There is a hierarchy of facts; some have no reach; they teach us nothing but themselves. The scientist who has ascertained them has learned nothing but a fact, and has not become more capable of foreseeing new facts. Such facts, it seems, come once, but are not destined to reappear.

There are, on the other hand, facts of great yield; each of them teaches us a new law. And since a choice must be made, it is to these that the scientist should devote himself.

HENRI POINCARÉ
The Foundations of Science, p. 544

Preface

In a very real sense this book was created by popular demand. Murchison's *Handbook of General Experimental Psychology*, published in 1934, went out of print before World War II, and by 1946 many psychologists were feeling a need for a technical survey that would systematize, digest, and appraise the mid-century state of experimental psychology.

This need for a handbook is a periodic occurrence. When the mass of new material in the journals becomes unmanageable, a secondary digest is called for, and psychology has had about half a dozen handbooks in the last century: Müller (1833), Wagner, Hermann, Schaefer, Nagel, and Murchison (1934). Of course other books have partially served the handbook function, and specialized handbooks have appeared in the various segments of psychology as the subject has expanded in the twentieth century.

In experimental psychology proper, then, a handbook was fully due. Among the official bodies of the American Psychological Association there was talk of preparing such a book—perhaps as an official venture of the APA. Meanwhile, however, several publishers were alive to the idea, and when one of them came forth with concrete plans the APA withdrew in favor of private enterprise.

It was immediately plain, in 1946, that this private enterprise would have to be highly public, for a modern handbook requires the collaborative efforts of a community of experts. No single specialist can marshal the erudition required for an inventory of experimental psychology's facts and findings. It was also plain that between the covers of a single volume it would be impossible to survey all of psychology that is truly experimental and that many limitations would be forced by circumstances. There would need to be arbitrary slicings made in a subject matter that is essentially continuous, and these slicings would need to coincide with the talents and interests of living experts. There would need to be compromise between the ideal of consistency throughout the volume and the democratic right of scientists to disagree and to correct one another's errors.

Equally clear was the fact that the handbook should address itself directly to the advanced scholar—to the graduate student who would use it as a textbook and to the specialist who would use it as a reference source and as a guide to matters outside his own specialty. Therefore it should be neither elementary nor esoteric.

These principles have indeed governed the writing and editing of this work. If an occasional practical exigency has forced us to content ourselves with less than our initial aspirations, other developments have certainly conspired in

our favor. The chief beneficent conspirator has been the enthusiastic devotion of the contributors.

Let me say a little about the concrete circumstances of the labor. In the first place, the scramble of postwar reconversion was upon us and many of the authors were resuming their academic functions under conditions less than utopian. In the second place, the editor felt himself deficient in editorial wisdom. He tried to make up for this by seeking the advice of two wiser men, E. G. Boring and C. T. Morgan. The three of them argued about how the book should be organized and who should contribute chapters. The decisions were not always unanimous, but eventually a plan was adopted and contributors solicited. (Boring conducted most of the correspondence at this stage—and a lively correspondence it was.) Inevitably, of course, emendations of the original plan were necessary from time to time and the editor made them as the work progressed. Since neither the editor nor the authors had fully grasped the magnitude of the undertaking, the early optimistic deadlines had to be revised and it was November 1949 when 86 pounds of manuscript were finally shipped to the publisher. We then had hopes for publication in 1950. The authors had been patient with the editor. They had diligently revised the editor's revisions of their manuscripts and had gracefully put up with deletions and compressions of varying magnitudes.

But the end of the editing was still months away. The manuscript was carefully marked for the printer and the process uncovered many matters calling for revision. In the meantime, someone had counted the words and found them to run to more than a million, which was far more than had been bargained for. The entire manuscript was then returned to the editor who had another go at revision and compression. Several thousand words and a few figures were squeezed out on this final round.

The individual authors proofread their own galleys. Most of them faithfully suppressed the natural desire of authors to rewrite on the margins of the proof. Where the temptation proved too great the editor wielded his pencil with high censorial hand—which effectively makes him responsible for what may still be wrong with the text.

No one, of course, ever edits a work of this sort singlehanded. I have already mentioned the contributions of Boring and Morgan. But the person who did more work on this handbook than anyone else is Geraldine Stone. While I am writing this preface she is busy organizing the index.

The contributions of the authors speak for themselves in the pages that follow.

Mathematics, Measurement, and Psychophysics

S. S. STEVENS
Harvard University

The stature of a science is commonly measured by the degree to which it makes use of mathematics. Yet mathematics is not itself a science, in the empirical sense, but a formal, logical, symbolic system—a game of signs and rules. The virtue that makes mathematics more than trivial is its capacity to serve as a model for events and relations in the empirical world. Like any model used to represent something other than itself, mathematics “fits” better in some places than in others, but at no place is there perfect correspondence between the mathematical model and the empirical variables of the material universe. Generally speaking, the fit is better to the degree that the dimensions and qualities of the things we study are measurable on well-founded scales. When description gives way to measurement, calculation replaces debate.

Measurement, then, is a concern of psychology. It is only remotely an aspiration in those fields of the discipline where uncharted complexity confronts the inquirer and where the cast of the basic topography

is revealed only to men of bold insights. It is more immediately the goal in the experimental corner where the patient sifting of facts and relations has disentangled some of the relevant variables. Measurement is an especial preoccupation of psychophysics—not only of psychophysics in the narrow sense of the term, but of psychophysics in its older and broader spirit, which tries to discover rules relating the responses of organisms to the energetic configurations of the environment and which, as we shall see, resolves itself into seven basic problems.

But measurement is a relative matter. It varies in kind and degree, in type and precision. In its broadest sense measurement is the assignment of numerals to objects or events according to rules. And the fact that numerals can be assigned under different rules leads to different kinds of scales and different kinds of measurement. The rules themselves relate in part to the concrete empirical operations of our experimental procedures which, by their sundry degrees of precision, help to determine how snug is the fit between the mathematical model and what it stands for:

Measurement is possible in the first place only because there is a kind of isomorphism between (1) the empirical relations among objects and events and (2) the properties of the formal game in which numerals are the

This chapter had the helpful criticism of several patient colleagues. E. G. Boring, G. A. Miller, F. C. Frick, and Frederick Mosteller gave it a most thorough combing, but theirs is not the responsibility for the errors it still contains.

Its production was carried through at the Psycho-Acoustic Laboratory, Harvard University, under contract with the U. S. Navy, Office of Naval Research (Contract N5ori-76, Project NR147-201, Report PNR-76).

pawns, and operators the moves. When this correspondence between the formal model and its empirical counterpart is close and tight, we find ourselves able to discover truths about matters of fact by examining the model itself. Thus we calculate the flight of a bullet or the course of a comet without laying hands on either. And we are awed by the prodigious power of mathematics to see what is beyond our own vision.

In this mathematical puissance the ancients detected a mystical splendor — a proof that number rules the universe. The moderns see this as just another instance of man's creating his own gods, for mathematics is a human invention, like language, or like chess, and men not only play the game, they also make the rules. Of course the rules for much of mathematics (but by no means all of it) have been deliberately rigged to make the game isomorphic with common worldly experience, so that ten beans put with ten other beans to make a pile is mirrored in the symbolics: $10 + 10 = 20$. It is interesting to note, however, that a vast amount of what we call mathematics is not isomorphic with any known reality and is in this sense useless to the practice of science.

Nevertheless the structure of mathematics is studied by the scientist because it is the language in which he sets forth his precise propositions. Hogben oversimplifies it for the "million" by explaining that mathematics is the language of *size* as opposed to English which is a language of *sort*. In any case, mathematics is a specialized language with a rich and rigorous syntax — as every schoolboy knows. And, as every psychologist knows, there is no profit in trying to expound the technicalities of mathematical syntax in a single chapter. All we shall attempt here is an understanding of how it serves as a model to represent empirical operations. We can talk a little *about* mathematics without being skilled in the art of its use. For a book on the skills of mathematics applied to psychology, see D. Lewis (1948).

Syntactics, Semantics, and Pragmatics

When we discuss the nature and use of language — mathematical or otherwise — it is convenient to distinguish three regions of inquiry (Morris, 1938; see also Carnap, 1942):

1. Syntactics is the study of the relation of signs to signs.
2. Semantics is the study of the relation of signs to objects.
3. Pragmatics is the study of the relation of signs to the users of signs.

For examples, see Table 1.

TABLE 1

EXAMPLES FROM THE THREE LEVELS OF LANGUAGE INQUIRY

Level	Examples
Syntactics	Rules of algebra: $a^2 = a \times a = \sqrt{a^4} = a^6 \times a^{-4}$, etc.
	Rules of punctuation: Unpunctuated: That that is is that that is not is not is that not it it is. Punctuated: That, that is, is; that, that is not, is not. Is that not it? It is.
Semantics	Geometry: Let h be the length of the hypotenuse of a right triangle. Objects: "Square" is the name for figures like this: \square . Metalanguage: The word "horse" is a noun.
Pragmatics	Propaganda: "Progressive" is a "good" word in the view of most people. Usage: Educated people do not say "ain't." Idiom: The sentence, "We must rise equal to the occasion," is bad idiom. Insult: The word "nigger" is insulting to a negro.

Syntactics refers to the formal disciplines of logic, mathematics, and syntax, where the relations among signs are *abstracted* from the relation of the signs to objects and to the users or interpreters of signs. The propositions of syntactics are devoid of empirical content. They say nothing about the physical world. They are statements like the laws of algebra, which set the rules for the combining and arranging of the signs of algebra. In short, abstract mathematics is a branch of syntactics.

Of course, in order to *talk about* a syntactical system we have to get out of the sys-

tem and into another language — a *meta-language*. Thus, when the textbook describes in English the syntactical laws of algebra, English is the metalanguage, and the ‘objects’ to which the words of the textbook refer are the signs of algebra. In other words, the terms of the metalanguage are related by semantical rules to ‘objects’ that are themselves terms in another language. Or the ‘objects’ may even be terms in the same language, as when the grammar book discusses in English (metalanguage) the syntax of English (object language).

Semantics refers to the rules that relate signs to objects. What object do we call a chair, what a table? In our algebraic formula what does x stand for, and what do the other signs represent? Obviously, if a formula is to stand for something, its terms must be linked by semantical rules to objects or events; its terms must have a meaning. Semantical rules are basically arbitrary, in the sense that we make them up for our convenience, but the satisfactory definition of words and symbols is not always easy to come by. It is generally accepted that semantical rules should be in the nature of *operational* definitions (cf. Stevens, 1939*a*), but the problem of contriving definitions that meet the operational test of meaning is, as Bridgman showed in 1928, a serious, difficult business. It is easy enough to say, “Let x represent the ratio of responsibility to liberalism,” but it is hard to know what, if anything, we are talking about.

Closely related to the problem of the operational definition of individual terms is the issue of the “truth” of empirical propositions. *Terms* have *applicability* to objects or events when the semantical rules governing their use satisfy operational criteria. The sentences or formulas created by combining these *semantically* significant terms into propositions are *empirically* significant (have truth value) when their assertions are confirmable by means of concrete operations. The operational definition of terms does not guarantee the operational validity of for-

mulas. Thus H and W may stand unequivocally for a man’s height in inches and weight in pounds, but the mathematical sentence reading $H = \sqrt{W}$ may be empirically false.

The confirmation of an empirical assertion, it should be remembered, is never absolute and final. Repeated tests can add to its *probability* but never clinch its certainty. Induction, as Hume said, is not a watertight method of proving anything empirical, and propositions about nature always have a degree of probability that is less than certainty (cf. Reichenbach, 1938). Not so with syntactic (mathematical) statements, however. There we find theorems and equations that are absolutely true or absolutely false. They are true if they are consistent with the rules laid down for playing the game; they are false if they break the law. But these absolutely true statements say nothing at all, unfortunately, about objects or events, and they reveal no secrets of nature.

It is by way of semantical rules that we tie the mathematical model to the empirical world, and it has already been pointed out that the model often fits as poorly as a borrowed hat. Some of the reasons for this lack of congruity can now be made more specific:

1. There are always empirical errors of measurement. We can calculate the area of a circle to far greater accuracy than physical operations can measure it. (Actually the irrationality of π precludes even an exact calculation of the area, but we can add on decimal places as long as we please.)

2. There are often uninterpretable mathematical terms for which we make no semantical rules. The length of the hypotenuse of a right triangle is gotten by solving: $h^2 = a^2 + b^2$. One solution is $+\sqrt{a^2 + b^2}$; the other is $-\sqrt{a^2 + b^2}$. We throw out the negative solution because negative lengths make no sense.

3. The rules of classical mathematics imply infinite divisibility, but matter, we have reason to believe, is not infinitely divisible.

4. Only a few of the many aspects of any natural phenomenon get themselves represented in a given mathematical formulation. Most aspects are neglected, deliberately or by oversight, and those that we try to depict may be ill chosen or ill defined. The shortcoming is then basically a matter of semantics.

Pragmatics refers to the relation of signs to scientists. Here belong the problems of how the scientist, as a behaving organism, uses signs, how he reacts to signs, how the choice of signs influences behavior. About this obviously fascinating problem no more will be said here, except to point out that the paralytic terror instilled by those clever souls who can calculate in those who cannot is a problem in applied pragmatics. It is the same terror that routed Diderot when Euler confronted him at the Russian court with a symbolic non sequitur to prove the existence of God (Bell, 1937).

THE MATHEMATICAL MODEL

The formal rules of mathematics are arbitrary conventions. Historically this fact was discovered late. The early mathematicians thought it proper to prove their mathematics empirically — to demonstrate that $2 + 2 = 4$ by sorting pebbles. The seeming success of this pebble counting as a test of many mathematical propositions still makes it hard for us to keep an understanding grip on the important truth that the “process of induction, which is basic in all experimental sciences, is forever banned from rigorous mathematics” (Dantzig, 1939, p. 67). Counting on the fingers may be a handy method of meeting computational emergencies, but all it proves about the nature of arithmetic is that the rules of number invented by our ancient ancestors are isomorphic with certain digital operations. We are not startled by this correspondence between fingers and arithmetic, because we know that in some dim era of the past somebody invented the system of natural num-

bers for precisely this purpose of providing a formal model to represent what he did with fingers and pebbles and enemies and cattle. That the forgotten genius of that historical day may have been unconscious of the *formal-empirical* dichotomy, which we now regard as so crucial, is beside the point. The fact is, he built a formal model to stand for an aspect of his empirical world, just as an architect draws a plan for a house.

The details of this primitive model making are lost to the record, but it is easy to imagine how it might have come about. Many things exist in obvious quantity, like fingers (in whose names we find the names of the numerals in many old languages, cf. Harkin) and pebbles (in whose Latin name we find our word *calculus*). To collections of these things primitive man applied the *principle of correspondence* — the basic mathematical process of setting things in one-to-one relation. He might have added one pebble to a pile for each fish in his cache, and if someone filched a fish he could have discovered the theft by *pairing* each of the remaining fish against a pebble.

This pairing of members until one or both groups is exhausted leads directly to the concept of *cardinal number*. If both fish and pebbles pair up evenly with none of either left over, the two groups have the same cardinal number. Which is why Frege in 1879 and Russell (independently) in 1901 defined number as the class of all classes that show a one-to-one correspondence with a given class (cf. Bell, 1937, p. 567). The cardinal number 3, for example, is the class of all trios; 2 is the class of all pairs, etc.

The ubiquity of the cardinal principle is evident in many systems of numeration, such as those of Rome and Egypt (Harkin). The Egyptians wrote the numeral nine thus: $\overset{111}{111}$. But cardinal number, resting solely on the principle of correspondence, implies *no counting*. Our primitive forebear who knew only cardinality had resort to a motley array of models, unsystematized and *ad hoc*. In order to create a counting process he had

to devise a system: he had to arrange his set of models in an ordered sequence. This he probably accomplished in a few thousand years by setting successive piles of pebbles in an order such that any pile paired with its next-door neighbor would leave one pebble left over. In these ordered piles he had a model of a very tidy sort, one having ordinality, or succession. Next he named the successive piles (he made up semantical rules), and he remembered the order of the names. Then he was ready to *count* his fish. He simply paired them against the successive names until he ran out of fish. The name assigned to the last fish was the *ordinal number* of his catch.

This fanciful account of how our ancestors got from cardinal to ordinal numbers is intended to clarify the distinction between the two kinds of numbers. As history it is undoubtedly false. It is pleasant to surmise that cardinal number, based on matching, antedates ordinal number, which calls for both matching and ordering. "Yet the most careful investigations into primitive culture and philology fail to reveal any such precedence. Wherever any number technique exists at all, both aspects of number are found" (Dantzig, p. 9).

The reader should be alerted here and in what follows to the intensely controversial nature of some of the basic notions at the frontiers of mathematical inquiry. At these frontiers the mathematicians, like ordinary mortals, exchange incivilities and shout each other down. One of the noisiest of recent battles was that between the formalists, led by Hilbert, and the intuitionists, led by Weyl and Brouwer. The skirmish is vividly chronicled by Bell (1945, pp. 565-570) and I mention it here mainly because intuitionist Weyl does not agree that the cardinal (class) concept of number is primary. It seems to him "unquestionable that the concept of ordinal number is the primary one" (p. 35). The present account of things is more in line with the formalist tradition. Let us return to it.

The names for number we now call numerals, and the fact that they have a "natural" sequence—an ordered succession—makes possible an arithmetic, i.e. a set of rules for combining numerals. The rules, of course, are so chosen that the system can continue, as it began, to serve as a model for ordered piles of pebbles. Thus if two piles are pooled the result is a collection having the same cardinality as some one of the ordered piles. The model reflects these facts under the so-called rules of addition. Subtraction in the realm of numerals (e.g. $7 - 4 = 3$) reflects, with no change in the semantical rules originally laid down, the operation of taking one pile of pebbles from another. Multiplication is successive addition, and division is successive subtraction. Thus we arrive at whole-number arithmetic. And incidentally in the process we have achieved a scale of measurement—a scale for the measurement of "numerosity"—the cardinal attribute of physical collections of objects (Stevens, 1939*b*).

Numeration

The invention of ordered numerals was a momentous accomplishment. But how should they be written? A different numeral for each of the numbers represented by endless ordered piles of pebbles is a theoretical possibility but a psychological suicide. We could never remember them all. We must have a learnable set of different symbols and a learnable rule of succession. Given a numeral we must know how to produce its successor. Nearly all systems of numeration are based on a repetitive procedure that makes it possible to indicate large numbers by combining the symbols for smaller numbers (cf. Ore).

Many systems, like the Roman, are based on an obvious cardinal principle: I, II, and III, for 1, 2, and 3. This procedure is psychologically easy and obvious, provided the indication of magnitude is the only goal. But when we try to create an arithmetic we find it impossible to devise for Roman numerals a

multiplication table that a human being can learn the way a fourth-grade pupil learns the Arabic table. To see what this means try multiplying MCDLVIII by XIX. The difficulty, we now know, is that the Roman system has no zero — no symbol for the empty column — and it can therefore make no use of the *principle of position*. The Greeks and the Romans, for all their intellectual brilliance, never hit upon the simple, powerful device of indicating *nothing* by means of a symbol. The Romans wrote DV where we write 505. Our numeration says explicitly: five hundreds, no tens, and five units. Our ability to say “no tens” in this manner is the secret of the power and simplicity of our reckoning. “When viewed in this light, the achievement of the unknown Hindu who some time in the first centuries of our era discovered the *principle of position* assumes the proportions of a world event” (Dantzig, p. 29). The Hindu called zero by the name *sunya*, which meant *empty* or *blank*, presumably because he used it to indicate that there were no marks in one of the columns of his counting board.

Most systems of numeration repeat on the base *ten*. The choice of this base is an anatomical accident and attests the anthropomorphic nature of our counting. If the three-toed horse had learned to calculate, he would probably have used the base six or twelve for his arithmetic. Contrary to popular belief, there is nothing sacred about the decimal base. Any base is possible, and other bases are sometimes used for special purposes. Modern binary computing machines use the base *two* because only two numerals are required, and they can be represented by a switch that is open for one numeral and closed for the other. In binary notation our number 22 is written 10110. For Leibniz the binary system had a mystic elegance because out of unity and nothing all numbers can be created!

Actually the base ten is an unhappy choice. It would have been better had we had no thumbs, for then the base would have been

eight. The case for base-eight arithmetic has been argued by many (cf. Tingley). The advantage is allegedly psychological: it would make mental calculations easier because it more readily allows for successive halvings, and halving is psychologically the simplest of all numerical operations. On base ten and base eight the process of successive doubling gives:

Base Ten	Base Eight
1	1
2	2
4	4
8	10
16	20
32	40
64	100
128	200
256	400

Tingley points out that the world's moneys, weights, and measures try to follow the principle of successive doubling, but the base ten makes it impracticable. The coins and bills of our currency, for example, show the following ratios each to the one below it:

Coins (in cents)	Ratios
1	
5	5
10	2
25	2.5
50	2
100	2
200	2
500	2.5
1000	2
2000	2

If we used the base eight, all these ratios could be exactly two, and change counting would be vastly easier for both geniuses and morons. All the factors of base eight are twos, and in this age of binary computing machines it would be a happy economy if we could make this glorified binary the base of our counting.

But anatomy has chosen our base for us, and mere psychological advantage is probably not going to change it.

Extension of the Number Domain

The positive integers, which early in history became ordered into a system of ordinal numbers, are only a small part of what we now call the domain of number. And the story of mathematics discloses successive extensions of the domain, painfully and laboriously achieved.

The first accretion seems to have been the fractions, or, as we call them, the *positive rational numbers*. With these new elements added the mathematical model becomes adequate to the representation not only of things countable but also of things that vary in magnitude, like length. Unit fractions date back to Ahmes of Egypt (1700 B.C.), and Euclid considered commensurable ratios of the form m/n , but he did not himself regard these ratios as numbers (cf. Young, p. 101).

If later men were less conservative than Euclid in admitting new elements to the domain, the interesting question is why. This is not to inquire into Euclid's temperament, but to pose the problem of the rationale of new numbers. What should they be? What criteria must they satisfy? The answer to this question was not known to the ancients, who never mastered the distinction between the formal model and the empirical world of things and objects, and who put their trust in empirical induction. The possibility of syntactics (the study of signs and rules) divorced from any consideration of semantical definitions is a modern discovery. The notion of syntactics is *implicit* in the work of the early mathematicians, but it is only when we make *explicit* the nature of signs and rules that we are able to formulate criteria for the admission of new numbers to the number union.

Put crudely, the idea is this: any new number is admitted provided it obeys the old rules. It is analogous to the admission of a state to the union: the new state must agree to obey the federal laws. The laws of the number union have to do with addition, multiplication, subtraction, and division, and the

new numbers must behave themselves when these operations are applied. Since rational fractions exhibit the proper decorum when they are added, multiplied, etc., we vote them in.

Actually, of course, new kinds of numbers do not step forth from nowhere to test themselves against the rules that were generated when the arithmetic of natural numbers was created. Rather the reverse is true. The attempt to apply the rules of arithmetic occasions these new numbers. Thus we subtract 4 from 7 and get 3; but suppose we subtract 7 from 4. In the system of natural numbers this subtraction is not possible, and until about the time of Descartes (1596–1650) operations of this sort were ruled out as “absurd” or “fictitious.” But, if we admit *negative numbers* to the domain, subtraction is always possible, and after years of struggle and controversy these absurd new outlanders became naturalized citizens. In analogous fashion the rational fractions had wormed their way into citizenship because they made division always possible.

What we observe here is an involuntary tendency on the part of mathematicians “to employ rules under circumstances more general than are warranted by the special cases under which the rules were derived . . .” (Klein, p. 26). This tendency to generalize has become a highly respectable attribute among the moderns, and in 1867 Hankel gave it explicit dignity by claiming it to be a guiding principle in arithmetic. He called it the *principle of the permanence of the formal laws*, and by it he intended what we have already seen, namely, that in mathematics the rule's the thing. Unlike the ideal state where the laws are made for men, in mathematics the elements are made for the laws.

With the introduction of the negative numbers under this “principle of permanence” mathematics so changed its aspect that men began to see the reasonableness of the point on which we have been insisting: that mathematics is a syntactical sport. Faced with numbers generated by taking

something large from something small (e.g. $4 - 7 = -3$) we find that it becomes harder to regard arithmetic as a system of concrete numerical magnitudes and that it becomes easier to see it as a formal symbolism. With the extension of the number domain so that there is *no least number* it becomes more obviously impossible to prove arithmetic empirically as the ancients tried to do.

With negative numbers admitted to the system an amusing thing happens. Felix Klein, one of the modern greats, quotes Max Simon to the effect that, "whereas negative numbers were created to make the operation of subtraction possible without any exception, subtraction as an independent operation ceased to exist by virtue of that creation" (p. 24). Subtraction becomes merely the addition of a negative number.

Of course, once new formal elements have been introduced into the system it often becomes possible to relate them by semantical rules to objects or events, or even to the elