitive competencies, however, seemed to be more important than intelligence with regard to different performance indicators of the problem-solving tasks under investigation.

The hypothesis that greater differences between gifted and average would be found with increasing age was confirmed by Swanson (1992). Studying problem-solving behavior and employing a metacognitive questionnaire with 11–12-year-old children, the author was able to demonstrate that gifted children scored significantly higher on the metacognitive questionnaire as well as on the problem-solving task.

In contrast, Borkowski and Peck (1986) report that gifted 7–8-year-old primary school students turned out to be better than their average peers in diverse aspects of metamemory. These advantages, however, were not reflected in better strategy use. Carr and Borkowski (1987) report independent impact (partial correlation) of metamemory and intelligence on achievement variables, but they did not find relations between metamemory and intelligence in their sample of ninety-eight 11- and 12-year-olds.

Kurtz and Weinert (1989) gave questionnaires about attribution, aspects of metamemory and a sort-recall task to fifth and seventh graders of high and average intelligence. The sort-recall task was to provide information about the use of organizing strategies in learning clusterable items and about the memory performance. In their analyses, Kurtz and Weinert only found a few significant differences in metacognitive knowledge. Intelligent pupils showed a better metareading and gifted pupils were superior to average pupils in the use of ordering strategies and in memory performance. Correlation analysis showed that the metamemory scores

employed are more closely correlated with the clustering and the recall scores than the intelligence tests used.

Shi Jiannong (1990a, 1990b) compared twenty students of a Beijing special school for the gifted with twenty students from a normal school (10–11-year-olds). The children of the elite school showed better memory performance, better strategic behavior, better memory monitoring, and better metamemory. This study has been criticized (Perleth, 1992) from the methodological and other points of view. Nevertheless, the study is one of the few which produced some evidence for a big clear superiority of gifted students in metacognition.

Perleth (1992) conducted a series of studies with primary school students to investigate differences in strategy use and metamemory between groups of different levels of giftedness and to analyze whether training and transfer effects depend on the level of giftedness. In the first study, strategy use and metamemory were investigated with the aid of a sort-recall task and a metacognition questionnaire in gifted and average children. The sample consisted of 204 second grade (approximately 8-year-old), and 260 fourth grade pupils. The major results were (a) determination of a relatively small relationship between metamemory scores, strategy use, and memory achievement, (b) for grade 4: the percentage of strategic children was higher in the more gifted pupils, and, (c) in comparison with metamemory, the intelligence test used turned out to be a better predictor of memory performance.

Because of some limitations and unclear results, as well as reliability problems in the metamemory group questionnaire used, Perleth (1992) conducted a second study on strategy use and metamemory in thirty-nine second and thirty-six fourth graders with different levels of giftedness ($IQ \leq 90$, $95 \leq IQ \leq 105$, $115 < IQ$) assessing strategy use and metamemory in single sessions. The results of the first study were more or less confirmed. Only for grade 4 a small superiority of the gifted in strategy use and metamemory was found; intelligence was more strongly correlated with amount of memory than metamemory. On the other hand, strategic fourth graders showed better memory performance, got better school grades, and were less anxious and more stress-resistant. The finding of larger differences with older children or adolescents confirms the results from Dover and Shore (1991).

In an intervention study, Perleth (1992) trained second graders in the use of a clustering strategy and investigated training effects on tasks of different transfer distances in dependence from the level of giftedness. While strong training effects for near transfer, and smaller training effects for middle and far transfer tasks were found in general, only small giftedness \times training interactions could be confirmed, indicating a tendency that more gifted pupils profit more with growing transfer distance.

The research reported to this point concentrated on the original issues of metacognition: memory and metamemory. Some more studies can be found on

metacognition in general (metacognitive knowledge and executive control), although most studies were conducted with adolescents or adults and not with (young) gifted children. As a result, on a very general level, one can state (e.g., Heller, 1991a) that gifted can be distinguished from the average by their better information-processing competencies (see the chapters by Shore & Kanevsky or Sternberg in this volume). They make use of relevant information for problem solving, they perform comparison processes more quickly, and spend, however, more time for the encoding phase (more careful problem analysis). Gifted use more and better strategies for problem solving in different areas, they substitute more favorable strategies for unsuitable ones more quickly, and their cognitive monitoring is better (for a summary see Waldmann & Weinert, 1990).

Davidson and Sternberg (1984; also Davidson, 1986), for example, report a series of studies which aimed at examining aspects of Sternberg's giftedness theory. The authors investigated performance on mathematical insight problems in elementary school children. The investigators analyzed the cognitive components of insight and knowledge acquisition, namely selective encoding, selective combination and selective comparison. The results confirm the summarized characteristics of gifted children.

The opinion above that there are hardly studies about metamemory and use of (memory) strategies in gifted children, is also shared by Muir-Broadus and Bjorklund (1990). These two authors establish a general deficit of research which compares the aspects of the memory performance of gifted and average children. At the same time they point out that such studies have thus far delivered an inconsistent picture. This is also valid for the studies mentioned in this section.

Motivational Characteristics

CASUAL ATTRIBUTION AND SELF-CONCEPT

"Little is known about the attributional beliefs of gifted children. However, research indicates that successful learners tend to credit their success to high ability, and their failure to a combination of lack of effort, bad luck, and task difficulty" (Borkowski & Kurtz, 1987, p. 144; see also Lewis & Michalson, 1985). In Covington's (1987) review on achievement motivation, self-attributions and exceptionality, for example, not a single study conducted with gifted or even above average children younger than 9-10 years is cited. In children of that age, Fincham and Barling (1978) found that gifted attribute less externally, while Karnes and Wherry (1981) report a higher self-concept for gifted children of grades 4-7.

In the above-cited study of fifth and sixth graders, for instance, Kurtz and Weinert (1989) were able to show that average children attribute success to effort, while highly gifted children attribute it to their

abilities. Using questionnaires comparable to Kurtz and Weinert (1989), Perleth (1992) found similar but weak trends and confirmed that the more gifted children attribute success to their abilities while they attribute failure to lack of effort. The results of these studies might, however, reflect specific German socialization. As Schneider, Borkowski, Kurtz, and Kervin (1986), as well as Carr, Kurtz, Schneider, Turner, and Borkowski (1989) pointed out for German and American elementary school children, attributional styles and strategy use as well as interdependencies between these variables vary with the culture.

Borkowski and Peck (1986) report that gifted children were more aware that self-interest effects learning results. According to Weed, Ryan, and Day (1990), intelligent fourth grade children with a high ability self-concept initially show advantages in new memory tasks, but with increasing experience, the influence of these factors diminishes in favor of strategy and metamemory variables.

In a representative and methodologically well controlled study in primary school children, Rost (1993; see also below) found that gifted children can be positively distinguished from average controls with respect to achievement motivation and causal attribution. Moreover, their strategies of working through their failure are more favorable. Concerning other aspects of personality, only a few differences were found, but when, then to the advantage of the gifted children.

CURIOSITY AND INTERESTS

An important motivational aspect important for development of high ability can be seen in the curiosity and interest of even the young infant, i.e., the attention and preferences which are given to objects in the environment (Howe, 1990). These motivational characteristics manifest themselves in a child's behavior. Because of their curiosity, gifted children already attract attention in early stages of development (Schneider, 1987). Berg and Sternberg (1985) view curiosity as an integral part of giftedness. In a meaningful and profound manner, the gifted children typically integrate the information acquired into their knowledge base. On the basis of their knowledge and a critical analysis of the consequences of their knowledge, they make decisions on courses of action geared to their original intention (acquisition of knowledge). Even at an early age, the behavior of gifted children is marked by a clear goal orientation. That orientation and its development is facilitated by these children's enhanced concentration power (Freeman, 1990).

During childhood, curiosity manifests itself in exploratory behavior. Therefore, the latter may be used as an early indicator of intellectual functioning. Exploratory acts are forms of active learning typical of young or preschool children. We are dealing with these when children expand and differentiate cognitive structures or when they incorporate these into a wider system

(Keller, Gauda, Miranda, & Schölmerich, 1985). In the course of mental development, the forms of exploratory behavior undergo change. These forms range from simple experimentation (mouthing, beating, shaking things) through functional/relational manipulations (assembling and integrating objects) to the asking of questions, a language-based information-seeking process. For differential diagnostic purposes, exploratory behavior may be used in a particularly impressive way, as a “response to novelty”. In such situations gifted children focus their attention on relevant pieces of information. It may be that this has to do with the exceptional ability of gifted children to identify problems (Renzulli & Delisle, 1982).

Empirical work (Lehwald, 1988, 1990) has shown that gifted, curious children make impressive use of their exploratory skills in puzzles. They relate single objects to complex units significantly more frequently than do less curious children. Thus, in a largely unstructured situation (at play, for example) they generate information themselves, and in doing so are engaged in an intensive information-gathering process about the properties of objects, how objects are interrelated, what functions they have, and what functional relationships can be established. In the long run, such active learning is conducive to the development of cognitive abilities. Follow-up studies using an intelligence test showed curious children to be clearly superior to less curious children. Thus, the exploratory actions which gifted, curious children engage in are of high “cognitive relevance”. If environmental conditions are fortunate, they perform a developmental function. If a child’s social environment provides an abundance of information, exploratory actions will build up a rich knowledge base, which is characteristics of gifted children (Sieglar & Kotovsky, 1986).

Child Expertise and Precocity

Language Development

There is much evidence in the literature (e.g., Bartenwerfer, 1978; Roedell et al., 1989; Terman & Oden, 1947) to suggest that gifted children differ from peers with regard to their language development. Freeman (1979, 1983), in particular, emphasizes that the intellectually gifted children she is familiar with were speaking early much more frequently than those of moderate intelligence. This precociousness includes not only children with proven verbal performance on IQ tests, but also those whose non-verbal performance scores are high are often found to be verbally precocious.

There are reports of a developmental superiority with respect to these children’s vocabulary and sentence formation, i.e., they allegedly have larger vocabularies and more complex sentence structure formation than is typical of their age level. Vocabulary development has long been correlated with intelligence (e.g., Terman,

1925). Guilford, Scheuerle, and Shonburn (1981) as well as Lewis and Louis (1991) report that linguistic abilities are often considered to be a manifestation of giftedness (and thus, often a subtest or subscale of various intelligence tests such as the Wechsler series [author’s note]). Particularly the following characteristics are emphasized: advanced vocabulary for age and grade level, use of language in a meaningful way, richness of expression, elaboration, and fluency. The above authors also report a high frequency of questions and good memory skills (see also Lewis & Michalson, 1985). Research by Milner and Elrod (1986) generally links giftedness in language production to improved competence in language comprehension even at the kindergarten level.

Retrospective accounts from parents of gifted children also indicate a great interest in language reflected in use of puns and rhymes as well as earlier first words and speech. Of course, such reports have methodical problems, but seem to indicate a parental awareness of child precocity (see also Louis & Lewis, 1992). Tuttle, Becker, and Sousa (1988) cite a mother of three highly gifted children as reporting that such children acquire language early which is typified by the following: large vocabulary, long sentences, early and frequent speech. Many of these children do not, however, speak early but wait until they are older and then display a remarkable talent for language. Research findings by Browder (1993), however, with an unselected group of preschool children age 4–6 are in sharp contrast to this. Parents did not differ significantly in their reports of children’s speech development regardless of whether their children belonged to the above-average group in intelligence (IQ > 125) or the average to below-average group (< 95).

In fact, other research does indeed link precocious language development to intelligence. Beginning with thirty children who were regarded as linguistically precocious, Robinson, Dale, and Landesman (1990) examined the validity of the Stanford–Binet: FE for young children. The toddlers here were selected for their advanced receptive and/or expressive language skills. This does not, of course, guarantee high performance on cognitive development tests (here: Bayley Mental Scales, Peabody Picture Vocabulary Test and Stanford–Binet L-M) since children at the age of 2 or 3 years develop rapidly in other areas such as nonverbal cognitive skills, etc. The children studied here received consistently high verbal scores and showed good short-term memory. And, impressively, these children had a mean Bayley Development Index at 20 months of 134.2, thus indicating that there are substantial contributions from non-language areas. This would suggest that *precocious language ability* should be considered as an indicator of giftedness when attempting to identify gifted children. Interestingly, research findings show a tendency for young gifted children to achieve significantly higher scores on the verbal than on the performance section of the WPPSI (Speer, Hawthorne, & Buccellato, 1986). This lends support

to the belief that the more substantial contribution to the IQ is due to advanced language skills.

Reading and Writing

The topic of reading and writing in gifted children is another of the myths/expectations that has established itself in the early identification of gifted children without empirical evidence. For example, language indicators are frequently subjectively felt to indicate giftedness by directors of preschool programs, preschool teachers, and parents. Abraham and Hartwell (1985, cited according to Urban, 1990) reported that the following language and number-related items were named by *all* three of the above-mentioned groups:

- can read, likes to read;
- knows which numbers are larger than other numbers;
- has a larger vocabulary containing more complex words than other children of that age;
- can carry on a meaningful discussion.

These four items make up almost half of the items selected by these directors, teachers, and parents out of those from the Preschool Gifted Behavioral Checklist (44 items total) as relevant and important indicators of giftedness in preschoolers.

If we consider the literature on gifted preschoolers' precocity, the majority focuses on early reading and rarely on early writing. The reason for this would seem to be the dysynchronous development of the two: reading develops faster and earlier than writing which requires not only comprehension of the letters/words but also fine motor control generally not yet perfected in 4- and 5-year-olds. As Terrassier (1985) comments: "The concomitant problem with children who read so early is their exceptional difficulty in learning to write. Their early attempts produce awkward hand movements, and they find it hard to coordinate writing with their natural, fast mental rhythm" (p. 267).

It is also somewhat difficult to approach the question of which age should be considered precocious in reading. Nancy Jackson, one of the leading researchers in this field, defined *precocious readers* "as children who have made substantial progress in reading comprehension before entering the first grade" (Jackson, Donaldson, & Cleland, 1988, p. 234). Advanced reading skill is complex and levels of subskills vary greatly. While there are great interindividual differences in this area, an additional difficulty in interpreting studies is a cultural one. School entrance ages vary from country to country (from approximately 5-7), so that the beginning of school teaching of reading may vary as much as two years. The definition of reading is also fuzzy, depending on whether letter or word recognition or reading comprehension is considered to be the criterion. "Reading encompasses a large number of separate subskills. . . . Consequently, it is not possible to state a precise age at which a child has mastered reading" (Howe, 1990, p. 77). Since

large numbers of children begin to read early (before formal school teaching), it is difficult to compare the gifted and average child in this area, i.e., it is not only children with higher intelligence who begin to read before school entry. "Although precocious reading ability is moderately associated with general intelligence, some highly intelligent children do not read early and some precocious readers are of average or subnormal intelligence" (Jackson, 1988, p. 200).

There are a number of tests used for measuring reading ability in studies of precocious readers, but these are seldom comparable in their content. On the one hand, early reading is considered to be an indicator of giftedness and related to other measures of verbal ability (Jackson et al., 1988), on the other hand differences are examined between gifted readers and nonreaders (Burns, Collins, & Paulsell, 1991; Salzer, 1984).

According to Howe (1990), most children seem to be capable of learning to read a minimum of one or two years earlier than it is usually taught. When a child has learned to read precociously, i.e., before attending school, it is usually due to someone working with a child closely, at least in an interpretive way (see also Freeman, 1979). Thus, despite claims to the contrary that early readers have taught themselves to read, this is discounted in the literature. "No child (and no adult either) can learn to read entirely on his or her own. There must be someone to draw the child's attention to the particular features and associations that reading draws upon. . . . Learning to read, like a number of other human accomplishments, is only possible if the learner receives a fair amount of help from people who can already do it" (Howe, 1990, pp. 79-80).

The increasing numbers of early readers is also having other effects on the identification of the gifted. As Whitmore (1985) points out, the early reader may be expected to be gifted and vice versa, the gifted child is frequently expected by educators to be an early reader. A gifted child with less precocious reading and writing skills may not be identified as readily as an advanced child. In addition, certain skills with letters, sounds, and phonemes are related to progress or difficulties in learning to read (see Howe, 1990). If teachers assume that preschoolers have such skills but are making poor use of them (instead of lacking in experience or exposure), then such children, including highly able ones, may be misdiagnosed as learning disabled or dyslexic.

The role of intelligence in learning to read seems to be unclear. Accelerated reading seems to be related to home environment and nurturance of reading and/or language skills (Grant & Brown, 1986; Mills & Jackson, 1990; Salzer, 1984) as well as to intelligence (Freeman, 1979, 1985). Influence from educational television programs such as Sesame Street (e.g., Jackson et al., 1988; Salzer, 1984), reading exposure at home (Grant & Brown, 1986; Jackson et al., 1988; Stroebel & Evans, 1988), preference for reading readiness toys, such as books and alphabet cards (Thomas, 1984),

and frequency of story reading in the home and child engagement therein (Crain-Thoreson & Dale, 1992) have frequently been correlated with early reading. Freeman (1979) reports that social class and sex affect reading learning (in favor of higher classes and girls). She also feels that not only background but personality structure and mental adjustment play a role in reading development. The high IQ children she viewed were more frequently early readers, being precocious in talking and reading. In a claim about their long-term development, Freeman claims that children who had been verbally precocious developed into more avid readers than usual. In a study by Crain-Thoreson and Dale (1992), however, although early talkers remained verbally precocious in preschool, they were not especially likely to read early. This is probably due to the fact that although verbal precocity would intuitively seem to be related to reading, in fact, learning to read requires several verbal, nonverbal and spatial skills. The later reading development of these children had not yet been measured at time of publication. In a later publication, Freeman (1985) points out that the quick and easy mechanical reading of the highly able children should not overshadow other cognitive and linguistic skills of reading in their importance for academic achievement (p. 179).

Other factors related to early reading include personality factors such as motivation in learning the alphabet (Salzer, 1984), recognition that reading/writing serves a purpose in their environment (see Burns et al., 1991), and cognitive components such as verbal ability, letter naming speed, and short-term memory factors such as forward and backward digit span (Jackson et al., 1988). Moore (1983) found that children developed marked metacognitive knowledge about reading between ages 7 and 11 and good readers were more conscious in a metacognitive sense of important reading parameters.

But with regard to the early identification of the gifted, Jackson (1988) raises an interesting question: Do precocious readers continue to perform exceptionally well later in life? The evidence is unclear especially with regard to the question of whether early reading is a cause of improved performance (e.g., closely related to schoolhouse giftedness or a statistical predictor of continued performance which might be correlated with other factors such as parental emphasis on achievement, intellectual abilities (see Jackson, 1988, p. 201). Conclusions from a more recent publication (Mills & Jackson, 1990) indicate that individual differences in later reading comprehension can be predicted from tests given 5 or 6 years earlier, but that verbal ability is at least as good a predictor. This would mean that early reading is perhaps not as important as early verbal abilities as a predictor. In addition, Mills and Jackson found that advanced readers continue to perform well on tests of comprehension, vocabulary and other language achievements but are not extraordinary. In fact, early reading seems to have some positive effects for the child but is no guarantee of later academic giftedness.

However, as Jackson (1988) writes, exceptionally early attainment of the ability to read is a demonstration of gifted performance as she (and frequently others) would define it.

Mathematics and Calculation

Although extraordinary mathematical skills are regularly considered very important items in checklists for the early identification of gifted children (e.g., Stapf, 1990), there is very little research on outstanding mathematical skills in young children. Most studies have apparently been conducted with students older than 10 years.

Studies by Benbow and associates in mathematically gifted 12- to 14-year-olds produced evidence that mathematically gifted boys and girls distinguish themselves from average by higher nonverbal reasoning abilities (Benbow & Minor, 1990) as for example measured with Raven's Progressive Matrices (see above). In addition they show outstanding spatial abilities and outperform their nongifted peers in memory performance. Dark and Benbow (1990) could demonstrate that mathematically gifted students have better skills for translating verbal problems into equations and that they are superior in problem representation and manipulation in working memory. Finally, Dark and Benbow (1991) confirmed the better working memory manipulation of the mathematically gifted, while the verbally and not the mathematically gifted showed enhanced encoding speed.

According to Krutetskii who conducted (longitudinal) studies with 6- to 16-year-old students, mathematically gifted children can be characterized by superior analytic and synthesizing perception of mathematical problems. They can generalize quickly and broadly about the content and method of solving mathematical problems and are able to easily switch from one cognitive process to another (see also Lester & Schroeder, 1983).

Case studies with calculating prodigies in which cognitive processes and aspects of memory were investigated are also rare (for a review see Radford, 1990). In his study with a 13-year-old girl with outstanding skills in mental multiplication, Hope (1987) found an exceptional memory for squares of 2- and 3-digit number as well as a high digit span. While Jensen (1990) could not find extraordinary large digit span, unusual high reasoning abilities, or superior reaction time in his female adult calculating prodigy, he also reported on the role of an outstanding long-term memory and the automation of cognitive processes needed for calculation. Bredenkamp, Klein, von Hayn, and Vatterrodt (1988) also stressed the fact that their 21-year-old male calculation expert does not have higher capacity of working memory but a well organized and highly specialized long-term memory (he has memorized, for example, all multiplications with two-digit numbers).

Automatic rules, highly effective retrieval from the long-term memory, and a relatively long space of time for processing or storing digits enabled the expert of Bredenkamp et al. (1988) to produce correct results for most difficult calculation tasks with enormous speed.

Bredenkamp et al. (1988) report that their calculation expert practiced calculation problems for at least 1 hour per day since he was 4. Moreover he used car signs, television reports on economic data, and other things for calculation practice as a sort of hobby. Jensen's (1990) prodigy also narrated that she had "played with numbers for hours every day since early childhood" (p. 269).

Radford's (1990) reports on prodigies in the domain of mathematics show that early self-directed dealing with numbers might be an indicator of later exceptional performance, but "calculating ability does not necessarily show itself early" (p. 88). This author also stresses that calculating skills are not necessary for becoming an outstanding mathematician and judges interest and motivation to be central factors. The interest and motivation which are necessary for an intensive occupation with mathematical problems often seem to develop (at the earliest) in adolescence. According to Marjoram and Nelson (1985), the work of Stanley and Benbow with youth in the seventies and eighties showed the eminent meaning of self concept and role taking for the development of gifted mathematicians, especially for gifted girls (see also Beerman, Heller, & Menacher, 1992). Marjoram and Nelson (1985) also cite indicators for early identification of mathematically talented children such as preference for logical connectives in their language, interest for and occupation with geometric patterns and order systems, pleasure in puzzles and construction toys. Empirical evidence for these indicators, however, is not cited.

Although most of the research reviewed in this section does not deal with young gifted children, it provides evidence for the hypotheses that innate abilities alone cannot explain outstanding mathematical skills. Instead, the results confirm the important role of effective organization of processes in (working) memory and the significance of a large and well-organized knowledge base. Hard training is necessary for many years to build up such a knowledge base. This necessitates high motivation and interest and even an emotional affinity for numbers. Moreover, the findings of Krutetskii on problem solving and transfer of the mathematically talented fit well with those of Campione et al. (1982) which define intelligence or ability in terms of transfer or generalization.

Social Environment of the Young Highly Able Child

As Tannenbaum (1992) pointed out, many children showing signs of giftedness as toddlers or in the preschool age, do not achieve an outstanding level of achievement in school and/or life. According to Lewis and Michalson (1985), one explanation for this

discrepancy between promise and fulfillment can be the family background and educational-career opportunities. Families select and produce opportunities and experiences for the development of their children, and thus play an essential part in the growing of giftedness. Consequently, the development of giftedness is a function of individual characteristics, environmental experiences, and the interaction between both factors (also Browder, 1993; Perleth & Heller, 1993).

Analyzing the socio-economic background of the families of gifted children and adults, a number of typical factors were identified. The majority of the students identified and traced by the classical Terman study turned out to stem from a wealthy and intellectual milieu. These findings of above-average education and socio-economically well placed families of the gifted was replicated regularly in giftedness studies (see Lewis & Michalson, 1985).

Birx (1988), for example, reports that her sample of mathematically talented youth have parents who are, in comparison with the population of German adults of that age, highly educated. Berger (1984) who investigated 10-year-old gifted students (identified by teachers on the basis of their academic achievement) states that the parents of these students are elite from the educational point of view, especially the educational level of the mothers. Similar findings were described by Freeman (1979). Willerman and Fiedler (1977) report for boys a correlation of $r = .51$ between educational level of the mothers and IQ measured at 7 years of age. No relationship was found for girls. Interestingly, the parents of the children whose IQ diminished in the course of the longitudinal study had completed less education. Howe (1990) also points out that among extremely successful scientists (e.g., winners of the Nobel prize) religion, size of the home city, etc. distinguish them from the population in general. Considering these findings that so many identified gifted children come from the middle and upper socio-economic classes, Roedell et al. (1989) address the problem of identification of gifted from other social and educational classes.

The structural aspects of the family during the childhood of the gifted also differ from the population average. At least in Germany, families with two children seem to be typical, where the mothers do not work but stay at home (in spite of their high education; Berger, 1984; Birx, 1988). Furthermore, more gifted are found to be first-born siblings (see also Lewis & Michalson, 1985), a fact which Pfouts (1980) explained by a higher amount of nurturing of the firstborn children (see also Storfer, 1990).

According to Howe (1990), individuals who later became scientists in particular come from intact families, enjoyed their childhood, and their career was straight and not interrupted by (family caused) critical life events. The parents of the gifted children from Berger's (1984) sample reported that their children were planned, and that pregnancy and birth were free from worries and problems. Most children had attended kindergarten.

The more sociological family characteristics described, however, cannot explain why they favor the development of highly able children. To obtain more insight into the shaping of giftedness, factors such as educational style, family climate, or attitude about learning and schooling have to be analyzed. Lewis and Michalson (1985) assume that an optimal amount and balance of freedom and pressure most favorably influences a child's motivation to learn and to explore the environment. According to Berger (1984), however, gifted German children have parents who favor either liberal or suppressive educational style, most parents stressing discipline from the early childhood on (e.g., early toilet training). From his interviews, it was noticeable that the parents view their families as the center of education and socialization, while school as educational and socialization instrument does not count much.

Findings like Terman's or some of the other cited here are often criticized because families of the gifted were compared nationally with average families. Beginning with a representative sample totaling more than 7000 8-year-old pupils recruited all over Germany (all of whom were tested individually), Rost (1993) compared 151 gifted elementary school children with 137 average control children which were matched by social class, age, school, grade, and sex. The findings were quite different from most of those reported above. Comparable family structures and family relationships were found in both the gifted and the control group. Moreover, the fathers and mothers of both groups had the same educational goals, and no differences were found with respect to patterns of parental behavior and parental beliefs.

In any case, Howe (1990) considers the sensitivity of a mother to the unique needs of her child to be a variable of major importance. According to Storfer (1990; see also Browder, 1993) the mothers (or parents) of gifted infants and toddlers initiate more interactions with their children, use more complex language when talking to them, they respond immediately, provide more related ideas. As they are better able to get the undivided attention of their mothers, the firstborn profit most. However, it should be kept in mind that not the total amount of stimulation but the amount of stimulation directed towards the infant or toddler is important. With secondborn children, American parents, for example, use television to a greater extent for stimulation. Howe (1990) pointed out that active, not passive activities are favorable for the development of giftedness.

Based on an example of Jewish families descending from Europe, Howe (1990) describes mechanisms of how giftedness can be fostered by the family environment and background factors such as educational aims, attitude towards achievement, religion, and so on (see also Storfer, 1990). The Jewish families are mostly intact and stable, with two parents at home. Their living circumstances in urban or suburban environments provide good cultural opportunities. As demanded by the Talmud, the fathers are the first to teach their

children and this takes place at an early age. The parents encourage activities that lead to success at school, while little emphasis is placed on sports. The whole lifestyle is one where scholastic activities are enjoyed and respected, the families witness the successful outcomes of sustained efforts to learn new skills. Most interestingly, studying is allowed on the Sabbath but other activities are forbidden.

Roedell et al. (1989) draw the conclusion from research on the family environment of the gifted that parents should spend a great deal of time with their children, read frequently to them, answer their children's questions in a proper way, support their children's own reading attempts and interests, and all in all, demonstrate a positive basic attitude towards intellectual learning. According to Howe (1990), however, girls are often confronted with traditional role models and encounter severe opposition to careers from their families. Encouraging and helping every child to acquire knowledge and skills should be the focus of parental educational efforts. On the other hand, Howe (1990) warns that some parents are too anxious and too ambitious about the development of their children (see also Perleth & Sierwald, 1992).

Discussion

Issues and Problems in the Identification of Young Gifted Children

Before putting the research on indicators of high ability in young children to use for identification purposes, the question needs to be answered of why and for what purpose gifted children in infancy, preschool age, or in the early elementary school years are to be identified. These are, of course, crucial questions and not trivial ones. Usually answers refer to the danger that children who are not identified early are not adequately stimulated so that their gifts will not develop (Karnes & Johnson, 1990). Thus, "the main purpose of identification is to provide educational experiences that can enhance the continuous growth of every gifted child" (Fatouros, 1986, p. 23).

Concerning infants and toddlers, however, Robinson (1987, see also Chapter 27, this volume) is skeptical about the usefulness of early training to force the development of giftedness. Nevertheless the author draws the conclusion "that successful parents are flexible, in tune with their children's progress, and ready to introduce a new idea when the child is ready, but that even those who are most planful also work with the children's own skills" (Robinson, 1987, p. 164). This means gifted children need stimulation, and they may require a variety of material so their intellectual needs can be fully met.

Expanding this to all family, preschool, and primary school education, the task is to find out how every child—whether gifted or not—can be supported by the educational environment for optimal talent development. This implies broad and continual diagnosis of

aspects and state of development of intellectual abilities and skills, motivational characteristics, and learning opportunities available in the educational environment. Such a continuous, non-selective diagnosis and related nurturance of every child corresponding to its individual needs would best help to develop the gifts and talents of all children.

Due to financial and organizational limitations such as individualized education has to be judged utopic and cannot be realized. Thus, fostering of gifted children will also have to take place in special, but relatively homogeneous groups or classes (see Part IV of this volume, especially Chapter 27 by Robinson). A couple of problems are related to the identification and selection of young children for special courses and classes. One problem is the relative instability of abilities and skills of young children, thus making every prediction a risky undertaking.

Fatouros (1986), for example, recommends a sequence of group tests as a screening procedure and an individual test for identifying gifted children following the psychometric approach, but favors a broad approach using a variety of types of diagnostic sources and information on indicators of giftedness. During the screening phase, the use of parents and/or teacher checklists are to be recommended in addition (see Roedell et al., 1989; Mathews & Burns, 1987; Robinson, Chapter 27 in this volume).

Information obtained by checklists, however, has to be used carefully. Especially for young children, the competence of teachers to identify gifted children is often questioned (e.g., Fatouros, 1986) or nearly denied (e.g., Rost, 1993). Rost (1993) also judges peer and self nomination as totally useless for the identification of gifted (primary school) children (also Fatouros, 1986; Gagné, 1989).

Although some authors argue that the best information on gifted preschool children is available from their parents (e.g., Hagen, 1989), according to the results of Johnson and Lewman (1990), parental perception of giftedness indicators in 3- to 4-year-old boys and girls has to be doubted, as the answers of parents showed drastic role stereotypes. While, in comparison with girls, boys are nominated twice as frequently in the category "remarkable abstract thinking", 140% more nominations in "extraordinary curiosity", and 150% more nominations in "problem solving", girls are perceived as possessing a "large vocabulary" (30% more nominations).

As shown above, ability, skills, and knowledge develops in interaction with the child's environment, which is initially the family. Special attention has to be paid to children of risk groups (Heller, 1993): apart from girls, these include, in particular, handicapped children and children from low income homes (Karnes & Johnson, 1990). Especially the latter ones are difficult to identify, whereby the educational level of the parents seems to be the key variable. It is obvious that, with these children, conventional testing as well as the use of

(behavioral) checklists are not suitable. Both of them focus, as a rule, on the child's intellectual status not on its learning potential (Guthke, 1974, 1992). The repeated findings that the most gifted stem from middle or higher classes should be alarming for those engaged in the identification of gifted children.

Practical and Research Desiderata

Early identification of young gifted children necessitates methods which are able to discover those children who promise high achievement in later school or professional careers. With respect to psychometric tests and as well to other early indicators of giftedness described in this chapter or in (behavioral) checklists, this requires first of all high reliability, fairness, and high predictive validity. To prove that a test has sufficient reliability for purposes of identifying promising children, it is not enough to determine its parallel test or consistency reliability. Instead one has to show that the retest reliability is high since the assumption is that the measured trait or indicator is stable over the course of time and that the individual scores do not depend on the moment of measurement. The German WISC-R, for example, shows good consistency but considerably poorer stability so that irreversible selection decisions should be avoided.

For identifying young gifted children, proving prognostic validity of the test and the giftedness indicators used plays a central role. This seems to be a main problem as the predictive power of a method can only be demonstrated in longitudinal studies. In the case of identifying gifted children, such studies would require very large samples and the tracing of the sample over many years. Moreover, all tests and questionnaires should be completed under the supervision of trained researchers, as for example Rost (1993) did in his study. To check the prognostic validity of an instrument, it is not enough to watch a sample of gifted and checking whether they indeed achieve outstanding but it is necessary to do such research with appropriate design including different control groups (if not representative samples). If identification methods are used for selecting children for special programs, for example, at the very least, the levels of achievement which selected children are able to achieve with and without the program need to be examined, as well as the progress made by the non-selected with and without the program.

Therefore longitudinal studies with representative samples are extremely crucial for the evaluation of methods suited for the early identification of gifted children. Unfortunately, such research is difficult to organize, expensive, and requires a great deal of manpower. A possible solution therefore could be to reanalyze data of big representative longitudinal surveys to obtain information on the usefulness of the identification methods (e.g., the British Birth Survey cited earlier). In spite of their primarily pediatric character, such studies

collect numerous variables on the motor and cognitive development as well as on the academic achievement of the children. Their size enables the investigation of groups of gifted children recruited without dubious screening by parents or teachers as has to be done in most giftedness studies for practical reasons.

While most considerations up till now are valid for tests and behavioral indicators of high ability, two additional aspects would be desirable for psychometric methods. The first is the application of probabilistic test theories, for example the Rasch-model, to the construction of tests used for the identification of gifted children. Such tests would enable tailored testing and, in this way, above all lead to higher precision of the test results (see above; Weiss, 1983). Especially with regard to children from underprivileged families, the learning test approach (see above) would help to better fairness of the psychometric methods (Day & Hall, 1987; Guthke, 1992).

If indicators of giftedness—for example in the form of (behavioral) checklists—are employed, effective and practical statistical methods for the combination and weighting of the single information have to be used (see Hany, Chapter 11, and Feldhusen & Jarwan, Chapter 13, this volume). One possibility could be Bayes' rule which combines given probabilities of the occurrence of indicators in gifted and non-gifted children to evaluate the probability that a single child exhibiting some indicators and not exhibiting others is gifted. Modern statistics has provided more methods for combining probabilities. The mechanisms of these should be cautiously examined by practitioners and researchers. For example, especially with extremely seldom events (or indicators) the Shafer–Dempster theory which is widely used in expert systems, produces spurious results and thus seems to be inappropriate for the purpose here discussed.

At any rate, such a combination of probabilities demands knowledge about the frequency of the indicator in gifted and unselected or non-gifted population (or in every group which is diagnostically relevant) and therefore necessitates respective research with representative samples. It should be noticed, that especially with indicators used for checklists, sometimes myths arise and are spread (e.g., Tannenbaum, 1992, cites a table from Lewis & Louis, 1991, who report that Freeman, 1985, found that gifted children are characterized by their sense of humor, although Freeman, 1979, 1985, states the opposite; or see the section on sleep above).

As a quintessence, the literature reviewed and possibilities described in this chapter show that identification of young gifted children is problematic. Psychometric measures as well as diverse indicators of giftedness have up till now not proven to be suitable to identify these children who promise exceptional achievements later in school or in professional career. As early as 1896, the German founder of the experimental psychology, Wilhelm Wundt (1914) wrote: "The experimental method is almost without application

for early childhood, and the results of experiments which have nevertheless been undertaken should be more or less considered purely coincidental because of the unbelievable weighting of error sources" (p. 364). Even if, nevertheless, much research with high standards has been undertaken, psychometric measures as well as diverse indicators of giftedness have—to date—not proven to be suitable for identifying those children who promise exceptional achievements later in school or in professional life.

Aside from possible principal obstacles to early identification, this is due to a considerable lack of appropriate research. There are too few prospective longitudinal studies and too few studies with representative samples or at least with adequate control groups. Giftedness research in young children too often fall back on to samples of counseling centers with their highly preselected clientele, thus finding and generalizing results which are not representative for the population of gifted children (see for example, the different results which Freeman, 1979, found for her gifted target and her gifted control group). In addition, too little effort in giftedness research is made in minority groups, in underprivileged children, in the handicapped, and in other risk groups. A possible way out of this dilemma could be the reanalysis of data from large surveys and other representative studies at least to generate hypotheses which can be tested in following giftedness studies.

Acquiring Expertise: Determinants of Exceptional Performance

WOLFGANG SCHNEIDER

University of Würzburg, Germany

Introduction

This chapter focuses on the respective roles of cognitive ability and domain-specific knowledge in predicting exceptional performance. Since the beginning of this century, educational researchers and psychologists have tried to locate the sources of outstanding (academic) behavior and performance. At least two different ways of tackling this problem can be distinguished.

The earlier research paradigm explored the impact of giftedness on exceptional performance. According to this scientific approach, general intellectual abilities assessed in early childhood or adolescence strongly influence later academic or professional performance. As noted by Ericsson and Smith (1991), this approach is guided by the basic belief that behavior is predominantly influenced by inherited qualities. The paradigm seems particularly attractive because of its implicit assumption that only a few general, basic abilities are sufficient to predict and explain a large variety of specific performances. The longitudinal study of gifted children carried out by Terman and his colleagues (to be described below) is representative of this line of research (cf. Terman, 1925, 1954; Oden, 1968).

A second, more recent scientific approach differs from the giftedness paradigm in that exceptional performance is assumed to be primarily acquired. Accordingly, specific educational experiences and intensive as well as extensive domain-specific training and practice determine the acquisition of skill in particular domains. General abilities play a minor role in this explanatory approach (cf. Anderson, 1990; Ericsson & Crutcher, 1990). Since the late sixties, the study of expertise has attracted many researchers interested in human information processing. In particular, research on chess expertise has enriched our knowledge about the acquisition of domain-specific skills and the preconditions for outstanding performance in this domain.

Given the popularity of the expertise approach in current cognitive psychology, the merits of research on the impact of early intellectual ability on later academic performance seem dubious. Proponents of the expertise approach (e.g., Ericsson & Crutcher, 1990) claim that individual differences in intellectual ability do not account

for much of the variance in exceptional performance. Difficulties with evaluating this view are related to theoretical problems, that is, problems with defining and operationalizing intelligence and cognitive ability. Recent reviews on this issue emphasize the fact that research on intelligence has abandoned traditional lines, focusing on cognitive task analysis, processing strategies and features of context (see Ceci, 1990; Gruber & Mandl, 1992).

Although there seems to be broad agreement in the contemporary literature on exceptional performance that the old concept of basic intellectual ability has lost its importance and should be replaced by the concept of acquired skill, the relationship between cognitive ability and the acquisition of expertise has not been sufficiently considered in most of these studies. It is the major purpose of this chapter to explore this relation in more detail. In a first section, developmental research on giftedness and its impact on later performance is briefly reviewed. Next, an overview of research dealing with expertise in adulthood is provided. After a summary of the most important findings, theoretical assumptions and models concerning the process of acquiring expertise derived from this research with adults will be discussed in more detail. In the next section, developmental research on knowledge acquisition based on research with children will be reviewed. Here, the basic goal is to assess the generalizability of findings from work with adult experts to child samples and to broaden the perspective by adding data from prospective studies on the development of expertise to the predominantly retrospective inferences of acquisition processes derived from studies with adults. In the final section, theoretical models are introduced that describe possible relationships between aptitude and the acquisition of expertise.

Prospective and Retrospective Approaches Explaining Giftedness and Exceptional Performance

Prospective Studies

As noted above, the well-known Terman Gifted Children Study can be conceived of as the most impressive

attempt to explore the predictive power of high intellectual ability for subsequent academic performance and success in later life. In this study, about 1500 young Californian children with an IQ of 135 and above were recruited in the early twenties of this century and followed up until recently. Although the theoretical focus of the study changed over the years, the body of data seems suited to evaluate the relevance of high aptitude for academic and professional performance. At first glance, the findings seem to support Terman's expectations: On average, the gifted children performed very well in school and were rather successful in later life. However, a closer look at the findings revealed that the expected collection of "eggheads" and outstanding personalities was not found (cf. Sears, 1984). As noted by Howe (1982), the data collected by Terman and his colleagues provided little information that would have helped one to predict which of the children under study would be most successful in later life. Thus the conclusion to be drawn from this study is that educational achievement and success in life cannot be sufficiently predicted by indicators of high intellectual ability measured at an early point in time.

Further research indicated that the quality of the IQ predictor does not change much when aptitude is assessed considerably later, that is, during the college years (cf. Samson, Grane, Weinstein, & Walberg, 1984). In this study, an average correlation of about .15 was found between college students' aptitude and their professional productivity assessed several years later, indicating that the subsamples representing "schoolhouse giftedness" and "production giftedness" do not have much in common (cf. Siegler & Kotovsky, 1986). Obviously, information about intellectual ability alone does not allow for reliable predictions of later academic and professional success.

Retrospective Studies

Another line of research focused on subjects with reliably superior performances, with the goal to reconstruct their cognitive and noncognitive abilities. Most of that research was similarly motivated by the belief that exceptionally high levels of performance should reflect some basic cognitive ability like general intelligence, attention, or memory (e.g. Cox, 1926). Some researchers studied other stable individual characteristics, such as aspects of personality and motivation (Roe, 1952, 1953). In short, the results of these retrospective studies seem to confirm the outcomes of the prospective studies in that individual differences in intellectual abilities did not show up as the crucial determinant of outstanding professional careers. For example, Roe's analysis of the careers of outstanding scientists showed that noncognitive factors like endurance, concentration power and commitment to work turned out to be more important for professional success than the individuals' cognitive abilities,

despite the fact that the latter were generally above average.

More recently, Roe's findings were confirmed in an interview study with excelling scientists, sportsmen and artists organized by Bloom (1985). The data obtained from these subjects and their parents did not support the view that outstanding basic abilities were solely responsible for success in later life. Instead, the study provided strong evidence that no matter what the initial gifts or basic abilities of the individuals, extreme levels of capabilities in their fields of expertise were not attained unless there was a long and intensive process of encouragement, education and training. Bloom concluded from these findings that his research has raised serious questions about earlier views of special gifts and innate aptitudes as necessary prerequisites of talent development (1985, p. 3).

Taken together, prospective and retrospective studies focusing on the impact of intelligence and other stable cognitive factors on academic and professional success have been largely unsuccessful in identifying strong and replicable relations (see Ericsson & Smith, 1991, for more evidence on this issue). Instead, most of these studies have shown that noncognitive factors like motivation, concentration and endurance as well as parental and school support systems seem responsible for exceptional performances in later life.

Evidence From the Expertise Approach

Studies With Adult Experts and Novices

Undoubtedly, the pioneering work on chess conducted by de Groot (1946, 1978) and Chase and Simon (1973) has stimulated numerous studies on the nature of expertise. For most cognitive psychologists, an approach based on acquired characteristics seems much more suited to account for outstanding and superior performance than research on giftedness relying on stable inherited characteristics. The game of chess appears particularly attractive for researchers interested in the preconditions of outstanding performance because it is rather easy to produce and observe outstanding performance under standardized conditions. One advantage of this game over others is that it is possible to measure a subject's chess-playing ability from the results of matches against different opponents in different tournaments (cf. the index developed by Elo, 1978). Another, related advantage is that groups of chess players differing reliably in chess skill can be easily selected. As chess skill can be measured with remarkable precision, the domain of chess seems ideal for the study of acquired skill. Models of chess skill have strongly influenced investigations of expertise in other domains like physics, medical sciences, music and sports. The most important findings concerning cognitive and noncognitive characteristics of expertise in chess and these other domains will be discussed below. Before doing so, however,

general theoretical and methodological problems with the expertise approach will be briefly summarized.

PROBLEMS WITH THE EXPERTISE APPROACH

Despite its obvious advantages, the expertise approach still suffers from several problems. One of the problems is that the term "expertise" has a number of popular definitions, which all are somewhat vague (cf. Gruber, 1991; Saltouse, 1991). Although the broadly accepted definition that expertise refers to extreme or exceptional performance implies that the evaluation of expertise should represent some measure of actual competence, rather than a possible correlate of competence such as amount of experience, the categorization of a subject as an expert is still relatively arbitrary given that researchers disagree with regard to the particular level of competence that qualifies one as an expert. Although attempts to specify subcategories of expertise like layperson, novice, intermediate, subexpert and expert (cf. Patel & Groen, 1991) seem to represent an improvement, this classification does not solve the problem because the boundaries between categories remain unknown. In many empirical studies, the definition problem becomes obvious when the median of the distribution of a competence measure is taken as the critical boundary for expert-novice distinctions.

As noted by Ericsson and Smith (1991), another critical issue in the expertise approach is how to identify standardized tasks that will allow the real-life outstanding performance to be reproduced in the laboratory. As our knowledge of complex domains of expertise like writing, physics, or medical reasoning is incomplete, it seems impossible to specify a population of tasks to capture such expertise. The problem is also apparent in the domain of chess. For example, de Groot (1978) designed the task of selecting the best move for a number of different chess positions in order to simulate "real-world" problem solving behavior. Although the task seems valid at first glance, its problems relate to the fact that it is very difficult—if not impossible—to evaluate the quality of chess moves for an arbitrary chess position (cf. Ericsson & Smith, 1991). Given the vast number of possible sequences of moves and the fact that chess players employ a wide variety of chess-playing styles, it seems impossible to identify a single "best" move. Despite these obvious problems, however, it should be noted that de Groot was able to localize a few differences in cognitive processes between the grand masters and the other class experts in his study, by analyzing think-aloud protocols from his best-next-move task. Although the ecological validity of the task remains uncertain, it at least can be used to illustrate differences in thinking processes of more or less eminent chess players.

The same validity problem also holds for the various memory tasks repeatedly used in studies of expertise. Undoubtedly, performance on such tasks (i.e., recall or recognition) is much easier to evaluate than, for

example, a protocol of thinking processes obtained for the next-best-move task. It is questionable, however, whether those aspects of memory assessed in the laboratory really capture the crucial features of expertise in real-life situations. The reader should keep in mind that despite the popularity of the expertise approach, these problems have not been solved yet.

PERFORMANCE DIFFERENCES BETWEEN EXPERTS AND NOVICES

In the classic studies by de Groot (1946, 1978) and Chase and Simon (1973), exceptional performance in the domain of chess was linked with exceptional memory for information related to that domain. In order to capture skill differences in chess, de Groot used a task that assessed memory for briefly presented chess positions. He found that when chess masters were shown a chess position consisting of 20–30 pieces for a very brief duration (e.g., 5 seconds), they were able to remember the position far better than less experienced chess experts. Chess masters were able to recall the positions of all pieces virtually perfectly, whereas the positions recalled by the less experienced chess experts ranged from 50–70%.

Chase and Simon (1973) followed up de Groot's finding that there were major memory differences in regard to recall of briefly shown game positions. They added an important control, showing expert and novice players also random arrangements of pieces. As the experts' advantage in recall with structured positions disappeared when random positions were reconstructed, it could not be attributed to superior visual short-term memory on the part of the experts.

In order to understand the chess master's recall superiority for meaningful chess positions, Chase and Simon attempted to uncover the structure of his chess knowledge. They showed that the recall advantage depended on the master's ability to recognize familiar patterns or "chunks". That is, the master was able to recall pieces more effectively than the novice because groups of pieces, rather than single pieces, formed his chunks. According to this finding, quantitative differences in the memory performance of experts and novices can be largely explained by *qualitative differences* in memory behavior.

Research on expert-novice differences in the use of complex knowledge in other domains like electronics or architecture has also revealed the importance of higher-order chunk structures for superior performance (cf. Chi, Glaser, & Rees, 1981). Although the notion of chunking as a major determinant of expert-novice performance differences seems broadly accepted in the literature, findings from more recent studies have seriously questioned the assumption that chunking affects experts' short-term memory. Carefully designed studies of superior memory performance for chess positions have shown that experts store information about chess positions in long-term memory, not solely in short-term

memory as Chase and Simon (1973) originally proposed (see for a review Charness, 1991). These findings do not cast doubts on the basic assumption that there are qualitative differences in memory behavior of experts and novices. However, they indicate that Chase and Simon's (1973) original theoretical assumptions need to be replaced by more sophisticated views of skilled memory like those by Chase and Ericsson (1982; see also Ericsson & Staszewski, 1989), stressing the importance of domain-specific, easily activated retrieval structures in recall performance.

Qualitative differences in the problem-solving and memory behavior of experts and novices have also been reported in studies dealing with other domains like physics and medical diagnosis and reasoning (see Anzai, 1991; Chi, Glaser, & Rees, 1981; Patel & Groen, 1986, 1991). Evidence on such differences has been based on tasks different from those used in the domain of chess.

Basic differences in problem representations between physics experts and novices were suggested in an experiment by Chi, Feltovich, & Glaser (1981). Chi et al. were able to show that experts and novices in physics differ in their categorization of physics problems: Whereas experts classified the problems with respect to underlying principles, novices tended to use superficial meanings of words and diagrams for the purpose of classification. Expert–novice differences in the domain of physics can also be seen in procedural knowledge for problem solving. For example, Simon and Simon (1978) found blatant qualitative differences in experts' and novices' solution processes. That is, experts solved problems in a "forward" way from the given data to the goal, whereas novices tried to solve problems in a "backward" way, starting from the goal (e.g., an equation containing the unknown of the problem) in search for appropriate data to satisfy each subgoal. Although this finding seems counterintuitive at first glance given that the novices appear to use the more sophisticated strategy, there are at least two explanations accounting for the experts' problem solving behavior. The first is that experts know that they can achieve the goal simply by direct calculations of the unknowns from the given. Another interpretation is that experts do not require complex planning for simple tasks. Evidence for this explanation stems from research showing that experts change to very sophisticated means-end analyses when the physics problems become more difficult (Larkin, McDermott, Simon, & Simon, 1980). In summary, the studies on expert–novice differences in the domain of physics thus show that the superior performance of experts on a variety of problem solving tasks is mainly due to the experts' well-organized declarative and procedural knowledge. As a consequence, performance differences between experts and novices can be explained by qualitatively different strategies.

Further empirical evidence concerning qualitative differences in the way experts and novices recall and comprehend domain-related information stems from studies on medical expertise (cf. Lesgold, 1984; Patel & Groen,

1986, 1991). The work by Patel and colleagues seems related to the research on expertise in physics outlined above in that one focus of expert–novice comparisons was on reasoning strategies. Patel and colleagues used a basic experimental procedure where subjects were presented with a written description of a clinical case and were asked to study the text for a specific period of time, after which it was removed. The dependent measures used in the various experiments on medical expertise were free recall, diagnosis and diagnostic explanation. Diagnostic explanation was included to identify the direction of the reasoning strategy (forward or backward method). Here, subjects were requested to explain the pathophysiology (causal patterns) underlying the clinical case.

Based on their fine-grained classification of expertise (i.e., laypersons, beginners, novices, intermediates, subexperts and experts), Patel and colleagues analyzed differences among the subgroups concerning recall, diagnosis and reasoning strategy. When experts and subexperts were compared on these measures, no recall differences were found. Below that level of expertise, substantial recall differences could be demonstrated (i.e., for the novice and intermediate subgroups). On the other hand, diagnostic accuracy was considerably higher in the experts, as compared to the subexperts (for confirming evidence, see also Lesgold, Glaser, Rubinson, Klopfer, Feltovich, & Wang, 1988). In addition, forward reasoning was closely related to diagnostic accuracy. Patel and colleagues inferred from their results that diagnostic accuracy is monotonically related to expertise, whereas recall performance is nonmonotonically related to expertise. Reasoning strategies, on the other hand, should be considered an all-or-none phenomenon that may be related to the two extremes of the expert–novice continuum.

Taken together, research on expertise in different domains like chess, bridge, music, has shown that experts display superior memory performance for stimuli from their domain of expertise when adaptations of Chase and Simon's (1973) original procedure have been used (for a review, see Ericsson & Smith, 1991). Other studies using the expert–novice paradigm have shown superior recall of domain-related information as a function of the subject's amount of knowledge of the domain. Examples include the domains of baseball and soccer (e.g., Voss, Vesonder, & Spilich, 1980; Morris, Tweedy, & Gruneberg, 1985). Most of these studies have found evidence supporting a monotonic relation between recall of domain-related information and domain-specific knowledge. They have also supported the view that the main differences among experts and novices in a wide range of domains concern the speed of access to relevant knowledge as well as the sophistication of knowledge-based strategies.

THE ROLE OF BASIC ABILITIES

What do the studies on expertise tell us about the *impact of basic abilities* on exceptional performance? The empirical evidence for such an influence is rather scarce.

In the case of exceptional chess performance, superior spatial ability often was assumed to be important (Chase & Simon, 1973; Holding, 1985). However, a recent study by Doll and Mayr (1987) does not confirm this view. Doll and Mayr compared about thirty of the best chess players in Germany with those of about ninety normal subjects of similar ages, using an IQ test with seven subscales. As a main result, Doll and Mayr (1987) found no evidence that chess players were selectively better on spatial tasks. In general, the relation of IQ to outstanding performance seems rather weak in several domains (for a review, see Ericsson & Crutcher, 1990).

Although general abilities do not seem to make a major difference, the results of several studies suggest that *special abilities* like speed of information processing or basic memory abilities could be a source of individual differences. Regarding reaction times, for instance, it has been repeatedly shown that experts are faster and more accurate than less experienced subjects. A closer examination of these studies, however, does not confirm the view that experts outperform novices with regard to information processing speed. For instance, it was shown that experts' superior speed in their domain of expertise does not transfer to other tests of speed, like simple reaction times, or to general tests of perception (cf. Starkes, 1987).

Similarly, the exceptional memory performance shown by many experts for materials from their domain does not generalize to materials outside their domain, as demonstrated by Chase and Simon (1973). Studies focusing on exceptional memory performance have described in detail how subjects with initially normal memory skill acquired exceptional memory skill through extensive practice (cf. Chase & Ericsson, 1982; Staszewski, 1988, 1990). In these studies, subjects were provided with several hundred hours of practice on the classic digit-span task. After 50–100 hours of practice, subjects were able to increase their digit spans from about 7 to over 20 digits. Subjects going through a very extensive training program were even able to attain digit spans of over 100.

How was it possible to acquire this skill? The explanation is that these subjects were experienced long-distance runners with a rich knowledge base for running times. They were able to use their knowledge for recoding and interpreting incoming digit sequences as specific running times. The fact that exceptional memory performance can be successfully trained was further demonstrated in a recent study by Kliegl, Smith and Baltes (1986). Kliegl et al. trained young and old adults to memorize digits using phonemic recoding of digits into concrete words, which were stored in long-term memory using the ancient "method of loci". It could be shown that with extensive training, speed of memorization dramatically increased, approaching a rate of 1 digit per second.

Accordingly, exceptional memory performance demonstrated by many experts cannot be attributed to inherited basic abilities but has to be conceived of as an acquired

competency, that is, as an outcome of extensive practice and training in the domain of expertise. This competency was labeled "skilled memory" by Chase and Ericsson (1982) who identified three basic principles in the acquisition process. First, information is meaningfully encoded in terms of knowledge structures in semantic memory. Second, retrieval cues are constructed during the encoding process, which are explicitly associated with the encoded information and can be easily retrieved from long-term memory. Third, encoding and retrieval processes can be considerably accelerated by extensive practice. As a consequence of long training, the speed of these encoding and retrieval processes are assumed to approach those observed in short-term memory.

All in all, research dealing with the relevance of biological dispositions, innate talent and basic abilities for exceptional performance has been rather unsuccessful in establishing such relationships. The best evidence for the importance of inherited characteristics comes from the domain of sports, for example, the domains of basketball or gymnastics, where anatomical characteristics such as height obviously make a difference. For a few abilities, such as perfect pitch in music, tapping speed in the case of typists and specific abilities revealed by children and idiots savants, innate "talent" may be a plausible explanation. However, recent research on expert performance has convincingly shown that exceptional performance in many fields is primarily due to a vast body of acquired knowledge and experience as well as to acquired skills (Ericsson, Krampe, & Tesch-Römer, in press).

What follows from this is that practice plays a crucial role in the acquisition of expertise. Across a wide range of tasks, improvements in performance seem closely related to the amount of practice. Reviews of skill acquisition indicate that the relationship between performance and practice is monotonic (Anderson, 1982; Newell & Rosenbloom, 1981) and that a power function provides a very good fit for a variety of tasks and skills.

However, taking the amount of practice as the only important predictor of performance probably oversimplifies the problem. Our everyday experiences show that not all people practicing and working extensively in a specific domain end up as eminent experts in that area. Similarly, observations from laboratory experiments have indicated that providing motivated subjects with repeated exposure to a task does not ensure that they will attain the highest levels of performance on that task (Chase & Ericsson, 1981). In particular, inadequate strategies often account for suboptimal performance. The available evidence indicates that subjects can either discover or deduce superior strategies for performing tasks, or learn them through instruction. For instance, the training study by Kliegl, Smith, and Baltes (1989) showed that subjects were able to improve rapidly and attain exceptional levels of performance only after being instructed to use adequate strategies. Thus the *amount* of practice may be a necessary but not sufficient condition

for expert-level performance. Obviously, the *intensity* and *quality* of practice are at least equally important in order to reach ambitious goals. Recent theoretical models dealing with the acquisition of expertise have tried to take these different aspects of practice into account.

Theoretical Models Describing the Acquisition of Expertise

MODELS OF SKILL ACQUISITION

There have been several models of skill acquisition in the literature. The classic model developed by Fitts and Posner (1967) proposed three different acquisition stages: The “cognitive stage” can be characterized by an effort to understand the task demands and to distinguish between important and unimportant aspects of the task. The focus is on the acquisition of declarative knowledge about the task. The “associative stage” involves making the cognitive processes more efficient to allow rapid retrieval, thus transforming declarative knowledge into procedural forms. During the third and final phase, labeled the “autonomous stage”, performance is automatic and conscious cognition and control is minimal. See Anderson (1982) for a similar theoretical model.

Although these models of skill acquisition have been attractive for many researchers in the field, stimulating much important research, it remains unclear whether the learning mechanisms and developmental stages they propose do generalize from adult learners to children. We know from numerous reports on the careers of chess experts, eminent musicians, or world-class tennis players that these individuals have started their careers at a very early point in life, that is, between 6 and 10 years of age (e.g., Bloom, 1985). We also know from several sources that the time between experts’ first experiences with their domain of interest and attaining international-level performance is about 10 years (Chase & Simon, 1973; Krogus, 1976; Sosniak, 1985). As pointed out by Ericsson and Crutcher (1990), this 10-year rule is supported by data from a wide range of domains, including sports, music, chess and science.

Given that the attainment of exceptional performance in real life usually takes place in childhood and adolescence, it seems important to identify the learning mechanisms, rules of practice and support systems that enable this rapid development. Recent research conducted by Anders Ericsson and his colleagues (Ericsson, 1990; Ericsson & Crutcher, 1990; Ericsson, Tesch-Römer, & Krampe, 1990; Ericsson et al., in press) has led the authors to propose a theoretical framework for the acquisition of expert-level performance. The attractiveness of this model stems from the fact that hypotheses about the developmental history and practice intensity of expert-level performers have been systematically

evaluated against empirical evidence on exceptional performances in various domains.

A THEORETICAL FRAMEWORK FOR ACQUISITION OF EXPERT-LEVEL PERFORMANCE: THE ROLE OF DELIBERATE PRACTICE

The model presented by Ericsson and colleagues differs from the skill acquisition models presented above in that it explicitly considers developmental issues within a life-span perspective. Whereas skill acquisition has, for the most part, been studied with college students, most information relevant for Ericsson’s theoretical framework stems from observations and retrospective reports dealing with performances in childhood and adolescence.

Ericsson and colleagues adopt and extend the basic characteristics of a framework first developed by Bloom (1985b). Accordingly, the preparation period for reaching exceptional performance can be conceived of as a sequence of states, each representing rather stable characteristics for a specific time period in the individual’s life. The first stage corresponds to the playful introduction to the domain, the second to the start of systematic practice supervised by a coach or a teacher and the third and most crucial stage to attaining exceptional levels of performance (cf. Ericsson et al., 1990).

This model suggests that the type and intensity of training may differ as a function of developmental stage. Whereas it is most important to keep children motivated and interested in the domain during the first stage, methods of instruction and the quality of teachers become more relevant with increasing levels of performance. An early start as well as parental interest and support seem particularly important for the earlier stages. With increasing skill, factors like availability of excellent instruction, quality of practice equipment and access to practice facilities become most relevant. As noted by Bloom (1985b), performers at an international level have almost always been instructed by master teachers who themselves had once achieved that level.

Ericsson et al. (1990) provide multiple evidence from the domains of chess, sports and music that is in accord with the core assumptions of this model and that shows surprising parallels in developmental patterns observed across these domains. For example, the available data indicate that the average starting age for exceptional performers is uniformly young across the three domains (about 7 years of age), with the best performers on average having the youngest starting ages. Similarly, retrospective estimates consistently showed that the amount of practice increases as a function of age and expertise, regardless of domain. It appears that systematic practice is most often initiated by parents, who very actively support and reward the acquisition of practice habits. Increases in the weekly amount of practice occur throughout adolescence and reaches

its peak around the age of 20. In most studies, the reported amount of practice was often highly correlated with levels of performance and comparable amounts of practice were reported for subjects of the same performance level across domains. The empirical evidence collected and discussed by Ericsson et al. (1990) not only supports Bloom's original assumptions but also extends the findings by Bloom (1985b) and his collaborators, in so far as performers at levels below international level were shown to engage in less practice.

One apparent problem with this account is that it focused on the *extent* of practice, although individual differences in the *intensity* of practice were also observed. In a more recent review paper, Ericsson et al. (in press) take care of this problem in that they focus on the role of *deliberate* practice. This term refers to practice activities that aim at maximizing improvement. Deliberate practice is conceived of as a highly structured activity which requires effort and is not inherently enjoyable. According to Ericsson and Krampe, individuals are motivated to engage in deliberate practice only because practice improves performance, not because of monetary reward.

Ericsson and colleagues point to several methodological problems involved in demonstrating the fact that performance changes as a consequence of deliberate practice. During the first decade of preparation necessary for attaining exceptional performance, many aspects of training and evaluation change. It is important to note here that one reason for the difficulty to predict adult performance from early performance is that the criteria used to evaluate performance change with increasing level of performance. For example, whereas beginners in the domain of music are mainly judged on their technical skills, expert adult performers are predominantly judged on their interpretation and their ability to express emotions through music (Sloboda, 1991). Similar considerations may explain why mathematical prodigies can be unsuccessful as adult mathematicians.

According to the theoretical framework established by Ericsson and colleagues, other constraints inherent in the attainment of exceptional performance concern resources, effort and motivation. In many cases, it has been shown that parental support is a major variable and that extraordinary commitments by parents may be necessary to cope with the demands (cf. Bloom, 1985b). Further, as deliberate practice requires effort, fatigue is a frequent result. The success of deliberate practice seems to depend on a careful balance of intensive practice and recovery. Disregard of the effort constraint on deliberate practice may result in maladaptation, injury and even failure. Finally, as deliberate practice is not inherently enjoyable, the motivational constraint has to be given special attention. The loss of the goal to improve can have different causes. Problems with external support may be as relevant as problems due to a temporary stagnation of performance despite continued practice. These problems seem particularly related to the initial stages of the preparation period and may loose

their importance when individuals get more involved in a domain. As noted by Ericsson et al. (in press), at this point the motivation to practice becomes closely connected to the goal of becoming an expert performer and integrated in the daily routine.

The framework presented by Ericsson et al. (in press) differs from earlier views in that deliberate practice is the important factor mediating the observed relation between experience, full-time engagement and exceptional performance. Accordingly, extended experience or practice (the 10-year rule) is necessary but not sufficient for attaining the highest levels of performance in a domain.

In an attempt to test the validity of this framework, Ericsson et al. (in press, Study 1) compared three groups of elite, adult violinists regarding their current and past levels of deliberate practice. The group labeled "the best violinists" were rated by music professors as having the potential for careers as international soloists. The music professors also nominated a second group of "good violinists" with less potential but still very promising perspectives. A third group of students with comparably lower admission standards were called "the music teachers" because teaching was the most likely future profession for this group.

It was predicted that the highest improvement of performance and indirectly the highest attained performance, should be associated with the largest weekly amounts of deliberate practice. The assumption was that even among individuals with more than 10 years of practice, performance should be closely related to the amount of deliberate practice.

The analysis of interview data concerning the amount and distribution of deliberate practice confirmed this assumption. The best violinists estimated more practice hours per week than the good violinists during early adolescence and more than the music teachers during their entire developmental period. Regarding the diary data which included the practice hours for a full week, clear differences between the music teachers and the two best groups, but no differences between the two best groups were found. Also in accord with the expectations, the top violinists rated sleep as highly relevant for improvement of violin performance. As a matter of fact, the two best groups of violinists with the highest levels of deliberate practice were found to nap more in the afternoon than did the group of music teachers. All in all, the results of this study are in line with the predictions derived from the theoretical framework developed by Ericsson and colleagues.

In their discussion of results, Ericsson et al. (in press) emphasize the fact that individual differences in expert performances should not be attributed to individual differences in natural, innate abilities. Instead, they argue that expertise has to be conceived of as the result of extensive and intensive practice activities and that individual differences in ultimate performance can be accounted for by differential amounts of past and current levels of practice. The claim is that once individuals have

started deliberate practice, it is virtually impossible to distinguish the role of natural, innate ability from that of acquired skill in their current level of performance. According to Ericsson and colleagues, it is not the innate talent but rather the *perception* of talent that motivates parents to invest time and money to support deliberate practice. Needless to say, perceptions of talent should not be equated with objective indicators of innate ability.

Although Ericsson et al.'s theoretical framework for the acquisition of expert-level performance seems impressive and well-suited to account for much of the empirical evidence on the causes of exceptional performance, one possible problem with the empirical evidence described above is that it mostly consists of cross-sectional studies predominantly dealing with retrospective estimates of past behavior and interview data obtained from adults. In our view, prospective studies carried out with child experts and novices may add substantially to our knowledge about the origins and determinants of exceptional performance, particularly as far as the role of domain knowledge and basic abilities is concerned. As a consequence, the empirical evidence on determinants of exceptional performance based on cross-sectional as well as longitudinal developmental studies with child experts and novices will be summarized next.

Studies With Child Experts and Novices

Most developmental studies using the expert–novice paradigm focused on the impact of domain-specific knowledge on memory. In the field of memory development, numerous studies conducted during the past two decades have demonstrated the importance of the knowledge base for various aspects of memory performance (for reviews see Chi & Ceci, 1987; Schneider & Pressley, 1989). According to many developmental researchers, the knowledge base seems to be one of the crucial sources of memory development in childhood and adolescence, probably outweighing other relevant factors like capacity, strategies, or metamemory (cf. Bjorklund, 1990; Siegler, 1991). Although the number of developmental studies based on the expert–novice paradigm is still small, as compared to the number of studies on expertise with adults, their findings have attracted much attention in the developmental literature. In the next section, developmental studies focusing on the role of knowledge will be presented first, followed by those studies that explored the importance of basic ability in addition to that of the knowledge base.

DEVELOPMENTAL STUDIES EXPLORING THE IMPACT OF DOMAIN KNOWLEDGE ON PERFORMANCE

From a developmental perspective, the major advantage of the expert–novice paradigm is that knowledge and chronological age are not necessarily confounded. It is

not only possible to recruit adult chess novices but also to find young chess experts for experimental studies. The classic developmental study was conducted by Chi (1978) who recruited experienced and inexperienced chess players and gave them Chase and Simon's chess board reconstruction task (see above). The most interesting aspect of this research was that subjects' knowledge correlated negatively with age; the children were the experts and the adults were the novices. As a main result, Chi found that the children's short-term memory for chess positions was superior to that of the adults. On the other hand, the typical adult superiority in short-term memory capacity could be demonstrated for the memory span control task, dealing with a domain (i.e., digits) that adults were more familiar with. Chi concluded from her results that short-term memory capacity was not inherently a function of the subjects' age, but rather of their knowledge. The most impressive finding was that the impact of the knowledge base on recall resulted in a reversal of the typical age effect.

From a methodological point of view, both the small sample size of Chi's study and the fact that only two of the four possible groups (i.e., child and adult experts and novices) were included called for a replication and extension of Chi's work. Two subsequent developmental studies on chess expertise (Roth, 1983; Opwis, Gold, Gruber, & Schneider, 1990) found supportive evidence. Roth (1983) did not assess memory performance but tested child and adult experts and novices on a chess board comparison task. The magnitude of the knowledge effect was sufficient to eliminate any significant differences between child and adult experts. Further, the knowledge effect accounted for between-age group differences in that child experts outperformed adult novices. Thus Roth's findings for the area of perceptual speed seem to validate Chi's results obtained for short-term memory processes.

In the study by Opwis et al. (1990), groups of child and adult chess experts and novices were compared on various chess board and control board reconstruction tasks which included both replications and extensions of Chi's original work. The major extension concerned a procedure that aimed at identifying possible sources of the experts' superior memory performance. Opwis et al. believed that several aspects like the experts' greater familiarity with the constellation of chess pieces on the board (i.e., meaning of constellations) and their greater familiarity with the characteristics of the chess board (i.e., geometrical pattern, form and color of chess pieces) all contribute to superior performance. They expected all these factors to be effective in the meaningful chess board reconstruction task. The effects of expertise on performance should be considerably smaller (but still significant) in the random board reconstruction task because only familiarity with the basic characteristics of the chess board was assumed to be greater for the experts, as compared to the novices. Finally, no performance differences between experts and novices were expected for a control task that required

the reconstruction of wooden pieces on a board that had little in common with a chess board.

The results of the study basically confirmed these assumptions. Similar to the findings by Roth (1983), no performance differences between adult and child experts were found. Expert–novice differences on the chess board reconstruction task were most pronounced for the meaningful chess positions and considerably smaller but still significant for the random board positions. In accord with their hypothesis, Opwis et al. found that experts and novices did not differ in immediate reconstruction of items on the control board. Opwis et al. concluded from this finding that experts' performance on the chess board reconstruction tasks is facilitated by the two context factors described above. Probably due to these factors, experts are able to process information faster and in larger semantic units.

Although the results were inconsistent with those by Chi (1978) and also Chase and Simon (1973) in that no pronounced expert–novice differences in chunking were observed based on inter-response latency measures, the analysis of videotapes suggested qualitative differences in the reconstruction strategies used by the expert and novice groups. While most experts seemed to start with the reconstruction of specific meaningful units, the novices focused on aspects like color of pieces or specific positions on the board. From a developmental perspective, it seems particularly interesting that no qualitative differences in the strategies of the child and adult experts were detected.

Taken together, the findings from the developmental studies on chess expertise corroborate those obtained from studies dealing with expert/novice differences in adults in that performance differences can be attributed to qualitative differences in strategic processing. Due to their rich knowledge base, child experts seem to process information in a way very similar to that of adult experts. Although most developmental studies did not focus on the interplay of knowledge components (i.e., declarative and procedural knowledge) in the determination of performance, a recent developmental study on expertise in tennis (McPherson & Thomas, 1989) provides information on this point. McPherson and Thomas compared expert and novice tennis players (10–11 and 12–13-years-old) on tennis performance and tennis knowledge. Declarative knowledge about tennis was related to the development of procedural knowledge, that is, the quality of decisions and selection of actions made within the context of a game. Regardless of age, both knowledge components discriminated between experts and novices and were significantly related to tennis skill.

The developmental studies on expertise discussed above all have demonstrated the fast development of domain-specific knowledge in child experts and its close relationship to performance in the domain of interest. However, they do not inform about the relative importance of ability because this variable was not included in the design. As a matter of fact, only a

small number of developmental studies considered the impact of basic ability intelligence on performance in addition to that of domain knowledge. These studies will be summarized next.

DEVELOPMENTAL STUDIES EXPLORING THE IMPACT OF APTITUDE AND KNOWLEDGE ON PERFORMANCE

A series of developmental studies investigated the importance of domain knowledge and general ability for processing of text information related to the domain of expertise. They can be conceived of as replications and extensions of studies on text processing carried out with adults. As already mentioned above, Jim Voss and his colleagues (Spilich, Vesonder, Chiesi, & Voos, 1979; Voss et al., 1980) had used this paradigm in their studies on expertise in baseball. Voss and colleagues assessed subjects' declarative knowledge about baseball in order to form groups of baseball experts and novices. Next, a passage dealing with a baseball game was presented, which had to be recalled some time later. Not surprisingly, the baseball experts recalled more information than the novices. The more interesting finding was that the quality of experts' and novices' recall protocols differed considerably. Whereas the baseball novices recalled as much unimportant as important information, the experts mostly recalled important information.

A group of researchers at the Max Planck Institute for Psychological Research in Munich adopted this paradigm for developmental studies with soccer experts (see Körkel & Schneider, 1992; Schneider, Körkel, & Weinert, 1989, 1990). More than 500 third, fifth and seventh graders participated in this project. According to their performance on a questionnaire tapping knowledge about soccer rules and important soccer events, these children were categorized as either experts or novices with respect to soccer. The students at each grade level were asked to recall a story about soccer. In addition, information about metacognitive knowledge (i.e., knowledge about text processing) and subjects' intellectual ability was obtained. A second assessment using the same instruments followed about a year later.

The analysis of free recall data yielded significant effects of grade and expertise for each measurement point. While seventh graders recalled more text units than both third and fifth graders, experts outperformed novices at each grade level. The findings also confirmed Chi's (1978) result in that a reversal of developmental trends was demonstrated: third grade experts recalled more text information than seventh grade novices.

The measures of intelligence and metacognitive knowledge were included to explore the impact of these variables relative to domain knowledge. With regard to metacognition, the expectation was that in both the expert and novice groups, subjects with high metacognitive knowledge on text processing should outperform those with low metacognitive knowledge. The results clearly confirmed this prediction, indicating

that the combination of rich domain knowledge and metacognitive knowledge lead to optimal performance on the recall task.

The results concerning the impact of general ability were different. The experts and novices were classified into high-ability and low-ability subjects on the basis of their performance in the intelligence tests. Thus, four groups resulted at each grade level: high- and low-ability soccer experts and high- and low-ability soccer novices. When the longitudinal recall and comprehension data were analyzed using grade, expertise and general abilities as independent factors, only effects of expertise and grade were found. Most strikingly, neither a single effect was found for general ability, nor were there any significant interactions. Schneider et al. concluded from these findings that rich domain-specific knowledge can sometimes compensate for overall lack of general cognitive abilities.

As supporting evidence for this has been provided in a number of recent studies with children and adults (e.g., Ceci & Liker, 1986; Recht & Leslie, 1988; Walker, 1987), it appears that individual differences in general ability do not make a difference when the task is to process new information in a highly articulated domain. Please note that this is also the conclusion Ericsson and colleagues have drawn from their research on adult expertise. Thus research on exceptional performance in adults and developmental studies on text processing in child experts and novices lead to similar insights, as far as the role of basic abilities is concerned.

One problem with the developmental studies on the roles of domain knowledge and general ability in affecting text processing is that they have been based on a small number of tasks and paradigms. The question remains whether their main finding concerning the role of general ability can be generalized across different tasks and domains. A recent study by Schneider and Bjorklund (1992) shed some doubts on this assumption. Schneider and Bjorklund adopted the basic design used by Schneider et al. (1989). However, instead of assessing text processing, they tested second and fourth grade soccer experts' and novices' performance on a sort-recall task dealing with soccer words.

In accord with their expectations, Schneider and Bjorklund found significant effects of expertise on recall, thus confirming the results of the previous studies. However, soccer expertise did not modify a significant effect of IQ level, with high-IQ children recalling more than low-IQ children for all contrasts. The results thus demonstrate that domain knowledge played an important role in children's memory, but could not fully eliminate the effects of IQ on sort-recall tasks using domain-related materials. That is, although rich domain knowledge seemed to compensate for low aptitude, in that low-aptitude experts performed at the level of high-aptitude novices, its effects were not strong enough to eliminate performance differences between high- and low-aptitude soccer experts.

Schneider and Bjorklund (1992) concluded from their work that the findings from developmental studies

dealing with text processing did not generalize to the sort-recall paradigm, at least as far as the aspect of general ability was concerned. One difference between the text recall task used in the previous studies and Schneider and Bjorklund's sort-recall task concerned the role of strategies and memory capacity. Whereas neither strategies nor capacity seem particularly important in the case of gist recall (text recall), they are certainly more relevant when verbatim recall is required, as is true for sort-recall. It appears, then, that being an expert does not eliminate the effects attributable to individual differences in intelligence when deliberate strategies play a role in task performance.

One problem with most developmental studies using the expert-novice paradigm concerns the extent of expertise. For example, no official chess ratings were available in most developmental studies on chess expertise, making it difficult to judge the competence of child experts as compared to that of adult experts. Also, most developmental studies on text processing experienced problems with defining expertise. Taking the median of the distribution of scores in domain-specific knowledge tests as the critical boundary for expert-novice distinctions not only creates the possibility of misclassifications but can also imply that the average level of expertise is rather low.

This problem was not an issue in two recent developmental studies on the impact of domain knowledge and aptitude on domain-specific performance (Horgan & Morgan, 1990; Schneider, Bös, & Rieder, 1993), which thus will be considered next. Both studies included samples of true child experts, that is, young promising subjects with already extraordinary competencies in their domain of interest. In Horgan and Morgan's study, official ratings were available for all child chess experts ($N = 113$). The elite subsample consisted of the twenty best players of this sample. Most of the young elite players had skill ratings of 1300 and more (the mean for all U.S. tournament players of all ages is 1500 and the standard deviation is 200). The Schneider et al. study consisted of a reanalysis of data on the development of a group of 109 tennis talents collected about 10 years ago. At the beginning of the study, the children's age ranged from 10 to 14 years of age. As we know today, the careers of most of these tennis talents were very successful. Most players are still listed in the national rankings and more than 10% of the sample have made it to the top 100 in the world, with a few players even belonging to the best ten players in the world.

Furthermore, the two studies seem theoretically interesting because they were longitudinal in nature. In their correlational study, Horgan and Morgan (1990) examined children's chess records for one academic year. The reanalysis of tennis talent data by Schneider et al. (1992) was based on a 5-year longitudinal study, including repeated measurements of basic motor abilities, skill-related tests, psychological tests concerning achievement motivation and concentration skills and interview data focusing on parental support and amount of practice.

What does the chess study by Horgan and Morgan tell us about the roles of IQ and experience in developing chess skill? The elite subsample was given two tasks that tapped general abilities and one test of domain-specific skill. The Raven's Matrices test was used as a measure of intelligence because it was considered a measure of logical abilities as well as spatial abilities. The authors felt that the type of reasoning required was similar to chess reasoning. In addition, a Piagetian task measuring combinatorial logic in formal reasoning was used. Finally, the Knight's Tour, that is, a chess-specific test that is believed to be closely related to chess skill was provided.

As one main result of the longitudinal study based on the total sample, it was shown that improvement in chess skill was significantly correlated with experience. Using age and pretest ratings as covariates, Horgan and Morgan could demonstrate a close relationship between experience in terms of games played and posttest chess rating. In sum, the more improved players played more and won more.

Additional stepwise regression analyses carried out for the elite subsample showed that pretest chess skill accounted for about 65% of the variance in post-test chess skill. When the Raven's test was added as a predictor, the amount of variance explained in the dependent variable increased to 77%. Another 10% of the variance were accounted for by the addition of numbers of games played. Horgan and Morgan concluded from this finding that both experience and nonverbal intelligence significantly contribute to improvements in chess skill. As the Piagetian task showed no significant correlation with chess skill in the young elite players, it appears that the type of reasoning assessed in general ability tests makes an important difference in this regard.

One of the goals of the study by Schneider et al. (1993) was to test Ericsson and Crutcher's (1990) assumption that the basic findings concerning expertise in chess can be generalized to other domains, including sports. In particular, the reanalysis of tennis talent data aimed at estimating the relative impacts of basic motor ability and tennis-specific skills on performance in tennis, as indicated by national rankings. Indicators of motor ability included assessments of sprint ability, whereas measures like string-frame bouncing tests and target hitting tests were used to tap tennis-specific skills. In addition, variables like parental support, estimated intensity of practice, achievement motivation and concentration skill were considered in the analyses.

Results of causal modeling procedures showed that tennis-specific skills explained most of the variance in the tennis rankings obtained for the last year of the longitudinal study (1982). Similarly, intensity of practice and parental support during the early stages of the children's tennis career significantly predicted the tennis rankings. The impact of basic motor ability on tennis performance was comparably small but reliable. That is, when the basic ability construct was omitted from the model, it no longer fitted the data. The same pattern of

results emerged when tennis rankings obtained 7 years later were used as the dependent variable. Rankings obtained in 1982 and in 1989 correlated with $r = .70$, which indicates high stability of individual differences in tennis skill during adolescence and early adulthood.

Taken together, the findings by Horgan and Morgan (1990) and Schneider et al. (1993) basically confirm the theoretical framework developed by Ericsson and colleagues. They all highlight the importance of deliberate practice in developing domain-specific expertise in children. The results provided by Schneider et al. additionally prove the significance of parental support systems for skill development. However, both studies do not support the assumption that individual differences in basic ability can be completely neglected when it comes to predicting the development of expertise. In the case of chess expertise, intelligence as measured by the Raven's test accounted for a small but significant amount of variance explained in the dependent variable, that is, improvement in chess skill within a year. Similarly, the study by Schneider et al. showed that the relative impact of basic ability on performance was small but reliable. This finding seems particularly impressive given that the basic abilities found for the two elite samples in chess and tennis were clearly above average and that the range of scores was small due to the homogeneity of the samples. The results of these studies thus seem to indicate that experience, while extremely important, cannot completely substitute talent. As emphasized by Horgan and Morgan, no amount of experience will make an ordinary player into a grandmaster. Thus the message is that one should come up with models of skill acquisition that account for possible influences of individual differences in cognitive abilities. Theoretical models including the basic ability component will be discussed in the final section of this chapter.

Conclusion

In this chapter, it has been shown that exceptional performance usually is based on an extremely rich knowledge base, acquired through a very long lasting process of motivated learning. In order to reach this point, cognitive personality characteristics like high intellectual ability seem less important than noncognitive factors like endurance, dedication, concentration and motivation. The most important accomplishment of the skilled memory theory was to highlight and demonstrate the relevance of acquired skills in explaining exceptional performance. The findings by Ericsson and colleagues even suggest that individual differences in basic abilities can be ignored in view of the overwhelming effects of expertise on performance. However, one problem with most of the studies on adult expertise was that individual differences in basic abilities were not explicitly measured. Given the evidence from developmental studies on expertise which took those abilities into account, one is inclined to believe that the impact of innate, basic

abilities should not be completely ignored in theoretical models dealing with the acquisition of expertise. But as even the developmental studies do not show substantial influences of high ability or talent, one can easily accept that the original approach of prospective research in giftedness outlined above does not pay off in the long run. In most theoretical models relating giftedness to exceptional performance, the impact of early basic abilities on performance later in life has been largely overestimated.

On the other hand, it does not seem to require much effort to change developmental models derived from giftedness research into models compatible with the expertise approach. For example, Renzulli's (1986) three-ring model of giftedness includes several components highly important for the acquisition of expertise. According to Renzulli's model, aptitude, creativity and a motivation plus context component determine giftedness or talent. If one replaces talent by exceptional performance and also gives a low weight to the aptitude and creativity factors, as compared to the motivation and context factor, one only needs to add a big knowledge component in order to be in line with core assumptions of the expertise approach.

Another modification of the theoretical framework of expert performance was suggested by Schneider (1988, 1992). Schneider emphasized the fact that most studies in adult expertise dealt with subjects of at least average intelligence (e.g., physics professors, chess players). He voted for a "threshold" model of exceptional performance that can be described as follows: If the ability parameter of a subject is close to or beyond a critical or "threshold" value of ability (typically assumed to be slightly above average), then individual differences in noncognitive variables like commitment, endurance, concentration, or motivation decide about peak performance. In this case, it does not matter at all whether the subject is gifted or only of normal intelligence. Although this model appears intuitively plausible, one of its problems lies in the definition of critical or "threshold" scores for different domains (cf. Weinert, 1992). The boundaries may be well above average for domains/tasks where complex problem solving activities and strategy utilization are necessary components and may be clearly below average for less complex domains or tasks that mainly rely on automatic processes (e.g., pattern recognition processes or text processing).

Another model concerning the acquisition of expertise and including ability components was developed by Ackerman (1987). Following the theoretical assumptions of Fitts and Posner (1967), Ackerman assumes that three stages of skill acquisition can be distinguished: a first cognitive stage deals with the acquisition of declarative knowledge. This is followed by an associative stage, where elements of declarative knowledge are composed into larger units and procedural knowledge is gradually acquired and improved. Although the final, automatic stage of skill acquisition does not differ from the second as far as qualitative aspects of information

processing are concerned, its unique features may be seen in increased, optimal speed of processing as well as fine-tuned and automatized problem solving activities.

According to Ackerman (1987, 1988), different aptitudes are necessary to master the three stages described above. Regarding the first cognitive stage, individual differences in general intellectual ability seem to be most important. That is, the higher the general intelligence of an individual, the faster declarative knowledge about a specific domain should be acquired. During the second, associative stage, indicators of perceptual speed appear to be particularly important for combining elements of declarative knowledge and initializing the procedural knowledge component. Finally, individual differences in psychomotor abilities seem most relevant for mastering the stage of automatization.

This model suggests that the impact of individual differences in basic intellectual abilities on the process of skill acquisition diminishes as a function of time. Supporting evidence for this assumption can be derived from experiments conducted by Ackerman (1988, dealing with a variety of cognitive tasks. Although these findings confirm Ackerman's core assumption concerning the changing role of basic intellectual abilities during the process of skill acquisition, it still remains unclear whether the role of perceptual speed and psychomotor ability components can be generalized across a wide variety of domains.

Prediction of Excellence in School, University and Work

GÜNTER TROST

Institute for Test Development and Talent Research, Bonn, Germany

Introduction

The central questions to be tackled in this chapter are: (a) How predictable is excellent performance in school, university, and work? (b) What is the predictive value of a variety of information gathered in a variety of ways with respect to excellence in these three areas? The contribution will focus on measures of ability as predictors, but information on other variables such as previous achievement, motivation, further personality variables, and environmental factors will also be taken into account.

Before the empirical data can be reviewed, a clarification of the criterion named "excellence" and a brief discussion of some methodological problems inherent in studies on the prediction of excellence seem appropriate.

The Criterion of Excellence

"Excellence" is not a scientific term, and a clear-cut, unanimously accepted definition of it does not exist. In none of the standard textbooks on giftedness except one (Sternberg & Davidson, 1986) does the key-word "excellence" appear in the subject index. Nevertheless, the term is frequently used in literature and mostly in the sense of outstanding, exceptional achievement, brilliant performance as well as of "eminence" (Feldhusen, 1984; Hunt, 1983; National Commission on Excellence in Education, 1983; Tannenbaum, 1986). Ochse (1990) uses the term "excellence" in the title of her book as a synonym of creativity: ". . . creative people excel—they go beyond what others have done" and "produce something of cultural value" (Ochse, 1990, p. 3).

The borderline between "excellence" and "above average achievement" or "average achievement" has been drawn at very different points of the achievement continuum, depending on the author. Some set it extremely high, admitting only the epoch-making achievement of a genius brought forth once in a century, some use the fact that a person is listed in the *Who is Who?* as a criterion for that person's excellence, some have recourse to more or less exclusive awards or to peer nomination.

Another approach is to define excellence statistically, e.g., as an achievement which can be measured on a discrete scale and exceeds a certain value or as a characterization of persons who, when rank-ordered according to their respective accomplishments, reach positions beyond a certain percentile rank.

The small common denominator of all definitions is achievement far above average. Consequently, excellence can be observed in all domains of human performance. The scope of this chapter is restricted to the predictability of excellence in school, in extracurricular activities, in higher education, and in work.

Methodological Problems

Empirical research into the determinants of excellence faces several methodological problems.

It is a triviality that within a given unselected population only a relatively small number of persons will meet the criterion of exceptional performance. It takes great effort to gather samples of sizes large enough to promise statistically significant results, particularly if excellence is considered an area-specific rather than a "cross-domain" phenomenon. Case studies for the analysis of the development of single "eminent" persons, on the other hand, are useful heuristic tools for forming hypotheses about the predictors of excellence, but they do not yield generalizable results which can be used immediately as a basis of prediction in cases of persons other than those under study.

Another troublesome issue—which is connected with the one mentioned above—is the appropriate design of studies about the predictability of excellence. By far the largest part of research published in this area consists of retrospective analyses: Persons are selected on the basis of excellent performance, and documents of their personal, educational and vocational history (diaries, notes, certificates, expertises, marks, products of all kinds, biographies and autobiographies) are examined; the subjects themselves—and, in some instances, persons in their environment—are interviewed about various aspects of their past. As an alternative approach prospective studies can be designed in which samples are defined long before part of the subjects might achieve outstanding accomplishments, a set of potential

predictor variables are measured and the subjects are subsequently observed over a certain time span.

Even though retrospective analyses are economic in terms of time and effort, their disadvantages are ponderous: Many individual traits that are potentially relevant (e.g., abilities, motives, aspects of self-concept) cannot be properly assessed in retrospect. As a contrast, prospective designs imply a high investment of time and effort. Ideally such longitudinal studies start with very large unselected samples in order to insure that they contain the few who will later perform extraordinarily well. Their main advantages are that a great variety of potentially relevant factors—both individual and environmental—can be recorded at the time they appear and that control groups of “non-eminent” peers can be included right from the start.

In reality most longitudinal studies started with strongly pre-selected samples characterized, for instance, by extremely high scores in ability tests (e.g., Benbow, 1983; Terman, 1925). Comparable information on unselected control groups are for the most part missing. It is therefore difficult to judge “what really makes the difference”.

It should be kept in mind that because of the stiff pre-selection of the samples a strong restriction of range in both ability and achievement scores takes place. The reported correlation coefficients are usually not corrected for that effect and thus underestimate the “true” strength of the respective relationships.

In connection with pre-selection of samples, the “ceiling effect”, i.e., poor differentiation at the top end of the ability or achievement continuum, on both the predictor and the criterion side is another methodological problem, especially when ability or achievement tests are applied (Stanley & Benbow, 1986).

A further methodological problem is inherent in studies that cannot be carried out under controlled experimental conditions: Individual and environmental factors are almost inseparably intertwined at practically any given stage of development—a common problem in all educational research; in addition, in both prospective and retrospective studies on the predictability of outstanding achievement the measurement of the predictors as such has an impact on the variables that are being measured and on their predictive qualities: For instance, if in a longitudinal study pupils take an intelligence test, those who excel in the test will probably be influenced by this experience in their future self-concept and behavior and so will the behavior of other persons in their environment who learn about the test results. Or, in retrospective analyses, “eminent” persons asked about features of their biographies will certainly perceive the facts and experiences of their careers from the perspective of their later accomplishments.

As a consequence, clear-cut and generalizable figures on the precise size of effects certain predictor variables or their combinations have on future excellence cannot be expected. The researchers have to be content with rough estimates.

Prediction of Excellence in School

Excellence in school, defined as outstanding overall achievement, can be measured by grade point average, by rank in class or by teacher ratings. Excellent performance in particular subjects is reflected in top grades, teacher ratings or achievement test scores.

The predictors that have gained the most attention in this context are intelligence tests, scholastic aptitude tests, creativity tests, measures of interests, motivation and other personality traits, parent and teacher ratings.

Lewis Terman (1925) started his famous longitudinal study in 1922 on 1528 children who had scored at least 140 in an intelligence test before the age of 12; he and his co-researchers followed the persons in this sample over their entire life span. On an average, the highly intelligent children performed very well in school, but not exceedingly so (Terman, 1965).

In the context of the Munich Study of Giftedness (Heller & Hany, 1986) the predictive validity of a battery of cognitive ability tests and creativity measures was determined on three samples of 11-, 13- and 15-year-old secondary school students. The criterion was the average of school grades in German, mathematics and English three years after the assessment of the predictor data. The validity coefficients for the combined test score were 0.48, 0.45, and 0.32.

In the well-known Study of Mathematically Precocious Youth (SMPY) initiated by Julian Stanley (Keating, 1974) and carried on under the directorship of Camilla Benbow the predictive value of the quantitative section of the Scholastic Aptitude Test (SAT-M) with respect to high school achievement could be examined (Benbow, 1983). Students at the age of 12 whose results in the SAT-M were above the average score of the (5 years older) reference group of twelfth-graders and who were estimated as doing better in mathematical reasoning than 99% of their age-mates (Stanley & Benbow, 1986) were first followed up for five years until they had graduated from high school. The SAT-M, although designed for another age group, proved to be a good predictor of excellent performance in mathematics and in science during high school (Benbow & Minor, 1986; Favazza, 1983).

Teacher ratings on the achievement in a special mathematics course offered to gifted tenth-graders were the criteria in the Hamburg study on mathematically precocious youth carried out by Bix (1988). Among the predictors were the score in a German version of the quantitative section of the Scholastic Aptitude Test (GSAT-M) and the total score in an intelligence test. For two cohorts and a prediction period of two and three years validity coefficients of 0.43 and 0.17 were found for the scholastic aptitude test score and 0.37 and 0.17 for the intelligence test score.

From the many studies covering the whole range of general cognitive abilities it can be concluded that intelligence and related ability test scores are satisfactory predictors of success in school with correlations around

0.40 to 0.50 (cf. Bloom, 1976; Cattell & Butcher, 1968; Kuusinen & Leskinen, 1988; Parkerson et al., 1984). Not only in the average range but also for the prediction of high level performance in school, intelligence and scholastic aptitude tests seem to be useful instruments. The findings indicate, however, that even though high intelligence is a necessary prerequisite for top achievement in school, it is by far not sufficient. Other, noncognitive factors are needed in addition (cf. Helmke, 1992; Schiefele et al., 1992).

Not surprisingly, teacher ratings turned out to be fairly good predictors of later achievement in school.

In the Munich Study of Giftedness a combined teacher rating of the students' cognitive and creative abilities proved better than the combined results of the battery of ability and creativity tests as predictors of the average grades for the three subjects German, mathematics and English which were assessed after a three year interval; the coefficients were, for three cohorts, 0.56, 0.56, and 0.71 (Perleth & Sierwald, 1992; see also Perleth & Heller, 1993). Denton (1988) reports good agreement between teacher ratings of excellent students and their classroom achievement two years later. In two concurrent validity studies using teacher ratings as "predictors" and performance in achievement tests as criteria, correlations ranging from 0.39 to 0.60 were found (Renzulli et al., 1971; Swenson, 1978).

In a recent meta-analysis, Schiefele et al. (1992) examined the results of longitudinal studies from eighteen countries on the predictive validity of interest scales with respect to achievement in school, measured as grades or achievement test scores. As this review includes a great number of studies initiated by the International Association for the Evaluation of Educational Achievement (IEA) using achievement tests with a fairly high ceiling as criteria, the authors' findings deserve to be mentioned here even though the studies were not specifically focused on outstanding achievement. The mean value of 121 correlation coefficients was 0.31, after correction for attenuation it amounted to 0.40.

A similar average coefficient (0.34; 40 studies) was reported by Uguroglu and Walberg (1979) for the correlation between measures of motivation as well as self-concept and achievement in school. Hansford and Hattie (1982), in their meta-analysis of data from 128 studies on the predictive validity of self-concept measures, found an average value of 0.21. In Bloom's study (1976), "self-concept of ability" was the strongest predictor of success in school among three types of self-concept. For "affective characteristics" as predictors of school achievement, Fraser et al. (1987) found in their meta-analysis of 335 studies a mean validity coefficient of 0.12.

In summary, the findings suggest that teacher ratings, cognitive tests and measures of noncognitive features such as interests, motivation, and self-concept can be used for the prediction of outstanding achievement in school and that they should be used in combination. What the optimal combination is cannot be derived

from the available data. However, cognitive abilities far above average seem to be indispensable for excellence in school.

There is only indirect evidence as to the contribution parent ratings can make to the prediction of outstanding achievement in school. Jacobs (1971) and Cihra et al. (1974) report findings indicating that parents are reasonably successful in identifying gifted children. Other studies raise doubts about the predictive value of parent judgments (e.g., Ferdinand, 1961; Miles, 1965). In general, parents tend to overestimate their children's giftedness rather than to underestimate it (Ferdinand, 1961), while highly-educated parents tend toward an underestimation (Martinson, 1975). In all, parent ratings do not seem to be very valid predictors of achievement in school. However, parents are apparently in a position to identify, at an early stage of their children's development, high potential in music or in the arts, as the results of retrospective studies on eminent concert pianists (Sosniak, 1985a) and sculptors (Sloane & Sosniak, 1985) suggest.

Several studies dealt with the prediction of extracurricular achievement during school age.

A checklist of creative achievement outside the school curriculum was developed by Wallach and Wing (1969); Torrance (1981) constructed a scale measuring the number of such achievements.

In a 10-year follow-up study starting in 1965 with 400 seventh graders, Howieson (1981) found a correlation of 0.30 between the total score in the Torrance Tests of Creative Thinking (TTCT; Torrance, 1974) and the total score in the Wallach and Wing checklist. In another long-term validity study on 211 pupils who took the TTCT in elementary school, the correlation between the total test score and the number of creative achievements during high school was 0.38 (Torrance, 1988).

If it is agreed that high scores on the above-mentioned scales are indicators of outstanding extracurricular achievement, it can then be concluded that creativity tests such as the TTCT can make a useful contribution to the prediction of excellence outside the classroom.

The above-mentioned Munich Study of Giftedness (Heller & Hany, 1986) also investigated the predictability of excellence in extracurricular activities. Over a time span of 3 years the correlations between aspects of cognitive abilities and creativity measured by tests as well as by teacher ratings on the one hand and extracurricular achievements (in the fine arts, writing, music, social activities, natural sciences and mathematics, technical areas, and sports) assessed by an inventory on the other hand were analyzed on three pupil cohorts. The validity coefficients for the combined test score range from 0.21 to 0.56 (median: 0.36), those for the teacher ratings from 0.12 to 0.64 (median: 0.28) (Perleth & Sierwald, 1992).

Only a small number of studies have been conducted on artistically and musically precocious children and adolescents. In their 10-year longitudinal study of creativity on a group of young artists Getzels and

Csikszentmihalyi (1976) found that, besides perseverance, problem finding (flexible exploration of many options before settling on a particular problem to work on), esthetic ability, and originality were good predictors of eminent performance in the visual arts. Hendrickson (1986) reports results of a 14-year longitudinal study on four musically precocious children and a control group of musically able children with exceptional general abilities. Among the characteristics differentiating the two groups in their first decade of growth were psychomotor control, musical memory, and motivation towards goals of excellence.

In a retrospective approach Walberg (1969) identified, from a national sample of high school students, a group winning competitive awards in science, another group winning awards in the arts, and a control group not winning awards and investigated their biographies. Both high-achievement groups differed from the control group in that they were more self-confident, more interested in reading, more persistent in their activities, and did their work faster. Between the two groups of high achievers there were differences in social habits, interests, and in their self-concepts: The scientists had more confidence in their intelligence, the artists tended to higher confidence in their creativity.

Prediction of Excellence in Higher Education

Excellence in higher education can be operationalized by outstanding grade point averages or average marks in intermediary or final examinations as well as by awards and honors degrees.

It was possible to follow up on the participants in the above-mentioned Study of Mathematically Precocious Youth (SMPY) after graduation from high school, for another 5 years (Benbow & Arjmand, 1990). They had been selected, at age 12, primarily on the basis of above-average performance in the quantitative section of the Scholastic Aptitude Test which has been designed for a much older age group (Stanley & Benbow, 1986). Eighty-five percent received their bachelor's degree, over three times the rate of the general population; almost half of them ranked among the top 10% of their graduating classes; approximately 47% of the graduates continued their education beyond college. Eleven percent reported awards or honors in mathematics, 10% in science. Creative accomplishments were reported by 24% of the male and 15% of the female college students (Benbow & Arjmand, 1990). It can be concluded from the data that by an extremely strict selection on the basis of performance in a scholastic aptitude test, persons can be identified who will subsequently achieve academic accomplishments far above average.

Among the college graduates, two extreme groups were defined by high academic achievement (22%) and low academic achievement (8%); the canonical correlation for the SAT-M—when administered at high school

age—as a predictor of this achievement criterion was 0.30. Other important predictors were attitude towards mathematics and science, encouragement to pursue academic and career goals, and paternal educational level (Benbow & Arjmand, 1990).

In a 4 year follow-up study on 1,200 German students who had ranked among the top 10% in the final class of upper secondary school low, but highly significant correlations were found between both the average grade in the twelfth school year and the average grade in the first university examination (0.25) and between the total score in a scholastic aptitude test and the same criterion (0.16). Forty percent of those persons whose test scores were in the top quartile within the pre-selected group subsequently earned top grades at university (Trost, 1986).

Chauncey and Hilton (1965) examined validity studies on samples of highly able students; they concluded that scholastic aptitude tests can discriminate reliably even among very gifted students and predict their academic performance.

Willingham (1985) summarizes his review of empirical data on the predictability of success in college as follows: "The two traditional academic predictors, high school rank (HSR) and admissions test score (SAT) were by far the best at forecasting the scholastic types of achievement. In a comparison of the two, HSR was a somewhat better predictor of college honors (based on cumulative grade average), while the SAT was a somewhat better predictor of departmental honors. The latter were based on independent scholarship, arguably more characteristic of preprofessional work in the discipline than is grade point average" (p. 179). Willingham also presents data demonstrating that both high school records and scores in the Scholastic Aptitude Test have their highest predictive validities within student subsamples above 90% (p. 29).

There is also some evidence on the relation of superior intelligence with outstanding achievement in higher education. Hollingworth (1942) studied the educational development of twelve children up to their early twenties who had scored 180 or above on the Stanford-Binet intelligence test before the age of 12. They did exceedingly well in college, won a long list of prizes and honors, in short, constituted "the 'top' among college graduates" (p. 249).

Feldman (1984) identified those twenty-six persons in Terman's group of highly intelligent children of the year 1922 with an IQ of above 180 and compared their educational careers with those of twenty-six subjects selected at random from Terman's original group of 1528 persons. On the whole, both groups were highly successful throughout their college years, with a markedly larger percentage of persons winning honors and receiving advanced degrees in the above-180 IQ group.

For his total sample of highly intelligent persons Terman (1965) reports that "close to 90% entered college and 70% graduated. Of those graduating, 30%

were awarded honors and about two-thirds remained for graduate work" (p. 12).

The relative importance of noncognitive factors for achievement in higher education has been demonstrated in various studies (see, e.g., the reviews done by Cattell and Butcher, 1968; Khan, 1969; Lavin, 1965; Steinkamp and Maehr, 1983).

Nichols and Holland (1963) and Nichols (1966) attained a considerable improvement in the prediction of college grades of a highly selective sample of finalists and scholars of the National Merit Scholarship program when they included attitude, interest, and personality scales into the set of predictors: "For predicting college grades, high school grades were the best predictor (average validity 0.33), followed by the nonintellectual scales (average validity 0.27), and finally by the aptitude test (average validity 0.12)" (Nichols, 1966, p. 911).

Nichols (1966) also examined the predictability of extracurricular achievement at college age and found that the nonintellectual scales were the best predictors with an average validity of 0.19.

Another study of post-high-school creative achievements was carried out by Torrance (1988). As this author does not differentiate between achievements during the college and university years and achievements in the following years his results will be presented in the next section on "excellence in work".

The overall conclusions which may be drawn from the findings on the predictability of excellence in higher education are: Achievements in secondary school and performance in scholastic aptitude tests are the best predictors: high scores in intelligence tests also have satisfactory predictive validity. Other factors, particularly in the domains of interest, motivation, and self-concept, have, on their own, a lower predictive power, but they do add to the overall prediction of academic success, and, among the highly intelligent students, they seem to make the difference between the very good ones and the excellent ones. For the prediction of extracurricular achievements, noncognitive predictors such as interests, task commitment, and aspects of creativity seem to be most relevant.

Prediction of Excellence in Work

There is a great variety in the ways different authors operationalize excellence in work. Operationalizations can be: recognition as geniuses having revolutionary impact in their fields, more or less distinguished awards persons have won for their work, ratings of the persons' work by experts in the field, number of publications, patents, or exhibitions, etc.

One of the ways to find out about the determinants of excellence in work is the analysis of the biographies of eminent persons. The first study of this type is Sir Francis Galton's famous work on "hereditary genius" (1869). In the biographies of highly renowned representatives of various fields who he had selected with the help of

popular directories, he found three common elements: capacity, zeal and the power of hard work. His study on eminent scientists (1874) led to the conclusion that "these people were endowed with superior intellectual ability, tremendous energy, good physical health, a sense of independence and purposefulness, and exceptional dedication to their fields of productivity", as Tannenbaum (1986, p. 27) summarizes.

Half a century later, information on the early development of 300 famous persons from the past 450 years who had made outstanding contributions to their cultures were examined under the directorship of Catherine Cox (1926) as part of Lewis Terman's genetic studies of genius. The sample included Byron, Cromwell, Darwin, Kant, Luther, Michelangelo, Mozart, Newton, and Robespierre. From the information given in the biographies, estimates were made as to the persons' IQs and more than sixty other personal traits. Within her sample, Cox compared a subgroup of the most creative subjects with the total group. The intelligence ratings assigned to the persons in the total sample were high: For the subgroup of eminent philosophers the average IQ estimate in childhood was 173, for the scientists 164, for the statesmen 159, and for the soldiers 133. However, the estimated IQ did not differentiate between high and exceptionally high achievement. Cox concluded from her data that with high intelligence given, it depends on the individual's degree of persistence of motives and effort whether the highest level of accomplishment will be achieved or not. Other features that she found particularly characteristic for the 100 leading geniuses in her sample were confidence in their abilities, and strength of character. Subsequently, several authors selected persons from Cox's sample for their own research (e.g., McCurdy, 1957) or re-evaluated the Cox data (Simonton, 1984; Walberg et al., 1978).

Twenty-five years after the Cox study Anne Roe (1951a, 1951b, 1952a, 1952b, 1953) selected, on the basis of nomination by panels of experts in each field, 64 of the most eminent living American scientists: 20 biologists, 22 physicists, and 22 social scientists (psychologists and anthropologists). They had "received a staggering number of honorary degrees, prizes and other awards" (Roe, 1952a, p. 21). She examined them comprehensively by interviews and tests. Although there were marked group differences between the natural scientists and the social scientists, as well as between the biologists and the physicists, certain common patterns did appear in the group as a whole.

The scientists typically came from middle and upper middle class families. Fifty-three percent of the individuals were the sons of professionals, another 19% the sons of businessmen. Learning for its own sake was highly valued in their families. As to their early extracurricular interests no common pattern across fields showed up but there were rather typical configurations for each of the three groups. The final vocational decision was only made at junior or senior college level, mostly after the first personal contact with research.

The intelligence level of the eminent scientists—as measured at the time of the study—was very high, the average scores in verbal and quantitative tests equalling an IQ of approximately 160. Furthermore, the interviews revealed that one of the features all 64 eminent scientists had in common was the “driving absorption in their work” (Roe, 1952a, p. 25).

MacKinnon (1960, 1978) conducted a series of both retrospective and cross-sectional studies on creative architects, engineers, industrial researchers, mathematicians, physical scientists, and writers nominated by experts in the fields. Apart from features that were characteristic to each of the respective groups, he found the following traits common among the highly effective persons in all of these fields: openness to experience, independence in goal-setting and high tolerance of frustration on the way to creative solutions.

Goertzel and Goertzel (1962) and Goertzel et al. (1978) examined the biographies of 314 eminent personalities of the twentieth century. In their analyses they laid the stress on environmental rather than individual factors. Their results confirmed many of the previous findings. In contrast to other authors, however, they found that 85% of the eminent persons came from disturbed homes. Nevertheless, parents—as well as other mentors—seemed to play a significant role in evoking the children's and adolescents' motivation to achieve.

Walberg et al. (1981) asked biographers working for the *Encyclopedia Britannica* to rate the presence or absence of traits in the childhood of those persons from Cox's sample whose biographies the authors had written. According to the ratings, the most distinctive trait common to 97% of the 221 eminent men was intelligence; they also had superior communicative skills. Eighty-two percent were permitted by their parents to explore environments on their own. Eighty percent were very successful in school.

Simonton (1984, 1987) re-analyzed the Cox and the Goertzel family data. According to his findings, the eminent persons came from intellectually and culturally stimulating homes; they acquired numerous demanding hobbies and were omnivorous readers. In their later educational and professional careers they displayed an immense productivity. Simonton also gathered evidence that “intelligence is the single best personological predictor of leadership in general” (1988, p. 399). For all subgroups of eminent persons except for “celebrities” (including athletes, businessmen, editors, and performers) he found an inverted U-shaped curve for the relation between the attained educational level and eminence.

A series of retrospective studies on living persons who, before age 40, had attained high distinctions as concert pianists ($n = 21$), sculptors ($n = 20$), swimmers ($n = 21$), tennis-players ($n = 18$), research mathematicians ($n = 20$), and research neurologists ($n = 20$) has been carried out under the directorship of Benjamin Bloom (1985). Interviews with the individuals and their parents revealed a number of communalities over the six groups

of exceptional achievers. The majority of their parents placed high value on achievement, success, and persistence at work. The parents can be described as child-oriented. They encouraged and supported the interests their children pursued and were willing to devote time, resources and energy to provide the best conditions for the development of their children's talents. They viewed their children as gifted and expected hard work and high attainments from them. In terms of parental interests and activities the climates were favorable: The parents of the swimmers and tennis-players were interested in athletics (Kalinowski, 1985; Monsaas, 1985); in the homes of the concert pianists music played an important part (Sosniak, 1985a); there was a certain emphasis on the arts in the sculptor's homes (Sloane & Sosniak, 1985); the parents of the mathematicians and neurologists had themselves attained high levels of education and offered a wide range of intellectual stimulation to their children (Gustin, 1985; Sosniak, 1985b).

The children can be characterized as rather self-guided and independent in their interests and activities; they had soon become highly self-confident with respect to their abilities. In their adolescence they were strongly motivated to learn, to practice and to improve upon their accomplishments. The academic records of the pianists, sculptors and athletes were inconspicuous; those of the research neurologists were very good but not necessarily brilliant; most of the research mathematicians had attained excellent results both in high school and in higher education.

Several retrospective studies comparing exceptional managers with average managers yielded fairly consistent results as to the predictors of outstanding managerial achievement: superior cognitive abilities, high interpersonal skills, vigorous need of achievement, and strong self-confidence (Cascio, 1987; Klemp & McClelland, 1986).

While the studies mentioned so far were designed as retrospective analyses, other studies started with more or less selected samples of children or adolescents which were followed up in their careers until later life achievement could be measured.

The most famous longitudinal study of this kind covering a whole life span is the one by Lewis Terman. He started it in 1922 on a sample of 1528 6–12-year-old children with an IQ of at least 140 (Terman, 1925). For the 800 males in his sample (only a minority of the women had gone out for professional careers at that time) he found impressive records of adult life achievement: “By 1950, . . . they had published 67 books, . . . more than 1,400 scientific, technical, and professional articles; over 200 short stories, novelettes, and plays . . . They had also authored more than 150 patents . . . Of the scientists, 47 are listed in the 1949 edition of *American Men of Science*. Nearly all of these numbers are from 10 to 20 or 30 times as large as would be found for 800 men of corresponding age picked at random in the general population” (Terman, 1965, p. 12). According to Terman these figures prove that tests

of general intelligence, given at school age, "tell a great deal about the ability to achieve either presently or 30 years hence" (1965, p. 13).

However, comparing the 150 most successful and the 150 least successful men in his sample, Terman found that "the less successful subjects do not differ to any extent in intelligence as measured by tests" and concluded that "notable achievement calls for more than a high order of intelligence". Some personality factors turned out to be "extremely important determiners of achievement". The most and the least successful subgroups differed to the greatest extent with respect to "persistence in the accomplishment of ends, integration toward goals, self-confidence, and freedom from inferiority feelings" (Terman & Oden, 1959, p. 148).

In a different approach, Feldman (1984) compared the careers of the subgroup of twenty-six persons from Terman's sample who, before age 12, had scored above 180 in the intelligence test with the careers of a control group of twenty-six persons drawn at random from the same sample. For the men in both groups he found a "consistently high degree of professional achievement"; there was "a small number of distinguished men in the above-180 IQ group" but not in the control group (p. 520). In the female higher IQ group, there was much more evidence of professional involvement than in the female lower IQ group but no outstanding career was found in either of the female subgroups. The author summarizes: "In terms of professional achievement, then, the men as well as the women seemed to gain some margin of benefit from the extra IQ points . . ." But "the overall impression is one of lower achievement than the traditional view of IQ would have predicted for both groups" (p. 520).

Tomlinson-Keasey and Little (1990) factor-analyzed, in Terman's set of data, parent and teacher trait ratings from the year 1922, characteristics of the family of origin retrospectively given by the subjects, and variables of adult accomplishment, and they represented the relations in a path model. Of all the "early" predictors the factor "parental education" showed the highest correlations with the criterion factors "educational attainment" (0.26) and "occupational achievement" (0.13).

In a combined prospective and retrospective study Trost and Sieglen (1992) selected, from a nationally representative sample of 9000 graduates from secondary school in 1973, 166 adults who have been exceptionally successful as scientists, engineers, or businessmen. The greatest differences between the top group and the representative group, at school age, were problem-solving ability and motivation, initiative and leadership, search for knowledge, direction towards activity and independence at home, school record, and performance in the quantitative part of a scholastic aptitude test.

Torrance (1988) also conducted longitudinal studies on unselected groups. He operationalized "creative adult achievement" in various, however less exclusive ways, than the researchers who focused their attention on eminent persons. One of the criteria he used was

"quantity of publicly recognized and acknowledged creative achievements", another was "quality of creative achievements" on the basis of quality ratings by three judges of what subjects had identified as their most creative achievements (p. 58). On a sample of 254 high school seniors who had taken the Torrance Tests of Creative Thinking, two intelligence tests and a school-based achievement test in 1959 and were followed up until 1979, Torrance (1988) obtained correlations of 0.32 and 0.36 for the total score in the creativity test battery, of 0.21 and 0.38 for the total intelligence score, and of 0.27 and 0.47 for the total achievement test score with the quantitative and the qualitative criteria of adult creative achievement respectively. On another sample of 211 subjects tested at elementary school level and followed up for 22 years, Torrance (1988) found validity coefficients of 0.46 for the total creativity score with respect to the quantitative criterion and of 0.58 with respect to the qualitative criterion of achievement.

Empirical findings as to the predictability of job success in general (i.e., not only in view of excellence) complete the picture. They indicate that "general intelligence" is the best single predictor; for managers and professionals the predictive validity of intelligence measures is higher (with coefficients of about 0.30) than for semi-skilled or unskilled workers (Ghiselli, 1966, 1973). The correlation between college grade point average and job success is considerably lower; the coefficients typically range between 0.10 and 0.30 (Hoyt, 1965; Klitgaard, 1985; McClelland, 1973; Reilly & Chao, 1982).

Among the noncognitive variables, biographical data on past attainments in particular areas tend to be the best predictors of similar attainments in adult life, the validity coefficients being about 0.30 (Hunter & Hunter, 1984; Taylor & Ellison, 1967). The predictive validity of interests measured by questionnaires is lower, the respective values ranging from around 0.20 or below (Hunter & Hunter, 1984). The relation between general personality traits as they are assessed by personality inventories and measures of job success seems to be rather weak (Ghiselli, 1973; Klitgaard, 1985; see also Rutter, 1989).

Summary and Conclusions

What are, then, the characteristics which can be assessed at earlier stages of a person's life and contribute to the prediction of excellence at later stages?

In the first place, the results of all pertinent research clearly show that there is no such thing as the one exclusive predictor of outstanding achievement. Instead, excellent performance is the product of a highly complex intra-individual interaction of a variety of traits (cognitive and noncognitive abilities, motivational and emotional attributes, further personality variables) as well as of an interaction between these individual traits and environmental factors (influences of family,

peers, school, university, extracurricular experiences, the media, etc.). The prevailing conceptions of giftedness as they are proposed, for instance, by Feldhusen (1986), Gagné (1985), Heller (1989), Mönks et al. (1986), and Tannenbaum (1986) emphasize these interactions and thus are in line with the findings reported in this chapter.

Secondly, there is hardly any single predictor that accounts for more than 30% of the variance in any criterion of achievement if predictors and criteria are measured in longitudinal studies. And, in cross-validation studies, even optimal combinations of several predictors rarely explain more than 50% of the variance in later achievement. These statements hold true for the predictability of the total range of achievements; within the range of extraordinary performance, the expectations with regard to the degree of predictability have to be even lower because of the special methodological problems mentioned at the beginning of this chapter. It is therefore safe to say that even by using the best predictors available (both individual and environmental) and combining them in the most appropriate way, less than half of "what makes excellence" can be accounted for.

Within these limits, though, certain variables have fairly consistently proved to be more predictive than others.

For a large number of areas of excellence, intelligence and other cognitive abilities are the most important single predictors. This is particularly true for outstanding performance in school, in higher education, in vocational training, in the professions, in business, and in all fields of scientific research: "It appears that individuals who end up known in history as highly productive achievers in those fields requiring extensive formal schooling are likely to have an IQ of at least 145" (Albert & Runco, 1986, p. 349). Other abilities, e.g., psychomotor, perceptual and social abilities, hold the highest rank positions as predictors of exceptional performance in sports, in the fine arts and the performing arts, in music, and in some areas of leadership. Abilities assessed by tests are better predictors than abilities rated by parents or teachers. Whenever the accomplishment of something novel is the criterion, creativity is an important additional predictor. However, a fairly high, though not exceptional level of intelligence is also necessary for high degrees of creative achievement (Barron, 1969; Cattell, 1963; Roe, 1952b).

While the predictive value of specific abilities can be different, depending on the particular domain of achievement, some motivational, affective, and environmental characteristics are obviously relevant predictors across fields.

Aside from ability variables, probably the most powerful predictor of excellence is a high and task-oriented motivation. Its importance has been confirmed in practically all studies searching for the determinants of outstanding achievement. Aspects of it are the willingness to work hard and persistently on things that

are of particular interest to the individual, perseverance in the face of obstacles, a high level of aspiration, competitiveness, and ambition: the "desire to excel at performances . . . in which the person has his chief interest" (Cox, 1926, p. 173). High motivation without high abilities will not bring about extraordinary accomplishments; inversely, even persons endowed with maximum abilities but who lack "task commitment" (Renzulli, 1986) will never excel.

The link connecting abilities and motivation seems to be the individual's self-concept. It is a set of perceptions and evaluations of one's own traits. Persons characterized by outstanding accomplishments were, as a rule, quite aware of their extraordinary capabilities at the time of their childhood and adolescence. As a consequence, their self-confidence was boosted which encouraged them to set their stakes higher and improve their achievements. Thus self-confidence is another relevant predictor of excellence.

Persons who later excel in their educational records, their extracurricular achievements or their vocational accomplishments differ from their peers in childhood and adolescence with regard to some further personality traits. One of them is independence, both emotionally and intellectually. They are more self-directed in setting their goals and in choosing the objects of their activities and the problems they are going to tackle; they are more willing to work alone and to accept responsibility for their products. A tendency toward non-conformity, unconventionality, even radicality of thinking goes along with this independence.

However, the predictive validity of these personality traits as they are assessed by interviews or questionnaires is not very high.

Interests as measured by inventories can make a useful contribution to the prediction of outstanding achievement. They are obviously domain-specific predictors; in general, the predictive validity of interests is considerably lower than the validity of abilities.

Lastly, there are some aspects of home environment that can serve as predictors of excellent achievement, not just by themselves but rather as "catalysts" (Gagné, 1985) helping potentials to become manifest and abilities to develop. One relevant aspect is the parents' value system: Positive attitudes toward learning, practice, and achievement in general shape and foster the children's achievement motivation. A second aspect is stimulation in that the children are exposed to a variety of experiences—e.g., by frequent discussions, shared hobbies and other leisure time activities—that are incentives for the children to discover and develop their own interests and abilities. A third aspect is relative freedom left to the children to pursue their interests. The fourth relevant aspect is the parents' support of the children with respect to the development of their abilities. In the course of adolescence and thereafter, the importance of the home environment diminishes whereas the influence of role models outside home increases. It has to be pointed out that virtually all of the research data leading to

these conclusions were obtained in retrospect. The contribution of information on home environment to the prediction of excellence in longitudinal studies is presumably very modest, for two reasons: Home environment is a moderator rather than a genuine predictor variable; and it is difficult to assess reliable indices of the situational factors mentioned above.

There is a group of predictors that might be called "second-order predictors" because they are, in a way, predictors as well as (early) criteria of achievement: performance in school and in higher education and extracurricular accomplishments during all stages of education. Quite naturally, past achievement is the best predictor of similar future achievement. This is why teacher ratings of classroom performance are good predictors of school grades, school grades are good predictors of college grades, early accomplishments in the arts, in sports or in music are good predictors of later accomplishments in these areas, etc., especially in the upper part of the achievement continuum. Yet, whenever the prediction of outstanding achievement is attempted before the first accomplishments in a closely corresponding area can be observed, it is necessary to have recourse to the individual and environmental predictors discussed above.

An Outlook

Much has been done to uncover the predictors of excellence since Galton set out to study geniuses more than a century ago. Much still remains to be done. Most of the knowledge about this issue that has been accumulated so far stems from retrospective studies. The few longitudinal studies that have been carried out started with very narrow sets of virtual predictor data. There is an urgent need for more long-term longitudinal studies starting with large unselected samples and assessing a broad spectrum of predictor variables; or, if the samples of the prospective studies are already highly selected, at least unselected control groups ought to be included.

There is also a need for better instruments of assessment: Complex tests of cognitive abilities with high ceilings, i.e., discriminative power in the area of high performance, ought to be developed. Most of the tests presently used in studies on giftedness are based on concepts that were developed during the first four decades of our century when little was known about the specific ways of information processing and problem-solving in the heads of the highly gifted. Furthermore, better instruments are needed in order to assess the motivational, affective and environmental variables that have proved to be essential for outstanding performance.

Finally, more use should be made of methods of modeling the complex interactions of predictors and of their relations with the criteria of outstanding achievement which have been developed during the last three decades, such as structural models using path diagrams (e.g., Joerskog, 1979). Only very few researchers have

applied such models to the analysis of longitudinal data on the predictability of extraordinary achievement so far.

More longitudinal studies, better instruments of assessment and the use of more complex models for the analysis of longitudinal data could contribute to a better prediction of excellence in school, university, and work. A better understanding of the predictability of outstanding achievement is a precondition to more effective methods for identifying and nurturing individuals with an extremely high potential.

PART IV

Programs and Practices of Nurturing the Gifted and Talented

Theories and Practices for Differentiated Education for the Gifted and Talented

LEONORA M. COHEN

DONALD C. AMBROSE

Pacific University, Forest Grove, Oregon, U.S.A.

Introduction

Other chapters in this book relate to research and practices in identification, program provision, curriculum applications, and other aspects of serving gifted children. This chapter explores the role of theory in education for the gifted. The following questions guide this exploration: Why does gifted education need a theory? What is a theory? What theories are extant for education of the gifted? What are the key questions or issues that a theory for education of the gifted must answer? What criteria might be used to analyze or develop a theory for education of the gifted? What is the relationship of theory to research and practice? What should be the scope and scale of a theory for gifted education? Should a theory for gifted education be focused on intelligence, giftedness, or creativity? What are the contextual influences on theory development? How might the various theories be unified? Finally, what are the implications of theory for practice?

Why Does Gifted Education Need a Theory?

Much emphasis has been placed on the provision of qualitatively different educational experiences for gifted children. Yet Busse and Mansfield (1980, p. 132) described programs for the gifted as "little more than patchwork collections of random practices and activities", a statement still true today. In light of major cuts in funding to gifted programs, particularly during the recent world-wide economic recession, special provisions based on qualitatively differentiated curricula and services for gifted children must be justified for their very survival. Without such justification, the gifted child movement may be doomed.

According to Gowan (1979), gifted children can only be given qualitatively different educational programs on the basis of "differential cognitive structures that are

functional in gifted and in gifted alone" (Gowan, cited in LeRose et al., 1979, p. 478). This statement suggests that research is needed to ascertain whether the gifted truly have different cognitive structures and ways of thinking. Although useful research efforts have been carried out to this end (e.g., Borkowski & Peck, 1986; Davidson, 1986; Rabinowitz & Glaser, 1985; Rogers, 1986) research alone is not sufficient. Because research in gifted education all too often has dealt with small issues in a piecemeal approach, it has not portrayed the whole picture. Although important meta-analyses of major research questions such as effects of grouping or acceleration on the gifted have been carried out (e.g., Kulik & Kulik, 1992; Rogers, 1992), researchers in this field have thus far failed to provide a coherent picture; hence, they have been unable to offer justification for many practices currently espoused as particular to the gifted. Even the landmark work by Shore, Cornell, Robinson, and Ward (1991) only provides answers about whether research has been found to justify specific practices. Justification of qualitatively different programming and practices for gifted children is built on shifting sands due to a lack of coherent theory. Without theory, the "so what" of research doesn't become integrated into a cogent whole.

Theory provides the big picture for researchers and practitioners by illuminating the context needed for transcending the important but scattershot empirical findings upon which researchers necessarily focus. In a similar fashion, theory can unite the bits and pieces of fragmented practices that characterize the field. Theory is also needed to (a) provide a research heuristic; (b) explain the underlying reasons that gifted children might have different cognitive structures; (c) offer suggestions for identification; (d) provide a base for qualitatively distinctive educational experiences; and (e) explain the complex cultural, social, emotional, physical, perceptual, and intuitive relationships that underlie the distinctive nature of the gifted child.

The need for theory development in the field of gifted education has been well-documented (Borland, 1989; Cohen, 1985; Feldman, 1982; Gowan, 1977; Horowitz, 1987, 1992; Horowitz & O'Brien, 1985; Le Rose et al., 1979; Passow, 1983, 1986; Renzulli, 1980; Ronvic, 1989; Shore & Dover, 1987; Shore, Cornell, Robinson, & Ward, 1991; Sisk, 1980; Sternberg & Davidson, 1986; VanTassel-Baska, 1988; Ward, 1961, 1962, 1986). Although Ward (1986) has been calling for conceptual analysis and theory development for the field since the early 1950s, very little was written in this area until 1983 when *Frames of Mind*, the breakthrough work of Gardner, was published. The exceptions are the pioneering efforts by Ward (1961) and those of Gowan (1972, 1974). These works, and seeds in the writings of Feldman (1980), Gruber (1981, 1982), Jellen and Verduin (1986), and Sternberg (1981, 1985, 1986), may have catalyzed theory development in the field, or perhaps it was the recognition by curriculum experts such as Maker, Passow and VanTassel-Baska that a theoretical base was necessary. Despite the importance of theory development,

One of the least discussed but most glaring holes in gifted and talented education is the lack of theory. No overarching theoretical framework exists for the development of gifted and talented programs. The absence of a theoretical base makes the development of gifted and talented programs a vulnerable and shaky proposition at best. Without such a framework, a specific gifted program may show little relationship between a given curriculum and the development of intelligence (Fetterman, 1988, pp. 62–63).

A theory for differentiated education of the gifted is like a beautiful necklace—each link, each pearl and jewel must be crafted into an elegant whole which will be of immense value to the field. Each golden link of the necklace represents an aspect to be explained by theory. The jewels, like proverbial gems of wisdom, are research efforts; the pearls are the pearls of practice. While each pearl or jewel has intrinsic value, its value is immeasurably enhanced when it is linked with others, becoming an exquisite whole.

What is a Theory?

A theory is a unified explanation for complex, observed phenomena that systematically describes the underlying relationships or principles of those phenomena (Castetter & Heisler, 1980). A description of surface characteristics and their logical extension or application—for example, the characteristics of the gifted child such as the ability to generalize, related to the type of curriculum to be provided—is not sufficient to be a theory. This is because the underlying structures and their relationships must be uncovered: the reasons behind both the characteristics and the curriculum.

The purpose of theory is to summarize and order

extant knowledge; to provide provisional explanations for observed events by showing the variables and how they relate to each other, allowing prediction of yet unobserved events; and to stimulate development of new knowledge by offering leads for inquiry (Ary et al., 1990). It should allow going “beyond the present data both retrospectively and prospectively” (Bruner, 1973, p. 221). This means that a theory should account for research data already collected, and provide a source for formulating hypotheses, organizing research, and predicting results.

A theory can be as narrow as a personal explanation for dealing with information and events in the world, for example, a little child’s “theory” that chipmunks enter the record player when the speed is switched from 33 to 45 rpm. More commonly, however, a theory is considered to be a way of organizing existing multiple phenomena, and of generating predictions that can be empirically tested.

A broad theory will necessarily be complex, a narrow one should have the quality of simplicity. In both cases, a theory should be characterized by elegance, in that the parts and pieces fit the events and “hang together” in a clear, esthetically satisfying way. Difficulties with broad theories include understanding their complexity, communicating their essence to others, and applying them to specific events. A problem with narrow theories related to giftedness is that they account for only a small fraction of the complexities of human behavior. An important issue is whether prediction can be made on the specific level or only on the general level. For example, a theory of giftedness that describes the important role of responsive parenting, such as that of Clark (1992), could be applied to the development of gifted children in general, but probably not to a particular child.

Theories are evolving explanations created by the mind. “Scientific theories like humans are dynamic organic systems that must grow and change as new information and new insights arise” (Sigel, Brodzinsky, & Golinkoff, 1981, p. xiii). The same applies to theories of human behavior and learning. Piaget (1971) noted that “the organism only succeeds in preserving its form through a continuous flow of exchanges with the environment” (p. 350). If a theory is considered to be analogous to an organic structure, that theory must adapt to new elements or data in its environment in order to preserve its organization. In short, a theory must assimilate discordant data and be modified to deal with the discrepancies—a process of adaptation and reorganization. New pearls or jewels can be linked into the theory necklace, or old ones can be removed or replaced. A theory, therefore, must have both stability and flexibility, both a stable framework and the capacity to be modified to deal with elements that do not fit. In essence, a theory can be likened to a structure (Piaget, 1970) characterized by:

(1) Wholeness—The principles of the theory all fit together into a coherent, logical whole.

(2) Self-regulation or maintenance—The principles

and boundaries of the theory are firm and clear, providing a framework for integrating new data and giving stability to the whole.

(3) Transformation—Aspects of the theory change to accommodate discordant data.

This notion of theory as an evolving structure can be observed in several recent theories that are applicable to gifted education, such as those of Clark, Gardner, Sternberg, or Tannenbaum. These theories have been developed over time as the proponent of a particular framework evolves and transforms his or her own point of view. Little by little, the pieces are put together, usually within a rough or partial structure first, and then by adding on and changing elements and areas of focus. For example, Sternberg's first theory framing in 1981 dealt with only the componential aspect of his triarchic theory. The contextual and experiential aspects were added several years later as he struggled to account for other aspects of intelligent behavior.

Models on the other hand, "are not modified as empirical data are accumulated; they are either retained if the data confirm them or abandoned if the data do not confirm them" (Ary et al., 1990, p. 17). A model is a "conceptual analogue generally of a physical or mathematical nature which is used to suggest research" (Marx, 1966, p. 4, cited in Ary et al., 1990, p. 16). A model could also be used as a heuristic for appropriate practice, such as Williams' Cognitive-Affective Interaction Model (1986). Models aid understanding by providing simplified representations of complex phenomena.

Although a major distinction between a model and a theory is modifiability, when a theory can no longer explain a wide range of data, it may be overthrown. A new theory founded on different explanations may be constructed, possibly leading to paradigm change. Referring to the necklace metaphor, the links of the theory necklace may be broken apart. Some of the gems of research and pearls of practice may be eliminated and new ones included. The whole may become reconstructed as a very different necklace, or perhaps in a different form altogether such as a new theory tiara.

Finally, a theory offers the possibility of transcendence to a higher plane of understanding. By linking together the multiple facets that must be considered with explanation, a theory offers a change in context to a higher plane, as the principles underlying observable phenomena are provided. By describing the underlying relationships, by relating the facts to each other, a whole greater than the sum of the parts is established.

In summary, a theory is a construction of the mind that provides a heuristic for dealing with information. On a grander scale, a theory is a unified explanation for complex phenomena, systematically describing the underlying relationships and principles of what is observed in behavior. It links together past research and practice and provides a basis for future efforts, transcending the present context. It evolves to accommodate new data, unless it no longer can account for new data provided through research and practice.

What Theories Do We Have in Gifted Education?

There are three groups of current and past theories that have implications for educating gifted children: theories of intelligence, theories of giftedness, and theories of creativity. This section briefly outlines theories being used, or theories with potential for use, in the field. This is not an exhaustive list; rather, the theories highlighted here are particularly relevant to the education of gifted children. The nuances and implications of each theory may be fully explored through the references provided at the end of the chapter.

Theories of Intelligence

Theories of intelligence deal with the ability to adapt successfully to the environment and to solve problems related to one's particular setting. These theories have been evolving in an interesting direction in recent years. Most early theories were primarily based on the results of psychometric tests. More recent theories emphasize multiple abilities and modes of information processing, modified by cultural context (Sternberg, 1990). Another new development is a movement beyond an emphasis on mere adaptation to include a focus on modifying the environment to meet the individual's needs (Gardner, 1983; Sternberg, 1988). Six basic categories of intelligence theories focus on abilities that differentiate the gifted from others: (a) specific, stable cognitive traits characteristic of intellectual functioning; (b) factors or underlying latent variables that explain individual differences; (c) specific intellectual components, elementary information processes that operate on internal representations of objects or symbols; (d) biological explanations; (e) underlying cognitive structures that develop as a result of interaction in the world to an advanced or more extensive degree; and (f) social interaction and motivation theories that view intelligence as developing through interchange with others, or through the influence of motivational elements.

COGNITIVE TRAIT THEORIES OF INTELLIGENCE

Galton (1869, 1883) was the first modern theorist to focus on giftedness. His theory of "the human faculty and its development" is based on two general inherited traits, the abundance of which makes one intellectually able. The first of these is sufficient energy, or a high capacity for labor. The second is sensitivity. The highly able are more perceptive than their less-gifted peers, taking in more sensory data which provides a broader range of information. A broader information base, in turn, provides a stronger basis for intelligent action.

Binet's conception of intelligence emphasizes the importance of good judgment (Binet & Simon, 1916). A person of good judgment shows initiative, is practical, and adapts well to varied circumstances. An intelligent individual combines three essential strengths—direc-

tion, adaptation, and control. A person with strength of direction knows what tasks are important and how to go about accomplishing them. Strength of adaptation means the individual can effectively select and monitor strategies while performing a task. Control is the ability to critique one's own thoughts and behaviors, ensuring that they are appropriate to the task. In addition, there are two types of intelligence. The first, ideational intelligence, is based on logical analysis and verbal reasoning, and operates in the realm of words and abstract ideas. The second, instinctive intelligence, is based on intuitive feeling. Binet's theory, expressed through the Stanford-Binet intelligence test (Terman & Merrill, 1973), has been very influential in selecting intellectually gifted students for gifted programs and services.

Terman was more a researcher than a theorist, but his Genetic Studies of Genius led to conceptions of giftedness that had important influences on education. These conceptions emerged from a longitudinal study of almost 1500 gifted individuals (IQ 140+). For Terman, intelligent people are effective abstract thinkers. They tend to be physically superior, emotionally stable, and trustworthy. They cultivate interests in a spontaneous manner, and these interests are multi-faceted. In comparison with their less-able peers, the highly intelligent are generally superior in mathematical reasoning, reading, language usage, and mastery of the sciences, literature, and the arts (Terman & Oden, 1951).

Cattell (1971) conceived of fluid and crystallized intelligences as subfactors of general intelligence, suggesting that fluid abilities provide a basis for the development of crystallized abilities. For instance, the fluid abilities of general reasoning, association, and memory skills can combine, providing an individual with a strong mechanical aptitude. The latter is part of a set of crystallized aptitudes that have emerged over time through the individual's interests and efforts. In essence, people of great talent have crystallized and focused their fluid abilities upon particular fields of endeavor or domains of interest. This theory drew attention to the role of environmental context. Some programs in gifted education emphasize fluid intelligences but ignore the crystallization of those abilities through long-term experience, effort, and interest in a particular domain. A focus on the latter may be particularly beneficial to children of exceptional ability.

FACTOR THEORIES OF INTELLIGENCE

Guilford's (1967, 1977) Structure of the Intellect (SOI), which Meeker (1969) effectively applied to the education of the gifted, is a three-dimensional model featuring a total of 120 possible intellectual abilities derived through factor analysis. In the model, there are five primary intellectual processes called operations. These include memory, cognition, convergent thinking, divergent thinking, and evaluation. There are four primary contents of intelligence including semantic (language

and speech), figural (imagery and visual-spatial abilities), symbolic (representational mathematical, musical, or coded thought), and behavioral (understanding the self and others). There are also six products in order of complexity from units to classes, relations, systems, transformations, and implications. Guilford and Meeker moved beyond the early IQ test emphases on memory and cognition, broadening conceptions of intelligence and giftedness. They did so by suggesting many different types of intellectual abilities, and by portraying the gifted as good problem solvers who excel in productive thinking, both convergent and divergent, and in evaluative thinking.

COMPONENTIAL THEORIES OF INTELLIGENCE

Sternberg's (1988, 1990) Triarchic Theory of Intelligence portrays integrative relationships among the following subtheories:

(1) The componential subtheory relating intelligence to the individual's internal world—The mental states or processes that underlie intelligent thought include three types of information processing components—metacomponents (higher-order executive thought processes), performance components (lower-order processes that serve as tools for the metacomponents), and knowledge-acquisition components that enable the individual to learn how to do what the metacomponents and performance components eventually do.

(2) The contextual subtheory relating intelligence to the external world of the individual—The intelligence of an individual is normally applied to one or more of three goals: (a) adaptation to an existing environment, (b) shaping an environment to better suit one's needs, and (c) selection of an environment with optimal conditions for living and working.

(3) The experiential subtheory relating intelligence to experience—Effectively dealing with novelty and automatizing information processing are signs of intelligence. An individual who can efficiently automatize conserves mental resources that can be allocated to dealing with novelty. Conversely, a person who effectively deals with novelty can apply more intellectual resources to automatization.

Sternberg's work has generated a great deal of interest in the field. The triarchic theory promises an expanded and more coherent basis for identification and program development.

BIOLOGICAL THEORIES OF INTELLIGENCE

Gardner (1983), in his theory of multiple intelligences, claims that a collection of biologically-based intelligences make up the overall intelligence of an individual. An intelligence is defined as "an ability or set of abilities that permits an individual to solve problems or fashion products that are of consequence in a particular cultural setting" (Walters & Gardner, 1986, p. 165).

These intelligences are: (a) linguistic (reading, writing, listening, and talking skills), (b) logical-mathematical (computing, deriving proofs), (c) spatial-visual (discerning orientation in space), (d) musical, (e) bodily-kinesthetic, (f) interpersonal (understanding others), and (g) intrapersonal (understanding the self). Each intelligence develops and can be enhanced. Each has its own locus in the brain, its own symbol system, and its own transmittable cultural history. Each intelligence is universal to the human species, but is reinforced by the degree to which it is valued by a culture.

Each of these intelligences is a separate system, distinct from the others. Although independent of each other, they interact to produce solutions to problems, or to create products that are of value in a particular cultural milieu. Crystallizing experiences play a role in the manifestation of intelligence. An experience can be crystallizing if it involves remarkable and memorable contact between a person with unusual talent or potential, and the materials of the field or domain in which the talent will be used. The notion of multiple intelligences has expanded conceptions of giftedness by emphasizing that intelligence can manifest in alternative modes of thought.

Eysenck's (1988) Psychophysiological Theory of Cognition is a radical departure from most theories of intelligence and is based on extensive research with average evoked potentials and reaction-time experiments. By combining information processing notions within a biological framework, Eysenck relates levels of intelligence to the speed of error-free information processing. Perceptual channels and musculature support the necessary mental speed and error checking.

STRUCTURAL-DEVELOPMENTAL THEORIES OF INTELLIGENCE

Piaget's (1977, 1980) constructivist-developmental theory portrays intelligence as adaptation. Intelligence develops through the interaction of the child with the environment as a result of the child's actions (both mental and physical) and reflections on those actions using the mechanism of reflective abstraction. The individual evolves through distinct levels or stages of organization over time, actively assimilating and accommodating aspects that relate to its idiosyncratic organization. The individual develops to higher levels of organization through the mechanism of equilibration, a balancing process in which elements that do not fit the knowing structures are accommodated by modifying those structures (Piaget, 1977). Development is based on conflicts, disturbances or gaps that provide the impetus for reorganization. Thus, the organism adapts to the environment by modifying itself. In the process of reflective abstraction, the individual constructs relationships not inherent in the elements it is putting together. This represents a discontinuity with what was before. Each equilibration leads toward higher and broader levels of understanding. Related to gifted

education, giftedness may involve higher stages beyond formal operational thought, faster or perhaps somewhat different movement through the stages, or a difference in the construction of the structures (Cohen, 1985).

Feuerstein's (1980) Instrumental Enrichment Model focuses on the nature of retarded learners but it could be useful in identifying and serving the gifted. According to Feuerstein, intelligence is dynamic and modifiable, not static. The intelligent person is able to effectively gather needed information and to use that information to express solutions to problems, or to generate new information. Direct intervention in an individual's cognitive development through the mediation of a caring adult is needed to optimize the effectiveness and efficiency of that development. Through the benefit of such mediation the individual becomes more open to experience and more adaptable to new situations. Feuerstein proposes that several basic skills underlie learning.

SOCIAL INTERACTION AND MOTIVATION THEORIES

Social interaction theories portray intelligence as developing through interaction with others (Sigel, 1981; Youniss, 1981). Social growth and cognitive growth have a reciprocal relationship, and cognition is framed by social understanding. The recent debate about cooperative learning for the gifted, as well as the role of parents in metacognitive and cognitive development would be enriched by understandings of the role of social interaction in intellectual development.

Several theories attempt to explain motivation. Competence Motivation Theory focuses on humans as biologically motivated to master tasks in their environment in order to feel competent without external rewards (White, 1959). Bandura's (1982) Theory of Self-Efficacy looks at people's perceptions of their own success, suggesting that the highly able feel capable of succeeding at a task, and believe that their skill level is increasing. Cohen (1989) focuses on intrinsic interest as motivating. The individual attempts to answer profound questions through intense, long-term interests, which motivate the type of active, energetic involvements characteristic of gifted children. Weiner (1985) suggests Attribution Theory as the basis for motivation. Individuals attribute success or failure to luck, effort, or ability, and their perception determines how they will approach a new task. Csikszentmihalyi (1990) claims that humans, through deep involvements that stretch their capacities, experience a state of "Flow" that is profoundly pleasurable and motivating. Jenkins-Friedman and Tollefson (1992) have created a model that combines social interaction, cognitive, and motivation theories among others to explain the resiliency factor critical to full development of talents. These theories that focus on the non-intellective factors would be particularly important in counseling, and in dealing with underachieving gifted students.

Theories and Models of Giftedness

These theories all have direct applications to the identification and/or provision of curriculum and programs for gifted students. Some focus on particular aspects of education for the gifted while others are broader in scope.

Ward's (1961, 1980) *Differential Education for the Gifted* is a theory of curriculum differentiation. In a series of propositions, Ward highlights the need for a differential theory that recognizes gifted individuals as different from their non-gifted peers in their capacities for learning. The gifted are faster, more accurate, and more independent of thought. Their capacity for abstract thought is superior, and they are intrinsically motivated to a high degree.

Ward's theoretical framework implies a number of curricular adaptations to meet the needs of the gifted learner including flexible program planning based on the nature of the individual; and emphases on intellectual activity, high expectations, philosophical mindedness, the development of a scientific disposition, mastery of an extensive knowledge base, personal adjustment, social adjustment, character development, and teaching students how to learn.

Based on the work of Polish psychologist, Dabrowski, Piechowski (1979, 1986) theorizes that extreme sensitivity or overexcitability indicates potential for high levels of development, particularly for self-actualization and moral vigor. Five dimensions of psychic life provide the basis for development from lower to higher levels. These are (a) psychomotor (energetic restlessness), (b) sensual, (openness to the world), (c) intellectual (love of ideas and a quest for knowledge), (d) imaginational (vivid imagery and rich association), and (d) emotional (a wide range of feelings and compassion).

In Piechowski's theory, there are five levels of personality development from lowest to highest: Level (1) self-centered; Level (2) inner fragmentation and conforming to expectations of others; Level (3) vulnerable autonomy; Level (4) self-actualization, and Level (5) universal compassion and self-sacrifice. By considering personality characteristics that are beyond the scope of intelligence tests, Piechowski provides a rationale for scrutinizing identification procedures for the gifted from a wide-angle perspective.

Jellen and Verduin's (1986) *Taxonomical Approach to Differential Education for the Gifted* portrays giftedness as the confluence of three primary components—cognition (intelligence and imagination), affect (empathy and sensitivity), and conation (interest and motivation). Gifted individuals may develop a strong sense of values along with powerful specific aptitudes and talents. They may also develop general intellectual abilities such as personal and social knowledge and expertise, moral knowledge, or philosophical-historical knowledge. The gifted are excellent knowledge producers, and they are generally more cooperative, rational, and socially responsible than their less-able

peers. Jellen and Verduin provide useful suggestions for curriculum development.

Clark's (1986, 1992) *Integrative Education Model* synthesizes recent findings from brain research, the new physics, general systems theory, and psychology to develop a model of giftedness that emphasizes wholeness and integration. The model portrays the individual as one system of energy in a vast, intricately interconnected complex of systems. From this holistic perspective, the potential of the individual is expansive. Arbitrary disciplinary boundaries should not become impediments to learning. The optimal development of human potential depends upon the integration of all facets of the brain-mind system including cognition (both linear and spatial), intuition, feeling or emotion, and the physical-sensing function. Clark's model illuminates the growth potential of the mind, the importance of the responsive environment, and the significance of some degree of creative self-direction for the learner in a safe, supportive environment. It is one of the few models developed for gifted education that has been applied to regular classrooms.

Milgram's (1989) *Four by Four Model of the Structure of Giftedness* defines four categories and four levels of giftedness. The categories include general intellectual ability; specific intellectual ability; general, original creative thinking; and specific creative talent. General intellectual ability includes overall general intelligence, the ability to carry out logical problem solving, and abstract thinking ability. Specific intellectual ability enables one to become competent, but not necessarily original, in a given area. People with high levels of ability in general original creative thinking can perceive problems in unique ways; generate unusual, high quality problem solutions; and produce a profusion of ideas. People with specific creative talent can, over long periods of time, become creative within a specific domain or field. The four levels of giftedness identify the level of competence or expertise an individual has reached within each of the four categories. The levels are, in ascending order, non-gifted, mild, moderate, and profound. Eminence is associated with the profound level in the category of specific creative talent. Realizing one's potential depends upon a favorable confluence of environmental opportunity, cognitive ability, and personal-social characteristics.

Renzulli (1985) began with practical considerations and research to evolve the *Schoolwide Enrichment Model* for providing gifted education programs. In the model, the gifted are perceived to be producers rather than consumers of information. Giftedness is defined as a combination of demonstrated above average ability, task commitment, and creativity. Renzulli addresses how students should be identified, suggests educational experiences, and offers practical materials and strategies to meet the needs of gifted children in the schoolwide setting.

Renzulli's work has encouraged educators to expand their conceptions of giftedness because gifted programs

based on the Enrichment Triad Model typically include the top 25% of students, who pass through a “revolving door” of identification, rather than the top 3% who are identified and served in many other programs. Also, Renzulli’s emphasis on information production led to the notion of curriculum compacting, which streamlines information acquisition to make room for curriculum enrichment activities (Renzulli, 1977).

Tannenbaum’s Psychosocial Model of Giftedness (1983, 1990) involves five factors that enable the gifted to become “critically acclaimed performers or exemplary producers of ideas in spheres of activity that enhance the moral, physical, emotional, social, intellectual, or aesthetic life of humanity” (1983, p. 86). These factors are: superior general intellectual ability, special abilities or aptitudes, nonintellective factors (personality variables such as task commitment, ego strength, need for achievement, and meta-learning abilities), environmental factors (nature of the family, peers, school, community, and culture) that nurture gifted development and determine which talents are valued, and finally chance factors (luck, opportunities). To become a producer of ideas requires different configurations and levels of each of these factors depending on the field of endeavor in which one becomes productive. Individuals with early promise are potentially gifted. A gifted child was not necessarily a gifted adult.

Taylor’s Multiple Talent Theory (1986) is based on the egalitarian notion that everyone has brain-based talents that need to be developed, and that the ability to accumulate knowledge is only one type of gift. Taylor developed a “multiple talent totem pole” for identifying and cultivating all human capacities through educational programs. Talents included in the totem pole are: academic, productive thinking, communicating, forecasting, decision making, planning (designing), implementing, human relations, and discerning opportunities. Each student is seen to have a unique pattern of strengths in one or more areas and a unique developmental curve in each talent area. It is beneficial to both self and society to systematically develop the whole person by searching for and developing these talents. This is best accomplished through a “double curriculum” in which knowledge acquisition and talent development occur simultaneously. Taylor’s model has been further developed for mainstream and gifted classrooms by Schlicter in her Talents Unlimited Program (Schlicter, 1986).

Others are in the process of developing models or theories. Emerging theories and models of narrow focus include: (a) the SMPY model for identifying, teaching, tutoring, and accelerating mathematically precocious youth (Benbow, 1986; Stanley, 1974); (b) Frasier’s (1992) theoretical framework for identifying the gifted in economically disadvantaged groups; and (c) Hollingsworth’s (1985) application of enaction theory, which uses mental simulations involving representational, procedural, and heuristic knowledge to

develop thinking skills. Emerging theories or models of broad scope include: (a) Betts’ (1985) Autonomous Learner Model which meets the emotional, social, and cognitive needs of the gifted through five dimensions (orientation, individual development, enrichment activities, seminars, and in-depth study); Feldhusen’s (1986) Purdue Models for Gifted Education—Primary (with Koloff), and Secondary (with Robinson); and (d) VanTassel-Baska’s comprehensive curriculum for the gifted (1988, 1989), an evolving model that embeds curriculum for the gifted within the regular classroom. Time will tell whether these approaches move beyond models to become theories.

Theories of Creativity

Theories of creativity are particularly valuable to the field. A chart listing selected, major theories of creativity, their proponents, and the basic tenets of each theory is found in the section “How Might the Various Theories be Unified?” (Tables 1 and 2). Therefore, only those theories relevant to education of the gifted, which are not discussed on the chart or require elaboration, will be considered here. Three of these theories described at the end of this section (quantum-idealistic, economic, and chaos) are rooted in bodies of knowledge outside the field. These theories may enrich education for the gifted because, as Piaget (1981) noted, reading around the field avoids parochialism and promotes creativity.

Wallas (1926) proposes four stages in the creative process: (a) preparation, (b) incubation, (c) illumination, and (d) verification. Preparation is the initial stage in which information about the problem is gathered. In the incubation phase, subconscious mental processes take place in which new information is associated with old concepts. During illumination, the creator suddenly becomes aware of a new idea, concept, or problem solution. In the verification phase, the new idea is tested for validity. These phases do not necessarily occur in sequence, nor do all of them occur in every instance. For example, a creative insight about a minor problem may occur without any perceptible preparation phase. Wallas’ model enables educators to recognize and encourage the creative process in the classroom.

Gowan’s (1972, 1979) Periodic Theory of Creative Development integrates Piaget’s cognitive developmental stages with Freud’s psycho-sexual stages and Erikson’s stages of ego development, producing a periodic version of developmental stage theory. He proposes three stages beyond Piaget’s formal operations (creativity, psychedelia, and illumination) to match the last three of Erikson’s eight stages. Stages 1, 4, and 7 are latency periods in which the individual focuses on the world. Stages 2, 5, and 8 are identity periods in which the focus is on the self. Creativity blooms in the third and sixth stages. Movement from one stage to another is discontinuous, caused by energy escalation. Dysplasias are malformations in development in which

one aspect of the psyche continues to escalate while another is arrested in a given stage. Students could benefit if educators diagnose dysplasias, and recognize the differential nature of Gowan's stages.

Urban's (1990) Components Model of Creativity is a holistic, gestalt-orientated approach to creativity, which emphasizes the interactional structure of the problem, process, product, personality, and environment that comes into play in a particular situation. All of these factors are intricately interwoven, and influence each other. For example, macro-environmental conditions, such as the political climate of the time, and micro-environmental conditions, such as the socioeconomic conditions of the family, determine the range and recognizability of possible problems that require creative action. In turn, the product of a creative act may affect the environment or reformulate problems. Urban also describes the interaction of three cognitive components (divergent thinking, general knowledge base, and specific knowledge base) and three personality components (focus or task commitment, motives, and openness/tolerance of ambiguity). The components all work together as a functional system and no single component may be sufficient or responsible for the whole creative process. Urban's model enables researchers and practitioners to focus on specific aspects of creativity without losing sight of the whole.

Goswami (1988, 1990) proposes a theory of creativity based on the idealistic interpretation of quantum physics. He suggests that the brain-mind system has a quantum, nonphysical mechanism as well as classical, physical neuronal machinery. The quantum mechanism enables the creative mind to leap out of a system of persistent self-reference, enabling it to access transcendent archetypes that provide the inspiration for creative thought. Other physicists have also conceptualized connections between the underlying principles of quantum physics and creative consciousness (Bohm & Peat, 1987; Capra, 1975). Quantum physics theories highlight the importance of intuitive processes in creative thought, and explore the possibility that underlying, holistic interconnections influence those processes beyond the scope of sense perception.

Rubenson's Psychoeconomic Model (Rubenson & Runco, 1992) is rooted in the field of economics, yet it addresses many of the issues of concern to psychologists. It encompasses notions pertaining to personality traits and intrinsic motivation drawn from the psychological literature. Rubenson portrays creative activity as the product of an interaction between the individual, the field (which determines market demand for creative activity), and a particular domain (the market itself). Creative potential is viewed as a product of initial endowments, societal and family influences, and active investments the individual may make in that potential. The rate of investment in creative endeavors varies from one individual to the next in response to a number of extrinsic and intrinsic factors including the cost of producing innovations (time costs and psychic costs),

both intrinsic and extrinsic benefits, and discount rates (the ability to defer gratification). If the development of creativity over time is an objective in programs for the gifted, this theoretic perspective can inform the field because it highlights motivational elements that influence the willingness of a person to invest time and effort in creative work.

Sternberg (1992) proposes another economic theory of creativity he calls an "Investment Theory". Creators need to be able to recognize areas or ideas that are undervalued and to invest themselves in these ideas, using aspects of their intelligence, intellectual style, knowledge, personality, motivation, and environmental context to produce creative ideas.

Sterling (1992, in press) applies concepts from chaos theory to creativity, portraying the human brain as a nonlinear dynamic system. The content and behavior of a dynamic system constantly change in response to environmental conditions, and in a nonlinear system, cause and effect are interrelated in complicated ways. The whole is greater than the sum of its parts so analysis of the system is not possible through analyses of the component parts. In the creative act, a problem moves the brain system from a state of equilibrium into disequilibrium. As the system moves further from equilibrium it becomes highly sensitive to tiny changes in variables such as external events or thoughts, and minute changes can have enormous, unpredictable effects. Under such conditions, the system can move into a chaotic state in which it reaches a new level of cognitive or creative organization. The chaos view of creativity highlights the importance of unpredictability and the necessity of ambiguity in creative development, providing a useful perspective on curriculum development.

In reviewing these various theories, it becomes evident that the boundaries are no longer so clear between theories of intelligence, giftedness, and creativity. The three groups of theories are beginning to move toward each other. The intricacies of this overlap are discussed later in the section "Should a Theory for Gifted Education Focus on Giftedness, Intelligence or Creativity?"

What are the Key Questions or Issues that Theories for the Gifted Must Answer?

Although written some 2000 years ago, Aristotle's conception of a complete explanation is useful in determining what the golden links might be for framing a theory for gifted education. Aristotle reasoned that complete explanations are based on four distinct causes:

(1) Material causes—causes attributable to the substance of which the object is composed, such as the physiological, neurological or genetic features affecting the organism.

A theory for gifted education should, therefore, include explanations of the role of genetics, neurological differences, motivation and personality variables, physi-

cal growth and maturation, extraordinary bodily-kinesthetic abilities, and discussion of the very nature of the gifted individual. Such explanations must deal with what underlies the characteristics that typically describe the gifted child: great curiosity; ease and speed of learning and memory retrieval; intrinsic motivation and immersion in an interest or task; heightened sensitivity; the ability to abstract, to make relationships, to generalize, and so forth. Works by Amabile (1983), Clark (1986, 1992), Eysenck (1988), Gardner (1983), Piechowski (1979, 1986) and Storfer (1990) focus particularly on this category of causes.

(2) Efficient causes—causes due to an external agent, antecedent condition, or independent variable that move the object—the stimulus of environmental effects.

A theory for gifted education must include explanations of the effects of the physical, social, and cultural environments (including educational practices) on the development of giftedness. Theories and/or research on environmental effects by Albert and Runco (1986), Simonton (1984) and Tannenbaum (1983, 1990) and the environmental component of Sternberg's theory (1985); psychoeconomic theories of Rubenson (1992) and Sternberg (1990); and educational theories of Jellen and Verquin (1986), Milgram (1989), Renzulli (1977, 1985), Urban (1990), and Ward (1961, 1986) focus on efficient causes.

(3) Formal causes—causes arising from the pattern, organization, or form of an object—the underlying structure or rules that can explain temporary stability or organization.

A theory for gifted education must explain how the individual structures and organizes thought and metacognition; the ensemble of structures or systems within and outside of the individual that support or limit optimal development; and the patterns underlying both the characteristics of the child and the types of educational experiences provided. Works by Cohen (1985, 1988, 1992), Feldman (1980, 1982, 1989), Feuerstein (1979, 1980, 1988), Gruber (1981, 1988b), and Horowitz (1992) focus on formal explanations. Others who look at patterns in thought and metacognition are Shore and Dover (1987) and Sternberg (1985).

(4) Final causes—causes focusing on the end toward which an object develops that explain the organization and direction of change (teleological causes).

A theory for gifted education must explain the development of giftedness over the life span. The bridge between childhood giftedness and the productive creative giftedness of adulthood must be understood. Creative beings purposefully direct themselves toward creating (Gruber, 1981; Perkins, 1981). Purpose can be considered a final cause notion, in that it directs efforts toward an end point. The vision of possibilities that creators have in developing their efforts is also a final cause notion. Works by Cohen (1985, 1988, 1992), Horowitz and O'Brien (1985), Gowan (1972, 1974, 1979) and Gruber (1981) focus on final causes.

According to Aristotle, a complete explanation

involves all four causes: material, efficient, formal, and final; therefore, the most complete theory for education of the gifted will involve all four causes. In addition to the four causal explanations, certain structural and definitional aspects must also be included in a theory. In sum, the golden links in a theory will involve the following: (a) a definition of giftedness and related terms (talent, intelligence, creativity, genius, prodigiousness); (b) the biological base for giftedness (genetic factors; physical, perceptual, and maturational factors; neurological differences); (c) the nature of the gifted child (personality, motivational, and learning style factors; moral development; development of conation/purpose; vulnerability factors); (d) differences in thinking and learning (cognition, metacognition, intuition); (e) the environmental context that supports gifted development (physical, social, and cultural environments; interactions of the individual with the environment; social development; adaptation; chance factors); (f) educational practice (identification, including identification of the underserved; curriculum; provision of programs and services; teaching and teacher preparation; counseling; program and student evaluation); (g) metatheoretical considerations (philosophical orientation and conceptual lens; historical antecedents of the theory; relationship to other theories; mechanisms or principles that link one part of the theory to another; degree to which theory accounts for research and practice in a field; consideration of theories, research, and practice from outside the field; the scope and scale of the theory); and (h) how giftedness develops and evolves over the lifespan.

What Criteria Might be Used to Analyze or Develop a Theory for Education of the Gifted?

Most theories applicable to education of the gifted are pieces of the whole picture. Some focus more on personality variables, some on neurobiological explanations, others on social and cultural factors, and still others on pedagogical issues. Criteria are needed to analyze and judge the value and breadth of existing efforts, to weed out theories from program applications, and to give direction in furthering or developing theory.

A theory must apply to a wide array of behaviors, yet be guided by parsimony, internal coherence, and esthetics (Overton & Newman, 1982). It should describe and explain, predict and control, and be testable (Kuhn, 1970). According to Ary, Jacobs, and Rasavieh (1990), a sound theory is characterized by the following criteria:

(1) It explains the "why" of the observed facts in the simplest possible form, observing "the principle of parsimony" (p. 18).

(2) It efficiently accounts for, and is consistent with, observed facts as well as the accumulated body of knowledge.

(3) It provides a means for its own verification

through deductive hypotheses that state anticipated consequences if the theory is true. Rather than truth or falsity, however, a theory is accepted based on its utility in efficiently predicting events.

(4) It suggests areas in need of investigation and stimulates new discoveries.

Cohen (1988) presents four broad categories of criteria related to theory: the nature of the gifted child, education and identification, the framework of the theory, and criteria for the theory. Cohen further suggests that theories applicable to education of the gifted could be analyzed and rated for each criterion on a scale of 0 to 4. This type of analysis could show where a theory needs to be modified or expanded, and permit comparisons of theories. It could also provide a basis for combining the strongest aspects of a variety of theories into a metatheory for gifted education.

What is the Relationship of Theory to Research and Practice?

The pearls of practice and gems of research are crafted together by the golden links of theory. Ideally, the pearls, gems, and links should inform one another in a reciprocal manner. Research informs theory development just as theory provides a heuristic for new research. A theory must be able to account for extant research findings and organize these into a cogent whole. Although there may be gaps in what is known, a theory should help to locate where these gaps occur, as well as point out directions for new research aimed at finding the missing information.

Likewise, practice should inform theory and vice versa. A theory of giftedness should provide guidelines for application to educational practices. In addition, what works successfully for gifted children in educational settings should provide information for theory-building. Research and practice also have the same relationship.

Historically, the reciprocal relationship between research and practice probably is the most evident. Shore, Cornell, Robinson, and Ward (1991) describe the importance of such mutual relationships. Their study of whether research efforts support what experts have called for in practice suggests that more research is needed to justify certain practices and that some recommended practices are unsubstantiated. The relationship between theory and research or theory and practice also needs exploration. Unfortunately, the theory aspect is too often ignored by researchers and practitioners alike. But research without theory is banal and practice without theory has no foundation. Theorists should work together with expert researchers and practitioners in gifted education to build theories, plan research, and improve practice. By acknowledging and integrating the necessary and reciprocal relationships of theory, research, and practice, the field will gain a stronger foundation.

What Should Be the Scope and Scale of a Theory for Gifted Education?

The scope of a theory delineates its breadth—what it chooses to describe and not describe. Related to gifted education, each theorist appears to have a different vision of what the scope should be. Gruber (1981, 1988a, 1989) believes that the scope should involve constructing a theory of an individual, particularly highly creative, unique individuals. Others, like Feldman (1980, 1989) or Stanley and colleagues (1974), advocate the development of theory for a particular domain or field of endeavor. Some focus on a theory of intelligence (Gardner, 1983; Sternberg, 1985), others advocate a very broad theory that attempts to unite the parts and pieces characteristic of giftedness with pertinent theories from other cultures and different disciplines (Ambrose, 1992). The narrower the theory, the more specific and the more accurate the control and predictive capacity. The broader the theory, the greater the descriptive and explanatory potential. What may be needed is an integration of narrower theories into broader theories within compatible frameworks in order to strengthen the power of description, explanation, prediction, and control.

The scale of each theorist's work relates to the level of complexity from which theory development is viewed. At the macrolevel is a group of theorists focused on how a framework for a theory might be built. Works by Cohen (1985, 1992) and Overton (1984, 1990) are concerned with this level of framing. Next is a group concerned with overarching theories that could be applied to optimal development: general systems theory, developmental theories, chaos theory, psychoeconomic theories, and perhaps quantum theory. Theories of Feldman (1980), Goswami (1988), Rubenson (1992), and Sterling (1992) seem to fit well at this level. The next two levels deal with the person. Within this frame, the third level focuses on the thinking/creating processes: the metacomponents, cognition, intuition, and imagination as epitomized in works by Gardner (1983), Gruber (1981), Meeker (1969), and Sternberg (1985). A fourth considers factors that influence gifted development—environmental influences, chance factors, neurological aspects, inherent talents and abilities, personality variables, particularly in theories by Milgram (1989), Piechowski (1979, 1986), Runco (1990), Tannenbaum (1983) and Urban (1990). The final two levels emphasize applications. Level five focuses on educational frameworks seen in works by Clark (1992), Jellen and Verduin (1986), Renzulli (1977, 1985), and Ward (1961, 1986). Level six considers specific learning processes, seen in works by theorists such as Feuerstein (1980), Hollingsworth (1985), Presseisen (1987), and Shore and Dover (1987) (see Figure 1).

The difference between scope and scale is that scope accounts for the breadth of explanation offered, while scale describes the viewing point or level of focus in a theory. For example, both Ward and Clark focus

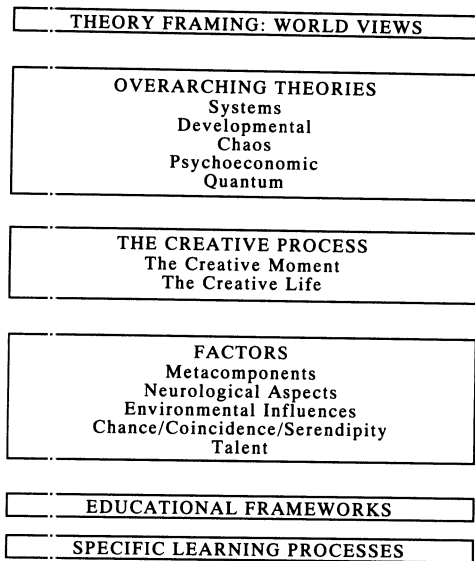

FIGURE 1. Theory building levels for optimal development of mind.

on educational applications as their level of scale. However, Clark's scope is broader, as it involves parenting, the evolution of giftedness, a focus on creativity, and biological explanations related to pedagogical considerations.

Theorists need to identify where their own theories fit in terms of scope and scale. To recognize where a theory fits is to understand the questions and issues being addressed by that theory, as well as the theory's limitations. Some theories deal with more than one level of complexity. All the levels, however, must be addressed to create a complete understanding of giftedness: from the macro-big picture world views to the microviews of specific learning processes and strategies.

Should a Theory of Gifted Education Focus on Giftedness, Intelligence, or Creativity?

It appears obvious that a theory of gifted education should focus on giftedness. But such is not the case. In reality, both theories of giftedness and theories of intelligence need to focus on creativity, for the following reasons.

Theories of intelligence essentially look at how successfully the individual adapts to the environment. An issue is whether theories of intelligence should require the individual to adapt to the world or whether the world should adapt somewhat to the individual. In theories of creativity, the adaptation is mutual. As Gruber (1988a, p. 41) stated, "It is safe to say that no case of early achievement occurs without a long apprenticeship [in order to master a field]". This is adaptation to the

world. But when the creative individual extends or transforms the domain in which he or she functions, that world of endeavor adapts to him or her (Cohen, 1989). For example, when Freud described the workings of the unconscious mind, he changed the way new learners learned the field of psychology (Feldman, 1980). The creator also transforms the self, constructing a framework for looking at, and organizing data and events from the outside (Gruber, 1981). The most recent theories of intelligence acknowledge this shaping of the world aspect, thus incorporating creativity, but they do not address the transformation of self.

Any theory of intelligence or cognitive development should be able to explain giftedness. Giftedness can be viewed as simply the optimal state or level within that framework, for example, two standard deviations above the mean on a scale of intelligence. But most theories of intelligence and cognitive development do little to explain why some individuals develop more fully and how to support that development, nor do they explain the difference between what is considered gifted development in children and gifted development in adults. These are issues of primary concern to educators and psychologists working with the gifted.

Most definitions of childhood giftedness focus on specific traits, factors, or abilities (usually as determined by tests of academic or mental ability) that in some way distinguish such children from others (Siegler & Kotovsky, 1986). Most definitions of giftedness in adults, however, involve creative productivity. But it does not seem that adult creative productivity can be predicted from childhood academic or intellectual abilities. For example, a brilliant secondary student selected as a presidential scholar for his or her outstanding academic performance may fail to accomplish much of anything in adulthood (Kaufman, 1981). Even Terman's longitudinal study of genius that looked at almost 1500 high IQ children and followed them over their life spans turned up many high achieving adults, but few creative producers or geniuses. If a theory should allow prediction, perhaps the field has been looking at the wrong dimensions.

A bridge between "schoolhouse giftedness" (Renzulli, 1986) and adult productive creativity must be found. Theories of creativity offer greater possibilities for understanding the end state toward which giftedness can lead—the creation of new and useful ideas, products, or performances that extend or even transform a field, hence, gifted → creative development (Cohen, 1985, 1989). To limit gifted education to concerns only for the current needs of extraordinary children may deny the development of their creative potential. In addition, the possibility for creative productivity may be overlooked in a child whose gifts are not obvious. Efforts should focus on creativity, working to understand how to support its development in children, so that they can become creative, productive adults.

Creativity in mature individuals is most often defined as the production of something new or rare, of value (Rothenberg & Hausman, 1976). In creativity, both

the self and the field of endeavor are extended or even transformed. There is a discontinuity with what was before—a change in context (Bateson, 1979; Cohen, 1992; Feldman, 1982; Goswami, 1988). The greatest difficulty in theory development comes in explaining novelty, how something new enters a system, a discontinuity. Also difficult to explain in current theories of giftedness are change processes (Feldman, 1989). A theory for gifted education must address not only how something new is created but also the change processes—how the self and a field of endeavor are transformed. Theories of creativity do so, while most theories of giftedness or intelligence do not.

Creativity is universal. Every human invents the world for him or herself, and all acts of real learning are creative acts (Piaget, 1981). Creativity, therefore, must be a brain-based function characteristic of the species. Giftedness, however, is not characteristic of everyone, but is a “best example” in any given theory. Giftedness is also context-specific: only the specific traits valued by a culture are acknowledged and encouraged. By focusing theory development on the universal human characteristic of creativity and explaining its optimization, the field of gifted education can be better related to general education, thus avoiding its relegation to a peripheral, dispensable frill in the schools. More must be learned about this basic function of mind and what allows some individuals to reach mature levels of creativity—or adult giftedness (Cohen, 1989).

What Are the Contextual Influences on Theory Development?

Lakoff and Johnson (1980) claim that our thoughts are implicitly shaped by metaphor, and that cultural and philosophical biases can permeate our thought below the level of awareness. Similarly, critical theorists suggest that the particular structure of communication in a group tacitly carries with it ideological predispositions that can reinforce the power of dominant groups within a culture or society, and undermine the opportunities for advancement among the weak (Hodge & Kress, 1988). Bohm and Peat (1987) illustrate how scientific inquiry can be influenced by the tacit infrastructure of commonly accepted beliefs and values that pervade a particular culture.

In essence, a particular brand of ideology can permeate the communications and ideas of theorists and researchers in a field, particularly if the leaders in that field are predominantly the products of a dominant culture. Bohm (1987) claims that a fish cannot see the water in which it swims. Theorists, researchers, and practitioners face a similar problem, swimming through the conceptual familiarity of an ideology that limits their focus to a narrow band of the human potential spectrum. Most of the leaders in the field of gifted education are predominantly the products of Western-industrial culture and, as such, may be prone to ideological

insularity. Eastern Asian, Native American, African American, Hispanic, and other cultural viewpoints may be underrepresented in the field.

Fortunately, many leaders in the field are at least aware of the need for theory, research, and practice that addresses cultural diversity, and some are actively advocating for a greater emphasis on theoretical frameworks related to underrepresented populations, most notably Frasier (1992). Nevertheless, it appears that theorists must be careful to ensure that their conceptual frameworks are not being tainted or warped by insular perceptions and biases. Theorists need to recognize such biases in their work, and to consider a broad spectrum of abilities in their deliberations concerning gifted education.

The same concerns apply to the breadth of disciplines represented in the theories being considered. Most of these theories are rooted in the behavioral sciences. A comprehensive theory for the field should be truly interdisciplinary in nature, encompassing disciplines such as philosophy and the arts, as well as the behavioral sciences. Ideally, the context from which a unified theory might draw will include as much of human experience as possible.

How Might the Various Theories be Unified?

The field of education for the gifted needs a unified theory that combines theories of giftedness with theories of intelligence and creativity in order to fully explain the development of gifted and creative individuals and how they should be identified and served. This might be thought of as somewhat akin to Stephen Hawking’s “Big Bang” theory of the universe wherein he combined theories of relativity, gravity, and quantum physics. Sternberg and Davidson (1986) state that we are at the brink of such a possibility, that the many, diverse conceptions of giftedness are on the verge of coming together, and that there is a need to combine theoretical methodologies and perspectives. Theories from different fields—the various psychologies, biology and neurobiology, genetics, anthropology, physics, philosophy, education—should be brought to bear on optimal development. To construct a unified theory will allow the field to move ahead, putting research and practice on a sound footing.

What is Currently Being Done to Unify Theory?

Some individual theorists are attempting to integrate the theoretical work of others in the field. For instance, Sterling (1992) is using chaos theory as a framework for spanning the gaps between theories of creativity. Meininger (1992) is using grounded theory methodologies to find common threads of meaning among some of the theories outlined in this chapter.

There have also been collaborative attempts at theory

unification, spearheaded by Cohen, her colleagues, and students. Cohen has encouraged theorists to organize symposia at major gifted education conferences to accomplish the following:

(1) Consider the definitions, needs, and purposes of a theory for the field, list possible theories to consider, and develop criteria through a panel or group discussion.

(2) Have a presentation by each theorist of his or her theory, perhaps with a scoring on each criterion by participants.

(3) Meet in a symposium or discussion group to illuminate where the strengths of various theories lie and to explore how to work together to "get ahead by getting a theory". An attempt would be made to reach the best possible explanation to link together definitions, identification, and educational practices for gifted and creative individuals from the participants' combined efforts. Such a synergistic product, a metatheory for gifted education, should allow the field to make some great leaps forward (Cohen, 1988).

In response to this encouragement, the National Association for Gifted Children in the United States established a new Conceptual Foundations Division in 1991 as a forum for the development of conceptual frameworks that will serve as a basis for appropriate research, curriculum development, and identification. The mission of the Division is to consider definitions, conceptions, and theories of giftedness; trends, issues, and future directions; historical perspectives; ideas from outside the field; and philosophical and ethical issues.

Another collaborative effort emerged through the founding of the Institute for Creative Intelligence in 1990. Theory Summit Conferences on Optimal Development of Mind were held at Mt Hood, Oregon in the fall of 1990 and 1991. The Summit group, which includes some of the seminal minds in a number of different disciplines, is attempting to provide the foundation for a unified theory of creative intelligence. With development of a consistent funding base, Summits can be planned for the next several years.

In order to streamline these efforts, particularly those involving collaborative groups, it is important to understand some of the obstacles that make the construction of a metatheory problematic.

Obstacles to Theory Unification

Efforts to unify theory involve complex, multidimensional processes that encompass a broad range of perspectives on the rather nebulous concepts of creativity, giftedness, and intelligence. Among the many problems that can confound attempts to unify theory are differing philosophical beliefs, a lack of shared language about the phenomena in question, and the tendency of participants to prefer different levels of discourse (see Figure 1). There are also a large number of difficult logistical problems that can hinder progress when theorists and researchers assemble to carry

out collaborative, interdisciplinary, theoretical work (Ambrose, 1992).

Perhaps the most fundamental difficulties faced by interdisciplinary researchers attempting to grapple with ill-defined theoretical problems are related to philosophical positions and world views. A world view is the conceptual lens or filter through which an individual perceives reality (Overton, 1984). In the scientific realm, it colors perceptions, shaping theory and ultimately, the practice that theory informs.

Overton suggests that there are two competing world views that currently underlie and influence scientific investigation. The mechanistic view considers reality as regular, stable, and fixed, predisposing researchers to reductive analysis and the search for causal explanations of phenomena. The central metaphor is a machine. The organismic lens portrays reality as dynamic, holistic, and evolving, encouraging the researcher to look for patterns in the whole and to infer the underlying organization or structure. The central metaphor is a living thing.

Organismic theories deal with universal structures and help in understanding both the direction and organization of gifted → creative development. They accept formal and final causes as central, and limit the value of material and efficient causes to explaining rate and terminal level of development (Overton, 1984; Overton & Newman, 1982). Because organismic theories accept qualitative, discontinuous changes, creative leaps or insights do not have to be explained by antecedent, contingent causes. Creativity, however, involves variation, non-universal systems, non-linear pathways, and an incredible coincidence of confluent factors to reach extremely high levels (Feldman, 1982). Organismic theories do not deal with these aspects successfully. Because mechanistic theories focus on environmental (efficient) and hereditary (contingent) factors, they are needed to explain the conditions necessary for creative development, individual variation, and the small steps in the creative process. But mechanistic theories do not accept organization (formal) and direction (final) explanations as natural or necessary.

Without an explicit awareness of these fundamental philosophical differences, a domain of inquiry can become fragmented, with different theoretical camps aligning themselves under the banners of incommensurate world views or paradigms. Such entrenchment and fragmentation inhibits communication across disciplinary boundaries, as well as within disciplines where the world views differ. At the same time, integration of these conceptual frameworks is needed to address all four of Aristotle's causes needed for a complete explanation. The field of creativity is a perfect focal point for an attempt at theoretic integration because its extreme breadth of scope will illuminate the completeness of explanation provided by each of the major world views.

In addition to different world views, lack of shared language increases the difficulty of collaborative attempts to unify theories. The same term can have subtle differences in meaning from one discipline to the next

and theorists can find themselves talking or even reading past one another (Anbar, 1986; MacDonald, 1986). Even within the same field, theorists have quite different definitions for the most commonly used terms: giftedness, creativity, talent, genius, prodigiousness, and intelligence.

Further communication problems arise from the tendency of researchers and theorists to prefer different levels of discourse (see Figure 1), a problem of scale. Participants in theory unification efforts can expend their energies attempting to convince peers to participate in dialogue at their preferred levels, and this detracts from the interdisciplinary conceptual bridging they are attempting to achieve (Ambrose, 1992).

Interdisciplinary research in theories of intelligence, giftedness, and creativity can be highly complex and problematic. It encompasses an enormous body of knowledge and several levels of inquiry. It also demands the resolution of seemingly incompatible theoretical perspectives that are rooted in competing world views. Time is an obstacle, as opportunities to work with other theorists are limited. Lack of criteria for such a metatheory also confounds theorists' attempts to "get a handle" on the issue. It will take a great deal of patience, time, and insight from the best minds in the field to overcome such obstacles.

Recommendations for Unifying Theories

The following are some strategies for unifying theories. Other suggestions may be found in Cohen (1992).

WORLD VIEWS: UNIFICATION BY "FAMILIES OF THEORIES"

The two major world views, mechanistic and organismic, can be used as a heuristic for the initial stages of theory unification. Theories within each world view can be thought of as a "family of theories" (Overton, 1984; Overton & Reese, 1973), each having common central notions and metaphors, as well as preferred research techniques.

The mechanistic family of theories related to creativity is included in Table 1. In the mechanistic world view, creativity is considered to be comprised of traits, factors, specific behaviors, or chains of associations that can be explained by antecedent causes. The view of the gifted→creative individual is present-focused, a cross-sectional slice in time, a being (as opposed to a becoming) view.

In the organismic conceptual lens or world view, creativity is portrayed as a process of necessary restructuring of systems or structures, usually in the direction of ever higher levels or goals (formal or final causes). The view of the gifted→creative individual is future-focused, a longitudinal or becoming view. The organismic family of theories is outlined in Table 2. More extensive explanations of these theories, and references for the work of the theorists included in Tables 1 and 2 can be found in Rothenburg and Hausman (1976) and in Cohen (1985, 1988).

Theories can be related to each other first within each family, because they share the same core notions and research heuristics. Theories within each of the two world view families should first be analyzed along criteria proposed for theory selection and development (Cohen, 1988). One approach would be for individual

TABLE 1
Mechanistic Family of Theories

Description	Proponents	Applications
Associationist Theories Creativity emerges from the number and unusualness of associations. Caused by bringing together two remote ideas.	<i>Mednick</i> — remote associations <i>Koestler</i> — bisociation theory (subconscious relating of matrices or frames of reference).	Highly influential basis for: Guilford's factors of ideational fluency, associational fluency, & originality; Torrance's verbal & figural test based on divergent thinking; Osborn's brainstorming & checklist of verbs; Eberle's scamper; Parnes' idea stimulating techniques; Feldhusen & Treffinger's forced relationships; Gordon & Prince's synectics.
Psychometric Theories Measurable, stable traits or factors differentiate gifted & creative from others. High IQ & creativity not synonymous.	<i>Galton</i> — hereditary traits <i>Terman</i> — longitudinal study of high IQ individuals age 10 onwards <i>Guilford</i> — factor theory of intelligence, structure of the intellect (SOI) <i>Meeker</i> — application of SOI to classroom.	Very influential, most identification procedures rely on IQ & achievement tests, some include creativity tests. Program evaluation sometimes based on standardized achievement tests or tests of creativity. SOI-LA programs (Guilford, Meeker) increasingly applied in TAG classes

TABLE 1 Continued

Description	Proponents	Applications
<p>Behaviorist Theories Creativity based on links between stimulus and response. Reward for creative behavior, or appearance of novel response stimulates additional novel behavior.</p>	<p><i>Skinner</i> — operant conditioning <i>Staats</i> — cumulative hierarchical learning <i>Berliner; Boles</i> — catastrophe theory accounts for creative leaps</p>	<p>Little applied in TAG classes except in positive teacher reinforcement as stimulus behavior.</p>
<p>Personality Traits & Cognitive Style Theories Relatively fixed or stable personality characteristics differentiate creative individuals from non-creatives, such as self-confidence, independence, risk-taking, preference for complexity, humor, task commitment, imagination, cross-sex identification, self-acceptance, intuition, sensitivity, and field independence.</p>	<p><i>Roe</i> — creative scientists <i>MacKinnon</i> — architects & others <i>Gough</i> — research scientists <i>Barron</i> — Air Force officers, creative writers, & other groups <i>Walberg</i> — eminent men <i>Cattell</i> — factor analysis of several groups</p>	<p>Use of personality inventories to help teacher learn about student and student learn about self (Khatena's SAM, Rimm & Davis' GIFT, Torrance's "What kind of Person Are You", Williams' "How Do You Feel About Yourself"). Emphasis on match of learning styles to appropriate teaching styles.</p>
<p>Environmental Factors Theories Identifiable environmental factors may cause creativity (special family position, parental encouragement, consistent discipline, lack of parental pressure, early exposure to many adults & eminent individuals; historical factors; availability of cultural stimuli, materials in field of eminence; & mentors early in life.</p>	<p><i>Roe</i> — male creative scientists <i>MacKinnon</i> — architects <i>Albert</i> — American presidents, British prime ministers, nobel laureates, eminent scientists <i>Walberg</i> — sociocultural events influencing creative development <i>Feldman</i> — coincidence of environmental factors <i>Amabile</i> — motivational aspects of social climate <i>Simonton</i> — political, social, cultural conditions</p>	<p>Much applied. Belief that students will be creative if teachers provide the right environment.</p>
<p>Experimental & Training Approaches Creativity can be increased through teaching or training of specific steps or techniques.</p>	<p><i>Covington, Crutchfield, & Davies</i> — productive thinking program <i>Feldhouse, Speedie, & Treffinger</i> — Purdue creative thinking program <i>Parnes</i> — creative problem solving program <i>Meyer & Torrance</i> — Torrance-Myer workbooks <i>Khatena</i> — Training of imagination & imagery</p>	<p>Extensively used. Best for establishing supportive environment & developing problem-solving heuristics, & for influencing production at non-professional levels. Transfer of skills best to problems similar to those used in training.</p>
<p>Cognitive Science/Information Processing Theories Humans are manipulators of symbols which they put into patterns. Specific, higher-level cognitive processes or components differentiate the gifted from average (e.g., knowledge acquisition components, reconstructive memory, insight, metacognition). Use of computer analogies to explain workings of the mind. Preferred research method is isolating variables using large sample methods.</p>	<p><i>Borkowski & Peck</i> — metamemory <i>Davidson</i> — role of insight <i>Dehn</i> — reconstructive memory <i>Jackson & Butterfield</i> — giftedness as excellent performance <i>Sternberg</i> — triachic theory (with componential, contextual, & experiential subtheories)</p>	<p>Beginning to be used in research (Shore & Dover, Hollingsworth). Little classroom application in literature yet.</p>

TABLE 2
Organismic Family of Theories

Description	Proponents	Applications
<p>Psychoanalytic Theories Unconscious or preconscious is source of creativity. Process involves bringing content to surface through imagery & imagination, & consciously acting on it.</p>	<p><i>Freud</i> — sublimation of sexual interests via unconscious <i>Kris</i> — stems from the preconscious caused by regression in service of the ego <i>Kubie</i> — source is playful preconscious <i>Arietti</i> — “magic synthesis” of unconscious & logical processes <i>Jung</i> — primordial archetypes surface from collective unconscious through dreams rather than free will <i>Rank</i> — focus on consciousness, will, & separation. Three types of personality development (adapted, conflicted, ideal-the artist)</p>	<p>Extensively used in gifted education, mainly in two ways: the notion of insight as meeting place for subconscious thought & conscious awareness (e.g., Osborn-Parnes creative problem solving includes subconscious access techniques; Prince’s work attends to censors of the unconscious); and the importance of imagery and imagination (Gowan, Khatena & Torrance; Gordon & Prince focus on metaphor through synectics).</p>
<p>Humanist Theories Creativity is a capacity in everyone, individual strives toward self-realization. Planning required for optimal development. Creativity is the ideal.</p>	<p><i>Maslow</i> — self-actualizing creativity is capacity in everyone <i>Rogers</i> — actualized person creatively lives & produces <i>Fromm</i> — comes from need for transcendence <i>Combs</i> — proposed a perceptual framework. Need classroom climate conducive to creativity <i>Erikson</i> — proposed eight stages of life cycle. Individual striving toward highest level as conscious choice.</p>	<p>TAG classroom applications seen in openness, goal of developing independent learners, call for creative climate. Torrance’s “checklist of creative positives,” Whitmore’s interventions with underachieving gifted, & Clark’s focus on early interactions that support becoming gifted.</p>
<p>Systems Theories General systems theory is an interdisciplinary model of organization that explores structural similarities across fields, serves as a vehicle for integrating, & generates more narrow theories. Distinct structures accepted as different, parts are distinguished from whole & may work differently, focus is on material & energy exchange with environment in the build-up of order & organization. Allows for “equifinality” — the same goal may be reached under different conditions & by different paths. A need to destructure in order to reintegrate is recognized.</p>	<p><i>Bertalanffy</i> — father of general systems theory <i>Land and Kenneally</i> — stage of the growth cycle; destructuring for creative transformation</p>	<p>Little application of systems theory to gifted education except in the works of Bruch, Langham and Torrance, Gowan and Dodd, & Khatena. Dabrowski’s theory of positive disintegration also ties in with the destructuring aspects of systems theory.</p>
<p>Gestalt Theories “Gestalt” means an organized whole, a set of structured configurations or patterns which must be understood as a totality rather than a collection of parts. Learner develops insights through a sense or feeling for patterns. Individual is purposive & striving, directed toward goals, & motivated by barriers to self-set goals. Productive thinking & psychological growth are gained through restructuring problems.</p>	<p><i>Wertheimer</i> — proposed way to impose order on disorganized field through Laws of Perception <i>Kohler</i> — demonstrated that insight was used by apes to solve simple problems <i>Koffka</i> — popularized gestalt psychology <i>Lewin</i> — used topology & vector analysis to represent the cognitive field <i>Schachtel</i> — focused on perception in productive thought</p>	<p>Outside the work of DeBono, who uses a lateral thinking approach & developed lessons (CoRT program) to force individuals to perceive structures in different ways, gestalt psychology has been relatively little used in TAG classrooms. Morphological analysis & field-dependent/field-independent concerns could fit into this theoretical camp.</p>

TABLE 2 Continued

Description	Proponents	Applications
<p>Developmental Theories Focus on the changing way the child understand the world as she or he develops. Growth of intelligence as a form of biological adaptation. As child grows cognitively through periods of relative stability in the way the world is viewed, he or she becomes better adapted because of a growing ability to anticipate, predict, or consider possibilities. This occurs through a process of equilibrating or balancing; changing the self to deal with discrepancies.</p>	<p><i>Piaget</i> — father of developmental theories. Reflective abstraction as mechanism for creating and learning <i>Feldman</i> — nonuniversals in cognitive development are base of creativity <i>Gruber</i> — evolving systems of cognition, purpose & affect. Network enterprises mark creative individual <i>Gowan</i> — periodic stage theory of creative development <i>Heller</i> — differential equilibrations in creative individuals <i>Roberts</i> — rapid & flexible equilibrations are characteristic</p>	<p>In spite of the research on developmental theories and giftedness, little (beyond the child as active and stage-material matching) is applied in the classroom. Developmentally appropriate practices are being applied in some classrooms.</p>
<p>Transcendental Theories Focus on explanations outside the organism, such as God, the Muses, or universal consciousness. Jung's collective unconscious might fit in this group of theories, as the individual is the instrument through which the collective unconscious emerges in creative acts.</p>	<p><i>Plato; Maritain</i> — creativity is a divine gift coming from outside the individual <i>Gowan</i> — creativity comes via drugs, trance or spiritual revelation <i>Goswami</i> — creativity analogous to quantum leap</p>	<p>Clark's respect for intuitive knowing, philosophical implications of quantum physics, & Eastern philosophies have been incorporated in suggestions for the classroom. Little else has been applied. Perhaps because of the association of some transcendental approaches with drugs or metaphysics, these theories have been generally avoided.</p>
<p>Biological Theories Two major groups of biological theories: (1) Mechanistic — focuses on the microlevel of neurological functioning, & seeks to understand specific neuronal connections or triggering of chemicals in the solution of a specific problem. A specific connection might be understood, but not creativity. (2) Organismic — looks at change through brain development over time & in relationship to environmental interactions.</p>	<p><i>Witrock</i> — generative brain which develops through use <i>Epstein</i> — brain weight changes over development, & relationship to Piagetian stages <i>Miller-Jones</i> — aspects of differential neural development <i>Gardner</i> — seven biological competencies <i>Clark</i> — giftedness is optimal neurological development <i>Pieckowski</i> — gifted display "overexcitability", a visceral reaction to experiences expressed in five modes</p>	<p>Clark's work on integrative education is the best known example. A few other brain-based classroom applications.</p>

theorists to determine what is missing in their theories and to seek other theories within the same conceptual framework to complement and enhance their own. A group attempting to unify theory might select only a few theories as a focus for analysis of phenomena. The common threads among these theories may become more explicit through in-depth work on case studies of creative people, products, or processes. By studying only a few theories at a time, the group might make real progress toward integration while sparing itself the overwhelming complexity of a large number of perspectives in aggregate (Ambrose, 1992). Clusters of

theories could then be brought together into a whole family theory, a common synthesis that focuses either on systems within and outside of the individual or on specific conditions, short term problem-solving steps, and influences of heredity. Ways to integrate these two giant frameworks, now containing a synthesis of organismic and mechanistic theories related to giftedness, intelligence, and creativity, can then be attempted (Cohen, 1992).

Overton (1990) recommends that researchers establish a "recursive cycle of knowing" by alternating between the two perspectives. Cycling between the

two vantage points would enable theorists to incorporate the work of many different theorists within a single macroframework.

During the first Theory Summit, Meeker and Ward suggested that the group might find a common language by developing a compendium of commonly used terms in each of the disciplines represented in the theory-building group. Each theorist could provide operational or constitutive definitions for the various terms for this "dictionary". The definitions could then be categorized and commonalities and differences discussed.

Theorists who recognize their own preferred level of scale could initially choose to work with others who share that level. At the same time, they need to extend into other levels of scale for a complete explanation. Chaos theory might be usefully applied to scale because of its notion of repeated patterns at different levels of scaling. For example, the pattern of a tree trunk with branches is repeated in looking at a given branch with still smaller branches, or a branchlet with twigs. Using this notion, theorists could look for the patterns that occur across each level of a theory.

The following suggestions are particularly applicable to group efforts. If each participant who joins a theory-building group has a basic understanding of his or her colleagues' viewpoints, the group will be better prepared to share and integrate diverse perspectives. Coherence conditions, simplifications that enable a researcher to grasp the essence of a large mass of complex information (Hesse, in Lincoln & Guba, 1985), can contribute to this understanding. Coherence conditions for theory-building could include abstracts, charts, graphs, mind maps, visual metaphors, and comprehensive lists of concepts and terminology from represented disciplines (Ambrose, 1992).

Individual synthesizers could extend the work of a theory-building group. For instance, one synthesizer could filter the dialogue of the group through the lens of a single theory, using that theory to provide a framework for understanding disparate notions from different disciplines. Another synthesizer could carry out a thematic analysis of the content in the group's dialogue, finding common threads of meaning that may bridge interdisciplinary gaps (Ambrose, 1992).

A theory-building group could approximate Overton's recursive cycling by breaking into subgroups by process preference. One subgroup could make explicit connections among the concepts and phenomena that are encompassed by the nebulous notion of creative intelligence. The other could attempt to integrate perspectives through metaphorical analysis and synthesis. Ideally, the emerging syntheses represented by the work of these groups would contribute to each other during plenary sessions. Such a parallel agenda may establish a productive dynamic tension between incongruous processes, while providing methodological triangulation to the group's work. It may also capitalize on the diverse learning and thinking style preferences of the participants (Ambrose, 1992).

Finally, theorists might look for the gaps and strengths across a variety of theories. Table 3 below represents the authors' attempts to use the "necklace" criteria to highlight the breadth and strengths of various theories of intelligence, giftedness, and creativity germane to education of the gifted. As with any analysis of extreme breadth and complexity, the authors' world views and values likely permeate the table; thus, the reader is advised to consider how he or she might apply the criteria to each theory. Such an analysis could be a starting point for looking at how theories might be combined. For example, the blank spaces indicate elements not emphasized by a theory, the plus signs indicate particular strengths. Cohen (1992) calls these strengths "luminous elements", as they have an esthetic rightness and light-shedding quality. By looking for the plus signs, the best features of given theories could be related to theories within similar conceptual frameworks first, and then across world views. Then the gaps on the chart can be addressed by theorists, researchers, and practitioners alike.

Theory Into Practice: Conclusion

Early approaches to education of the gifted focused on identifying and labelling children who demonstrated special abilities, or were characterized by specific traits. Often, educational provisions were offered in the form of pull-out programs or special classes that separated the gifted from their less-able peers. Such an approach may be a necessary first step in program provision as educators become aware of these children and try to serve them, often in climates hostile toward their needs. All too often, such programs are ad hoc or add-on affairs, such as a telescope-making day, or a competition in problem solving. Although such programs may benefit some gifted children, they cannot be justified as suitable for the gifted alone, nor do they provide the type of comprehensive, articulated, and sequential programming needed. Such programs lack a theoretical base. In addition, because there is little relationship to the total educational program and only a few children are served, such practices are often viewed as elitist, making them politically vulnerable.

More recently, a shift toward a focus on identifying needs has become evident in practice and is reflected in a variety of theories. Programs and services in schools are identified or developed and students are assigned to classes based on assessed need. For example, a student may be assigned to an independent study social studies project, accelerated math, or a counseling group for underachieving gifted students. A continuum of abilities is considered, the more exceptionally gifted, the greater the need for extended services. This approach represents a paradigm shift toward a special education view. Because the focus is on the current needs of the child, this view is generally beneficial, but without national mandates for the gifted (typically provided for other

exceptionalities), this approach also becomes vulnerable in periods of tight budgets.

A new shift is occurring toward linkages with regular education. Because the field has insulated itself and ignored a relationship to regular education for so long it is vulnerable to being eliminated (VanTassel-Baska, 1992). In the current economic recession worldwide, gifted education is seen as an isolated specialization that helps only a few, often the elite. Until theory and practice put gifted education squarely within the mainstream of education, the field will be vulnerable. This does not mean that gifted education must adapt to regular education programs; rather, gifted education could creatively transform the education system itself. In terms of educational reform, educators of the gifted long ago incorporated many salutatory practices. With a sound theory based on the universal human phenomenon of creativity, educators of the gifted could take a leadership role in bringing about changes in regular education by providing all children the opportunities needed to optimize development.

In addition to theories already discussed, political theories are needed that can explain the relationship of the gifted child movement to the rest of the world. Gallagher's (1986, 1988) political theory of the pendulum swings of love and hate for the gifted could be useful. According to Gallagher, when a nation is in a period of crisis, especially if threatened by outside forces, the gifted are supported and excellence is rewarded, with the look to escaping the difficulties. In periods of national calm, equity is supreme. Although the United States and the world have been in great turmoil in recent years, gifted programs are being axed. Gallagher's political theory may need to take into account economic theories, but it is a starting point. How to help nations recognize the need to support excellence and creativity for their very survival must be considered.

Theory unification should include political issues, perhaps considering various levels of systems in interaction. A metatheory that brings together the various luminous aspects of individual theories and identifies missing elements within the political context would be a giant step toward strengthening education for the gifted. This new theory necklace could then be tried on by researchers and practitioners until a better set of golden links is constructed.

Theory and Research on Curriculum Development for the Gifted

JOYCE VANTASSEL-BASKA

College of William and Mary, Williamsburg, Virginia, U.S.A.

Introduction

How can educators help a gifted student to excel? The answer to this question is a complicated one because much of our research on what impacts the lives of gifted individuals relates more to the roles of parents (Feldman, 1985; Bloom, 1985), of internal factors and significant others (VanTassel-Baska & Olszewski-Kubilius, 1989), of crystallizing experiences (Gardner, 1985), or of chance (Tannenbaum, 1983). Yet what happens to a child in school should have a significant positive effect on the processes of learning. The quality and character of a school's curriculum is a vital ingredient to the eventual realization of a child's capacity. Gifted and talented students, like all students, have the right to a continuity of educational experience that meets their present and future academic needs. When an organized, thoughtful curriculum plan is in place and when that curriculum is supported by an articulate, informed educational leadership, the probability of capturing the interest and energy of our ablest young thinkers is markedly enhanced. Certainly an organized curriculum is a key ingredient in this complex blending of circumstance so central to the transformation of a gifted learner's initial capacity for intellectual activity into a mature competence for academic and professional accomplishment.

Key beliefs and assumptions have guided the thinking of most recent curriculum theory in gifted education (Passow, 1982; Gallagher, 1985; Maker, 1982; VanTassel-Baska et al., 1988). These include the following:

- (1) All learners should be provided curriculum opportunities that allow them to attain optimum levels of learning.
- (2) Gifted learners have different learning needs compared with typical learners. Therefore, curriculum must be adapted or designed to accommodate these needs.
- (3) The needs of gifted learners cut across cognitive, affective, social, and esthetic areas of curriculum experiences.
- (4) Gifted learners are best served by a confluent approach that allows for accelerated and advanced learning, and enriched and extended experiences.

(5) Curriculum experiences for gifted learners need to be carefully planned, written down, and implemented in order to maximize potential effect.

(6) Curriculum development for gifted learners is an ongoing process that uses evaluation as a central tool for future planning and revision of curriculum documents.

Over twenty years ago, national reports ushered in a new era for educational and curricular change, predominantly in science and mathematics. Today American educators again are faced with a barrage of reports that describe deficiencies in current instruction in mathematics and science and in other content disciplines as well. *A Nation at Risk* (National Commission on Excellence in Education, 1983) reported on the failure of public education in exposing students to full secondary programs in science and mathematics. A Carnegie task force report (1986) further documented the need for more advanced course-taking in these subjects by larger numbers of the secondary school population. The College Board's Project Equality (1983) outlined maximum competency skills in academic areas that require mastery in today's technologically advanced world. The most stringent recommendations on curriculum were reported by the National Science Commission (1983) which prescribed four full years of science and mathematics for the majority of students in American schools.

In the early 1990s, the reform movement has moved to a global arena. All countries are focused on the importance of education. All countries see their future economic hopes linked to an educated citizenry, skilled in the world technologies. Moreover, the demographic make-up of many developed countries is pluralistic, thus globalizing the issues. The reform issues as they are played out in the United States represent an important case in point.

Some of the preeminent educational thinkers in the United States have published treatises on the nature of ideal schooling. Adler's *Paedaeia Proposal* (1984) advocated a basic liberal arts education for all, with a focus on traditional content and the objectives of knowledge acquisition, thinking skill development, and esthetic appreciation. This view has been reinforced by Hirsch (1989). From an administrative perspective, Goodlad's

A Place Called School (1983) explored fundamental deficiencies in how schools are organized to carry out instructional tasks. Subsequent work further explicated our structural problems, especially at secondary levels (Sizer, 1984; Boyer, 1983). The instructional focus of Bloom's (1980) work on mastery learning provided a model for the systematic and progressive development of skills in various domains of knowledge. Yet newer work in curriculum and instructional processes would favor deeper, more conceptual understanding over mere mastery of skills (Resnick, 1984). Moreover, studies of gifted students support the need for differentiated strategies based on cognitive differences (Rogers, 1986).

Based on the proliferation of reports on problems and remedies, it is clear that education has and is experiencing significant pressure for reform and curricular change. In particular, there is a strong interest in focusing efforts on raising the level of performance for all learners and a belief that the successful approaches to the achievements of the gifted can also enhance the educational enterprise for those who are less able.

Although many local school efforts have not been responsive to the perceived needs of a modern technological society, curriculum for the gifted and talented provides a starting point to upgrade these efforts, particularly in areas that reports have cited as most deficient: mathematics, science, technology, and foreign language. Practitioners of theoretical ideas about curriculum for the gifted must be sensitive to the organizational structure of the schools, contemporary K-12 curriculum needs, and the recommendations for change being advocated by the major studies.

The Forces That Drive Curriculum

Based on the calls for reform at steady rates over the last decade, one would expect a commensurate interest in curriculum development projects. Yet very few large-scale curriculum projects have been funded since the splurge of the 1960s. However, curriculum development in math and science is now in the forefront of educational reform. Examples include the Amoco Foundation's \$50 million grant to the University of Chicago to change the shape of American mathematics education at the elementary and secondary levels; new National Science Foundation-funded projects in science and mathematics with a heavy focus on technological application; and American Association for the Advancement of Science science projects that capitalize on new science concepts. Within gifted education, two major curriculum development projects have been funded by the United States Department of Education under the Javits Gifted and Talented Act. These projects presage a renewed interest in serious curriculum work for gifted learners.

What has caused this resurgence of interest in curriculum? One of the social forces at work is our concern as a nation for meeting future workforce needs. Wirsup

(1986) reported on the dismal status of America's students in math and science when compared to their Russian, Japanese, and West German counterparts. Numerous reports over the last few years continue to document similar deficiencies in performance (Darling-Hammond, 1990; Stevenson & Stigler, 1992). At the national level there has been a pronounced shift in focus from issues like discipline and community involvement to hard questions about the content and sequence of curriculum. The egalitarian philosophy that dominated the last twenty years of educational policy altered curriculum standards, reduced requirements, and created an elective system that spawned low test scores and gaps in traditional knowledge. A concomitant focus on the education of the handicapped sparked an examination of our educational priorities. The billions of dollars allocated to tailoring educational programs to the special needs of handicapped children as a result of the passage of the Education of All Handicapped Americans Act (PL 94-142) raised consciousness about the cost of responding to individual needs of learners at appropriate levels. The current concerns about changing demographics, work force, competency issues, and negative international education comparisons further exacerbate the need for reform.

Juxtaposed with these social, political, and economic forces within educational systems is new research that affects thinking about the nature of curriculum change desired. New studies about intelligence (Gardner, 1983; Sternberg, 1985) and how children learn are available to shape the curriculum process.

While limited research has been conducted on curriculum for the gifted *per se*, current research in teaching and learning appears important to our conceptual framework for understanding appropriate curriculum for the gifted. For example, curriculum planners for the gifted have long advocated the optimal match between learner capacity and level of experiences provided; new evidence for this principle has emerged from studies of human development that found that when both personal skill level and challenge level are correspondingly high, adolescents experience a state of "flow" which allows for optimal learning (Csikszentmihalyi, 1987).

Current learning research is also deeply rooted in the basic disciplines of reading, writing, mathematics, and science. Much on-going research is attempting to explain how children master complex knowledge structures and procedures (Brown & Campione, 1986). In both reading and mathematics, current research has supported a meaning-based approach that provides appropriate drill and practice in key activities (Anderson, Herbert, Scott, & Wilkinson, 1985; Resnick, 1984).

Studies of thinking also contribute to understanding curriculum directions for the gifted. Expert-novice comparisons in various fields (Berliner, 1985; Sommers, 1980) have yielded differences favoring experts in metacognitive acts like planning and revising. A collection of research on expertise has revealed that the successful utilization of these skills may be

content-specific. Rabinowitz and Glaser (1985) found that expert performance entailed a large knowledge base of domain-specific patterns, rapid recognition of situations in which these patterns apply, and the use of forward reasoning based on pattern manipulation to reach solutions.

Further support for such domain-specific research comes out of studies which use general content-independent cognitive strategies and which find no clear benefits outside the specific domains in which they are taught (Pressley, Snyder, & Carigha-Bull, 1987). Thus, research on transfer suggests that "thinking at its most effective [level] depends on specific context-bound skills and units of knowledge that have little application to other domains" (Perkins & Saloman, 1989, p. 119).

Curriculum is also being affected by larger social and political contexts. Computer technology has found its way into the curriculum as a "basic" subject rather than as a peripheral. Global interdependence has become a major organizational theme of special programs in all content areas, not just social studies. On the other side of the ledger, "moral majority" advocates have brought about the dissolution of values education, and other educational foci that encouraged free and open inquiry by students.

Goodlad (1979) posited that curriculum decision-making is done at two levels, each in isolation from the other. School boards effect curriculum policy, and teachers implement classroom curriculum. Little curriculum leadership is provided at a middle level by building principals or central office staff. Consequently, curriculum implementation as a standardized process does not occur in most public school settings. Even skeptical parents are not likely to challenge teachers in an area heavily loaded with issues of expertise and academic freedom.

But curriculum is still mostly driven by the inertia of the status quo, a system of skill-based areas of inquiry that proceeds on a continuum from first grade to twelfth grade, buttressed by basal texts and little examination of the "why" of a curriculum offering at a particular point in the sequence. For example, algebra was not in the school curriculum sixty years ago, and now the debate rages as to its appropriateness at the ninth-grade level where it was initiated and has tended to stay. Reading continues to follow a similar illogical path of development based on a curriculum model that ignores individual readiness issues.

Since curriculum is at a point of potential change, the opportunity for educators of the gifted to take a strong role in defining what it should be for the most able, the process by which it is formulated, and the diversity of products or outcomes to be anticipated is at hand. It is through appropriate curriculum design and delivery for the top 5% of the population that the whole of curriculum can be upgraded and enhanced. The curricular work for the gifted can spearhead higher standards and more rigorous methodologies in addressing the needs of the rest of the student body.

A Curriculum Philosophy for the Gifted

Eisner and Vallance (1974) presented five conceptions of curriculum that have shaped the thinking of gifted educators. The roots of each of these conceptions can also be found in extant curriculum for the gifted, and represent strong philosophical orientations for what a view of curriculum for the gifted might be. A sixth orientation related to career preparation is also considered.

(1) *Curriculum as the development of cognitive process.* This orientation in the education of the gifted has focused on process skill development and has led to the adoption of curriculum materials organized around higher level thinking skills. Having its roots in faculty psychology, it has fostered a content-independent model of curriculum that uses cognitive skills as the centerpiece of all learning activities. Implicit in this view is the assumption that learning cognitive skills will translate across, apply to, and enhance any field of inquiry a student may encounter. Many pull-out programs for the gifted, which reflect this orientation, have emphasized critical thinking, creative thinking, and problem solving as the substance of their curricula, treating these process skills as content dimensions in their own right. Recent research would support this orientation if there are also ample opportunities for applying cognitive skills directly to content (Perkins & Saloman, 1989).

(2) *Curriculum as technology.* This approach to curriculum is also process-oriented, but focuses on the organization of curriculum into student inputs and outputs. This view of curriculum relies heavily on stated behavioral or performance objectives with measurable outcomes that can be tested in order to determine educational progress or achievement. Learner outcomes developed in individual states and by three national groups attest to the current centrality of this curriculum orientation. It assumes that curriculum standards must be explicit, taught to, and tested for. This view of curriculum sees curricular effectiveness and efficiency as realizable if a learning system is adopted by schools rather than piecemeal changes (Spady & Marshall, 1991).

(3) *Curriculum as personal relevance.* This orientation promotes a child-centered model that values curriculum experiences which are tailored to individual student needs. The interest of students in specific areas guides the curriculum. The goal of such a curriculum is to be personally engaging and to offer consummatory experiences that will provide growth at each student's level of understanding. Several curriculum models in gifted education employ this orientation. Renzulli (1977), Feldhusen and Kolloff (1978), Betts (1991), and Treffinger (1986) favor this orientation because of its emphasis on self-directed learning. Gifted students become responsible for their own curriculum through contracts with a facilitator who assesses interest and ability. The interaction of student and facilitator in mutually agreed upon work form the central core of curriculum experiences.

(4) *Curriculum as a social reconstruction.* This view of curriculum holds that the purpose of educational institutions is to be agents for social change and that the content of curriculum should be viewed within the larger social and cultural realm. Topics to be studied are chosen to promote community action programs needed in a student's immediate environment and to promote individual and collective social responsibility. Engaging students in social action such as drafting a piece of legislation, taking a poll of neighborhood opinions regarding nuclear energy, or organizing a school anti-pollution campaign typify the curricular experience as part of social reform. Work in the education of the gifted that best exemplifies this orientation is the curriculum for global futures and the theme of global interdependence developed at sites like the Center for Global Futures in Muncie, Indiana. Whole school districts also organize curriculum this way to serve the high-school gifted student, such as at Glenbrook Academy in Northbrook, Illinois, and Morgan Park High School in Chicago. Multicultural trends in curriculum also have their philosophical roots in this orientation (Hernandez, 1989).

(5) *Curriculum as academic rationalism.* This curriculum orientation has its roots in the Western tradition of rational humanism. Specifically, it adheres to an ideal of education as a way of providing students with an understanding of great ideas and an ability to analyze and synthesize past achievements. It recognizes a core of work as central to our evolution as a culture (Hirsch, 1989). It further espouses a belief in the structure of knowledge as embodied in the organization of academic and artistic fields of inquiry, and seeks to instruct students within those content disciplines. Most of the "durable" curriculum that is used in gifted programs flows from this general orientation. The special National Science Foundation curriculum projects in mathematics, science, English, and social studies (MACOS) which were developed in the 1960s were all rooted in this orientation. Packaged curricula like *Junior Great Books* and *Philosophy for Children* also adhere to this view.

(6) *Curriculum as a precursor to career/professional life.* This view of curriculum has its roots in both the professional school and vocational school models that have influenced curriculum offerings over the last 20 years. A strong focus on the practical and the utilitarian has been a preoccupation at secondary and post secondary levels. In the field of the gifted, this orientation may best be seen through the career education models (see Hoyt & Hebel, 1974) that have appeared to help students view curriculum as a preparation for their future. The work experience programs for the gifted, loosely termed mentorships and internships, also have a utilitarian "real-world" focus. In these programs, students relate to the practicing professional in his or her domain and come to understand and appreciate their own potential as future practitioners of a particular craft. New conceptions of curriculum include a strong emphasis on developing the skills, attitudes, and traits of professionals (VanTassel-Baska, 1992).

Although educators are free to choose among these curriculum philosophies, the most effective curricula incorporate all of them to some extent. Whereas the academic rationalist's view most closely accommodates the current curricular organization of schools and has guided most long-term curriculum efforts, it currently is being seriously challenged by the social reconstruction orientation. This view holds that curricular decisions reflect social and economic biases. Thus any attempt to differentiate curriculum for the gifted may be seen, according to this orientation, as an elitism fostered by the educational forces that would oppress the poor and the minority members of our school community (Oakes, Gamoran, & Page, 1991). This viewpoint has led many school personnel to flee from issues of curriculum differentiation for the gifted to a more moderate position of higher curriculum standards for all learners that include the best features of curriculum for the gifted.

The other major challenge to the traditional view has come from those favoring individual student-centered approaches (e.g., Renzulli, 1977; Treffinger, 1986). In all fairness, this viewpoint has dominated gifted child education worldwide, especially at the elementary level. Thus while a confluency of these orientations may be most desirable, clearly none exists at the present time.

Research on Curriculum for the Gifted

Although the field of gifted education is not prolific with intervention studies, the body of literature on acceleration in curriculum areas places it in the category of an effective approach for many gifted learners. Perhaps more has been written about the efficacy of accelerative practices with the gifted than about any other single educational intervention with any population. Reviews of the literature on acceleration have appeared with some regularity over the last 25 years (Benbow, 1991; Daurio, 1979; Gallagher, 1969; Kulik & Kulik, 1984; Reynolds, Birch, & Tuseth, 1962; VanTassel-Baska, 1986). Each review has carefully noted the overall positive impact of acceleration on gifted individuals at various stages in the life span. Successful programs of acceleration, most notably offshoots of the basic talent search model developed by Stanley and others in the 1970s, have demonstrated significant positive impact on the learning of students (Benbow & Stanley, 1983; Kulik & Kulik, 1992; Swiatek & Benbow, 1991a, 1991b). Moreover, a broad-based research agenda has emerged in the field of gifted education, dedicated to understanding the long-term effects of educational acceleration of the gifted (Brody, Assouline, & Stanley, 1990; Brody & Benbow, 1987; Brody & Stanley, 1991; Robinson & Janos, 1986; Swiatek & Benbow, 1991a,b). These recent studies continue to show positive results in cognitive development from acceleration and no negative effects on social emotional development.

Much descriptive literature has been written about enrichment experiences that broaden a student's view

of the world of knowledge (Gallagher, 1985; Kaplan, 1979; Renzulli, 1977; Feldhusen & Kolloff, 1978). In a review of research on enrichment, Treffinger et al. (1991) found mixed results for programs that described themselves with that term. Counseling has also been mentioned as important to the emotional and social growth of the gifted learner as well as an important underpinning to any devised academic program (Gowan, Demos, & Khatena, 1965; Colangelo & Zaffran, 1979; Piechowski, 1984). Although acceleration, enrichment, and counseling represent the major interventions used with the gifted over the last eighty years, it remains to be determined which approaches are most effective under what circumstances with which gifted learners.

Beyond these basic approaches, research into appropriate curriculum for the gifted child is rather meager. Until the Sputnik era of the late 1950s, which resulted in programs that addressed specific content areas, few ideas about differentiated curriculum for the gifted were systematically studied. Even though special classes had been in operation since at least 1919 in selected locations, usually large cities, the actual differences in instructional strategies, content, or materials were not examined. Grouping based on intelligence and achievement was the predominant strategy employed, although individual grade acceleration was practiced to some extent, and curriculum outlines and sometimes units were prepared for use with the identified gifted students (Hollingworth, 1926; Hall, 1956).

Over the past twenty years, however, educators in the field of the gifted have formulated some general principles about appropriate curriculum for gifted children. Ward (1961, 1981) developed a theory of differential education for the gifted that established specific principles about appropriate curriculum. Meeker (1969) used the Guilford Structure of Intellect (SOI) to arrive at student profiles that highlighted areas of strength and weakness so that curriculum planners could build a gifted program to improve weak areas. Curriculum workbooks were structured to address this need in the areas of memory, cognition, convergent thinking, divergent thinking, and evaluation. Renzulli (1977) focused on a model that moved the gifted child from enrichment exposure activities through training in thinking and research skills into a project-oriented program that dwelt on real problems to be solved. Gallagher (1985) stressed content modification in the core subject areas of language arts, social studies, mathematics, and science. Stanley, Keating, and Fox (1974) concentrated on a content acceleration approach to differentiate programs for the gifted. Feldhusen and Kolloff (1978), Kaplan (1979), and Maker (1982) have stressed a confluent approach to differentiation of curriculum for the gifted that includes both acceleration and enrichment strategies. Passow (1982) formulated several cardinal curriculum principles that reflect content, process, product, behavioral, and evaluative considerations. VanTassel-Baska (1988, 1992) synthesized existing approaches to gifted education curriculum and

translated them into each content area using a traditional curriculum design approach.

More current work in curriculum for the gifted has focused on a merger with the curriculum reform principles advocating world class standards in all traditional curricular areas (VanTassel-Baska, 1992). The major shift in thinking regarding this orientation is from one that looks only at the optimal match between characteristics of the learner and the curriculum to a model based on professional competence in various domains, thereby letting the curriculum standard determine who may become proficient in an area rather than a predetermined test. Thus differentiation for any population is grounded in differential standards of performance at a given period of time. Standards are constant; time is the variable. Such a model holds promise for gifted students in that the level and pace of curriculum can be adapted to their needs, and the stated standards imply the kind of focus that curriculum makers for gifted students have long advocated—higher level thinking, interdisciplinary approaches, and emphasis on student-centered learning.

The other current approach to curriculum for the gifted has been instituted as a result of newer conceptions of giftedness, notably Gardner's multiple intelligences (1983). This approach assumes that the majority of children have some talent area or intelligence which can be developed through focused curriculum attention. Similar in practice to the Talented Unlimited model developed in the 1970s by Calvin Taylor, the talent development model also eschews identification of children as gifted but rather favors the use of diagnostic information to determine strengths that can be used to develop an appropriate curriculum. Highly individualized, this approach has been implemented successfully in several school-based settings (Bolanos, 1991).

Some combination of both of these approaches is probably most productive. Gifted students need high but realizable expectations for learning at each stage of development. Other students can benefit also from working to attain such standards. By the same token, gifted students can also benefit from a more developmental perspective on fostering their abilities at a close-up level. Lingering questions over both approaches will remain until there is research evidence that supports gifted student growth in a context that has done away with formal identification.

Theoretical Curriculum Models for the Gifted

Although research on curriculum for the gifted provides limited evidence regarding effectiveness, three relatively distinct theoretical curriculum models have proven successful with gifted populations at various stages of development and in various domain-specific areas. They are: (1) the content mastery model; (2) the process/product research model and (3) the epistemological concept model.

The Content Model

The content model emphasizes the importance of learning skills and concepts within a predetermined domain of inquiry. Gifted students are encouraged to move as rapidly as possible through the content area; thus content acceleration dominates the application of this model in practice. When a diagnostic-prescriptive instructional approach (D-P) is utilized, students are pretested and then given appropriate materials to master the subject area segments prescribed.

The D-P instructional approach has proved effective in controlled settings, but has not been widely practiced in regular classrooms for the gifted. Several reasons account for this. Like any individualized model, it requires a highly competent classroom manager to implement it. When used appropriately, each student may be working on a different problem, chapter, or book at the same time. Regardless of the rhetoric surrounding individualization, very little is actively practiced in basic curriculum areas. A second reason is that most pull-out programs do not focus on core content areas and therefore negate the possible employment of the model. Third, the approach has not been particularly valued by many educators of the gifted because of its insistence on utilizing the same curriculum and merely altering the rate. The lecture-discussion approach to the content model is more widely practiced at the secondary level, but its effectiveness is highly dependent on teachers being well-versed in the structure as well as in the content of their discipline. Too frequently the content model disintegrates into learning the exact same skills and concepts as all learners are expected to do in the school context, only tediously doing more exercises and drills in a shorter period of time.

In the D-P approach, teachers and teaching assistants act as facilitators of instruction rather than as didactic lecturers, although many content-based programs for the gifted place a strong emphasis on lecture and discussion. The curriculum is organized by the intellectual content of the discipline and is highly sequential and cumulative in nature, making a proficiency-based model for measuring achievement very feasible.

The D-P approach to the content model has been utilized effectively by talent search programs across the world, particularly in mathematics (Keating, 1976; Benbow & Stanley, 1983). VanTassel-Baska (1982) has shown the effectiveness of the model in teaching Latin, and foreign language teachers have used the model for years to ensure English syntactic mastery in their students. Clearly, it represents the most individualized instructional approach to basic curriculum for the gifted, and it embodies a continuous progress philosophy that schools readily understand.

The more typical approach to content-based instruction, however, is one that presets an early mastery level for students, frequently requiring more advanced skills and concepts to be mastered one year earlier than normal. The content model uses existing school curriculum and textbooks, so it is not costly to implement.

Although it responds to the rate needs of groups of students, allowing the able to advance a little more quickly through the traditional curriculum, it may still leave the highly gifted unchallenged.

In fairness to the content-based model, teachers who use it successfully have made important alterations in the organization of the subject matter being taught. For example, in the fast-paced Latin program, the concepts that are spread out incrementally over the first three chapters of the book are synthesized into a matrix study sheet, presenting students with all five Latin cases, three genders, and two numbers in their various combinations all at once. Homework is assigned only from the third unit, where all the interactions of gender, number, and case may be practiced. Thus 30 hours of instructional time may be reduced to four or five at the most, and gifted students can master the important concepts governing Latin syntax in an economical fashion.

What appears as a simple process of moving more quickly through the same basic material becomes more sophisticated in actual practice. The effective teacher reorganizes the content area under study according to high level skills and concepts. The focus of student prescriptive work is in larger increments that carry with it a holistic picture of the topic under study.

The content mastery model for curriculum and instruction also has the capacity to cover the regular skill-based curriculum in reading and mathematics in approximately one-third the time currently expended. This condensation process occurs as a result of two curriculum modifications. Students move through skill areas at a rate commensurate with their capacity. By testing for proficiency, by assigning work based on documented increased levels of development, and by reorganizing basic skill areas into high level skill clusters, mastery learning time is conserved, and more efficient and challenging learning experiences are promoted.

The Process/Product Model

The process/product model places heavy emphasis on learning investigatory skills, both scientific and social, that allow students to develop a high-quality product. It is a highly collaborative model that involves teacher-practitioner-student as an interactive team in exploring specific topics. Consultation and independent work dominate the instructional pattern, culminating in student understanding of the scientific process as it is reflected in selective exploration of key topics.

Reported in the literature under the rubric of the Enrichment Triad and the Purdue model (Renzulli, 1977; Feldhusen & Kolloff, 1978), this approach to curriculum for the gifted has also enjoyed success. At the secondary level, special science programs for the gifted have used the model (VanTassel-Baska & Kulieke, 1987; VanTassel-Baska, Gallagher, Sher, & Bailey, 1992), and institutions like Walnut Hills High School in Cincinnati, Bronx High School of Science

in New York, and the North Carolina School of Math and Science have practiced the model as a part of their high-powered science programs for years.

One manifestation of the model engages the student in problem finding and problem solving and puts the student in contact with adult practitioners. In the field of science, for example, scientists from national science laboratories work with academically talented junior-high students during the summer to help them develop research proposals for project work during the following academic year. Students are actively involved in generating a research topic, conducting a literature search, selecting an experimental design, and describing their plan of work in a proposal. The proposal is then critiqued not only by the instructor but also the scientist. In this way, then, students focus on process skill development in scientific inquiry and strive to develop a high-quality product. Another manifestation of the model emphasizes problem-based learning, an approach that allows the student to generate learning tasks based on a paradigm of the known, the need to know, and the process by which needed knowledge can be acquired (Barrows, 1985).

The process/product model for gifted curriculum differs from the content-based model in that content is incidental. Student interest is the mainspring for what "content" will be studied. The nature of the evaluation effort is product-based rather than proficiency-oriented, and the focus is on studying selected topics in-depth rather than moving through a given domain of inquiry in a fast-paced manner.

This curriculum and instructional model most closely parallels the recommendations of national curriculum groups in both science and mathematics who tend to favor a student-directed, hands-on, inquiry-based process of problem solving, where students are engaged in the act of constructing knowledge for themselves.

The Epistemological Model

The epistemological concept model focuses on talented students' understanding and appreciating systems of knowledge rather than the individual elements of those systems. It reflects a concern for exposing students to key ideas, themes, and principles within and across domains of knowledge so that schemata are internalized, synthesized, and amplified by further examples. The role of the teacher in this model is as questioner, raising interpretive issues for discussion and debate. Students focus their energies on reading, reflecting, and writing. Esthetic appreciation of powerful ideas in various representational forms is viewed as an important outcome of this model.

This model has been used with gifted learners for several reasons. First, the intellectually gifted child has unusually keen powers to see and understand inter-relationships. The whole structure of conceptual curriculum is based on constantly interrelating form

and content. Conceptual curriculum is an enrichment tool in the highest sense, for it provides the gifted with an intellectual framework not available in studying only one content area, but exposes them to many ideas not provided for in traditional curricula. Furthermore, it provides a basis for students' understanding the creative as well as the intellectual process through critically analyzing creative products and being actively engaged in the creative process itself. It also provides a context for integrating cognitive and affective objectives into the curriculum. A discussion of ideas evokes feelings; a response to the arts involves esthetic appreciation; and the study of literary archetypes creates a structure for self-identity.

Many writers in the field of gifted education have lauded the epistemological approach to curriculum (Ward, 1961, 1981; Hayes-Jacobs, 1981; Maker, 1982; Tannenbaum, 1983). Some extant curriculum has been organized around the model at both elementary and secondary levels. The College Board Advanced Placement Program relies heavily on this curriculum approach in its history (both American and European) and literature and composition programs. The *Junior Great Books* program, *Philosophy for Children*, and *Man: A Course of Study (MACOS)* are elementary programs that promote the approach. Each of these programs stresses the use of Socratic questions to stimulate an intellectual discussion among students on an issue or theme. Creating analogies across a field of inquiry is encouraged, and interdisciplinary thinking is highly valued. Recent curriculum development efforts for the gifted have also attempted to utilize the epistemological framework (VanTassel-Baska & Feldhusen, 1981; Gallagher et al., 1984), and larger curriculum projects in the past, such as CEMREL's mathematics program at the secondary level and the Unified Mathematics program at the middle school level, have utilized a holistic approach to the organization of content.

The concept-based model for curriculum and instruction differs considerably from the nature of the previous two models described (see Table 1 for an overview of key characteristics of each model).

The concept-based model is organized by ideas and themes, not subject matter or process skills. It is highly interactive in its instructional context, which contrasts with the more independent modes of instruction used in the other two models. Concern for the nature and structure of knowledge itself is a major underlying tenet. The evaluation of students engaged in this model typically requires evidence of high-level esthetic perceptions and insight rather than content proficiency. The nature of culminating products tend to be well-crafted essays that show evidence of synthesizing form and meaning across areas of study. Artistic products also demonstrate this synthesis of form and meaning (Eisner, 1990).

Effective curriculum and instruction for the gifted has reached a stage of evolution where existing theoretical and research-based models need to be systematically translated into practice at the local level. Competition

TABLE 1
 Contrasting Curriculum/Instructional Models for the Gifted

A. Content	B. Process/Product	C. Concept
<ul style="list-style-type: none"> ● Fast-paced ● Proficiency-based ● D---P approach ● Organized by intellectual content ● Teacher as facilitator 	<ul style="list-style-type: none"> ● In-depth on selected topics ● Product-based ● Resource-orientated ● Organized around scientific of other process model ● Collaborative 	<ul style="list-style-type: none"> ● Epistemological ● Aesthetics-based ● Discussion approach ● Organized by themes and ideas ● Socratic method

among these models has dissipated the effect of building a strong differentiated program for the gifted that addresses all of their intellectual needs within the core curriculum as well as at all levels outside it. The synthesis of the content, process/product, and concept models has provided a clear direction for new curriculum work.

This synthesis approach has been the dominant one employed in two recent national curriculum projects. These projects have attempted to look specifically at the content areas of science and language arts in order to integrate the three curriculum models in providing appropriately for the gifted. A brief review of the curriculum foundations of each project follows.

Mathematics and Science

Mathematics and science education are currently experiencing several major and interrelated problems in the United States. Current national reports recommend a major shift in the organization of science curriculum from a content emphasis to a focus on key concepts and scientific principles taught through hands-on, real-world problem-solving approaches (AAAS, 1989, 1990; Bennett, 1986; Hilton et al., 1989; National Science Board Commission, 1983; NAEP, 1988). Major curriculum reform efforts emanating from several disciplines have highlighted the need for curriculum change that moves away from the teaching of discrete facts toward the organization of significant content by concepts, away from content coverage toward selective examples to support principles, and away from passive learning towards hands-on inquiry-based learning experiences (Association for Supervision and Curriculum Development, 1990).

Current curriculum and instructional problems combined with the need to develop a literate scientific citizenry create a special kind of dilemma for science education. On the one hand, school organizational structure at all grade levels is too inflexible to accommodate serious science study. Laboratory time and hands-on classroom experiments require longer time periods than are typically allocated (National Assessment of Education Progress, 1988). Moreover, science instructional time is significantly less than amounts allocated to reading and math. Combined with the instructional time issue is the lack of training of teachers to do

science with children in an appropriate way (American Association for the Advancement of Science, 1989; Bennett, 1986; National Science Board Commission, 1983). Most elementary and middle school teachers rely heavily on textbook worksheets and canned experiments for conveying what science is. Because science is poorly and infrequently taught at the elementary level, it has failed to sustain the involvement of all but the most science-prone students, those who may also have extra curricular resources to spark their continued interest in science. The most tragic loss of continued involvement in science is among girls and minorities as well as other high ability learners lacking opportunity (Hilton et al., 1989).

An interrelated part of the problem is the failure to treat science as active inquiry and students as real investigators in the process of making meaning of their world. In order for science to be viewed as real inquiry, it must be taught in a way that demonstrates a strong emphasis on science concepts, on investigation of real problems, and on the integration of science with other disciplines.

The needs of science education may be perceived as complex, requiring solutions on several fronts simultaneously. These areas may be delineated as:

- (a) the development of model curricula that reflect the elements of the new science and standards appropriate to high ability learners;
- (b) changes in the selection of curriculum materials and how they are used;
- (c) instructional strategies that complement the new science and demonstrate effectiveness with a variety of learners;
- (d) teacher attitudes and behaviors that accept the importance of curriculum and instructional change and are capable of executing it; and
- (e) systemic change models that allow these dynamics to work together.

These general concerns about the state of science curriculum in schools are felt keenly by educators of high ability learners. The data clearly indicate that our top students are not ready to compete at world class levels (ASCD, 1990; Stevenson & Stigler, 1992). It is critical that high ability students have a functional knowledge of science, even if they do not enter careers directly related to scientific research or teaching. In a complex society, with the increasing involvement of science in matters of

health, the economy, and national security, the general population needs to have a better understanding and appreciation of science, mathematics, and technology. Many high ability students do not experience an appropriately accelerated and enriched science curriculum during their elementary and middle school experiences; often science is not even taught systematically at the elementary level. Yet high ability learners, including the intellectually gifted and the science prone, exhibit an unusual readiness to engage in inquiry and exhibit intense curiosity about the world around them, eager to participate in more concept-based work in science. It is also at elementary and middle grade levels that independent investigations involving science can most easily be initiated and scientific processes explored in an interdisciplinary framework. However, in the majority of school districts in America, the textbook approach is the major delivery system for science curriculum, used primarily as a passive learning tool where children read and answer factual questions (Lockwood, 1992). Consequently, many gifted learners face boredom and demotivation in this critical field of inquiry.

Gifted learners in science then need a curriculum that is sufficiently advanced and challenging, offering a sequence of tasks that extend their knowledge base. They also need a curriculum that provides opportunities for original investigations in science, using real world problems as a point of departure. Lastly, they need to study important scientific concepts that allow for making connections within science areas and across to other areas of study.

By overlaying the concerns of general science education with the special learning needs of gifted learners, common issues emerge: how to infuse the curriculum with appropriate content and methodology; how to impact positively upon science and technology literacy, especially among high ability students; and how to motivate students to see the joy of engaging in science inquiry. This complementation of science education and gifted education leads to the consideration of six key components necessary to curriculum development work that seeks to wed principles of the new science to curriculum principles for gifted learners.

(1) *Developing an understanding of scientific concepts.* In a world of fragmented information and knowledge explosion, there is a need to organize subject matter more effectively. One of the most powerful ideas that emerged from a study of 120 scholars conducted by Shane (1981) was a recognition among leading scientists that students need to understand key concepts in science more than specific facts and that scientists could agree on what these concepts were. Judson (1980) also used key science concepts to develop his powerful curriculum *Search for Solutions*, and concluded his text material with a set of unanswered scientific questions. Focusing on scientific concepts is also a cornerstone of new work in science curriculum, most notably *Science for All Americans* (Rutherford & Ahlgren, 1979).

(2) *Developing scientific inquiry skills in collaborative settings.* Just as one considers a shift in the organization of science curriculum toward key concepts, so too there needs to be a shift toward the student as investigator. Sternberg (1982) has outlined this major focus for gifted learners as the importance of engaging in problem finding, problem solving, problem evaluation, and scientific reporting.

An appropriate science curriculum should reflect an emphasis on more independent laboratory work, more extensive reading, more authentic library skills, and more true experimental work (Brandwein & Passow, 1988). Cothron, Giese, and Rezba (1989) suggest the use of a four-question strategy to help students internalize experimental design procedures, asking what materials are available for conducting experiments on a particular phenomenon, how a phenomenon acts, how one changes the set of materials to affect an action, and how one measures or describes the response to the change.

Closely related to an understanding of doing real world science is the ability to work collaboratively in a research team. Given the nature of the knowledge explosion, no one is capable of grasping all content knowledge for purposes of generating new knowledge. Consequently, an important model of science for the high ability learner to understand is that of collaboration. In the world of scientific research, many breakthroughs are made by scientific teams made up of individuals with specialized backgrounds, but with a scheme for working together on current scientific problems that requires combinational knowledge from several areas. Work in biochemistry is a good example of this, for biologists and chemists routinely address key research questions together. Even the recent practice of awarding the prestigious Nobel Prizes in the sciences is toward a joint award to a team that has made a major contribution. Mentorships and internships both offer structured program options for gifted students to appreciate the nature of collaborative work in the sciences.

(3) *Developing a knowledge base in science areas.* Another key component to an appropriate science curriculum for high ability learners is the opportunity to learn significant content in science areas. Emphasis on equal exposure of students to content in the biological, physical, and geological sciences is also necessary to ensure that intradisciplinary understandings are developed. In an analysis of the effects of curriculum materials, it was found that students generally learned the specific content areas of science (biology, chemistry, etc.) to which they were exposed. However, in the case of selected National Science Foundation curriculum materials, which are strongly content-oriented and include BSCS Biology, Chemistry study, IPS Science, and PSSC Physics, students improved more in the areas of process skills, analytical skills, and creativity when compared to students using other curricula (Welch et al., 1981). It appears that the science curriculum that has a significant content base organized conceptually

can enhance the development of skills critical for doing science. Where high ability students are exposed to a heavy content emphasis, as is still the case with some basal text materials, it is critical that opportunities for testing out of content already mastered are provided along with opportunities for advanced work in science topics. Rutherford and Ahlgren (1989) integrate scientific knowledge requirements into a set of scientific views of the world. These include:

- (a) the structure and evolution of the universe;
- (b) the general features of the planet earth;
- (c) the basic concepts related to matter, energy, force, and motion;
- (d) the human organism as a biological, social, and technological species;
- (e) the human life cycle through all stages of development and maturation; and
- (f) the basic structure and functioning of the human body.

The emphasis on learning an appropriate knowledge base in the sciences is then shaped by these views that guide the teaching of more discrete content.

(4) *Developing interdisciplinary connections.* In the last half of this century, the world has begun to recognize the awesome connection between scientific discovery, technological development, and direct impact on society (Kuhn, 1970; Bronowski, 1973). Perhaps the development of the atom bomb was the first time this connection was truly etched on people's collective consciousness. Since that time, however, the connections have been repeated over and over again. Consequently, to teach science as a totally objective set of processes is to misrepresent the role of science in today's world. High ability students need to be exposed to the social issues surrounding the scientific enterprise and to develop a philosophy of science and a code of ethics that includes concerns for the moral and ethical dimensions of doing science.

Infusion of technological advances into the curriculum should be a two-pronged approach: making use of technological tools that aid learning (e.g., computer simulations, video-discs, CD-ROMS) and inclusion in the curriculum content of the technological advances that affect society (e.g., telephone, laser, or medical technology). In each case, it is important for students to see the application of these advances and not just know of their existence.

Making the connection between science concepts and other areas of inquiry such as the social sciences, mathematics, and language is also crucial to meaningful science learning. As students study the concept of scientific systems, for example, it is helpful to link that study to systems of government, systems of economics, and various communication systems. This forging of deliberate connections to other disciplines of study provides a richer and more complex curriculum for high ability learners.

(5) *Developing investigations of real problems.* Integral to considerations in developing an appropriate

science curriculum framework is the role of the learner and her sense of connectedness to the enterprise of doing science as scientists themselves do. Traditional curriculum structure has a well-established order of instruction: information comes first, followed by questioning to determine student understanding, and ending with some sort of problem-solving activity. While this approach is very systematic and easy for teachers to manage, it does not reflect the kind of learning which takes place in the "real world", and especially in the science professions. The goal of problem-based learning, one technique to engage learners in real problem-solving, is to make learning in school more closely parallel the life-long learning which occurs in adulthood (Barrows, 1985).

With laboratory experiences carefully structured within the investigation of the problem, problem-based curriculum becomes an encapsulation of the entire process of scientific thought, investigation and impact. Moreover, problem-based curriculum has the advantage of easily incorporating study and discussion of the inter-relationship between science and social structures such as government and economics.

(6) *Developing scientific habits of mind.* Welch (1984) has noted the importance of understanding the activities, beliefs, and personal traits of scientists in order to make appropriate inferences about an appropriate science curriculum. Most scientists share a common set of fundamental beliefs about the natural world. These include such ideas as the existence of universal physical laws, the Copernican theory, and the belief of living things evolved over a long time period from simple to more complex forms. Such shared beliefs, unlike religious beliefs, are subject to question and can radically change if experiment or observation of the world indicates that they do not accurately reflect the true nature of things. Thus science is uniquely dependent on experiment and inquiry. It is therefore important to convey both the fundamental ideas of science and the methods by which they are tested and refined to learners.

Welch (1984) also notes that certain personality traits seem to characterize the more successful scientists, and this research provides us with important guidance on the appropriate way to structure a science program for high ability learners. The particularly important characteristics that scientists exhibit have been identified by Brandwein (1955) and Klemm (1977) to be curiosity, creativeness, and commitment.

Language Arts

Recent national reports in the language arts also have called for a reconsideration of language arts curricula that is sensitive to using high powered material and inquiry-based approaches (Marzano, 1992). As with mathematics and science, such reports also stress the importance of using such approaches throughout elementary and junior high school. Close and active reading of various genre is also encouraged even at

the expense of broad coverage (National Assessment Governing Board, 1992). Constructivist theory in the language arts has focused on the complex tasks of student as meaning maker (Spivey, 1990). Other theorists view the province of teaching language arts as promoting the classical canon and teaching traditional forms of writing (Flirsch, 1989; Thompson, 1990). Accompanying modes of assessment are also being advocated to reflect this intensive involvement with literary works, focusing more on the processes of reading, the thought patterns of students engaged in it, and the power of thought brought to bear in connecting one work to another (National Assessment Governing Board, 1992). There exists, however, a significant gap between theory and practice. Researchers in literary development generally have deplored the lack of curriculum research in testing what works in schools (Langer & Allington, 1992). One of the challenges, then, is to find ways to incorporate what is known about literacy development and the schooling process and put it into "testable" practice.

Glatthorn (1992) emphasizes learning as an interactive process that brings together the learner, an activity or task, and the situation that surrounds them. Thus there is concern for ensuring a "holistic view" in a language arts curriculum. A literate environment provides rewarding experiences where meaning is constructed in real situations. Students work collaboratively and use the teacher as a model. Learners engage in risk-taking and revising their work as a regular part of their school experience. An integrated curriculum uses communication skills as inter-related processes which support each other and as enabling skills across all subject areas. In the integrated language arts, learners employ three cueing systems: semantic (meaning), syntactic (word order or grammar), and graphophonics (sound/symbol). Outcome-based curriculum goals focus on whole-thinking processes (rather than sub-skills) that are at a sufficiently challenging conceptual level. A "thinking" curriculum requires awareness of one's own thinking, and the awareness includes attitudes, habits, and dispositions, as well as the critical and creative thinking processes about ideas. Such a language arts curriculum encourages student responsibility for learning as well as supports student choice, collaboration, and active participation. Finally, a key curriculum feature relates to an aligned curriculum where what is written is also taught and tested so that instruction and assessment become interrelated areas.

Tschudi (1991) reviewed the materials on K-12 language arts curriculum and suggested several key ideas for successful language arts programs. These ideas focused on the need to integrate the language arts with all content areas, the need to recognize and honor cultural differences in children through involving parents and community in the schools, an emphasis on open-ended activities that are judged through authentic assessment procedures, and the integrated teaching of all the language arts together.

Research on the effectiveness of the whole language

approach compared to the traditional, skill based approach to language learning suggests that they are approximately equal in their effects with several exceptions (McKenna, Robinson, & Miller, 1990). Whole language approaches seem to be more effective in kindergarten than first grade, may produce stronger scores on word recognition than reading comprehension, and produce weaker effects with populations labeled specifically as disadvantaged than with those not so labeled. More recent studies, however, show a trend toward stronger effects for basal reading programs relative to whole language programs (Stahl & Miller, 1989). Reading literacy, however, has been depicted as a multi-purpose, multi-level set of experiences (NAEP, 1992).

While arguments for a high quality liberal program of study in the language arts have been consistent over the past ten years (Adler, 1984), the current state of language arts curriculum may be characterized as fragmented by both philosophical orientation and areas of emphasis. The whole language movement has attempted to integrate language arts areas, to provide opportunities for interdisciplinary work, and to encourage "meaning-making" on the part of the learner. The cultural literacy movement has attempted to stress the importance of students developing a rich knowledge base in established works of literature and developing expository writing skills. A third movement to emphasize multicultural literature and a global perspective is also a primary orientation within the field.

Major Emphases within Language Arts Curricula for High Ability Learners

Based on the current language arts issues, and an examination of the major areas of the language arts curriculum that might be emphasized, the National Curriculum Project in the Language Arts has chosen to emphasize the following areas in curriculum development:
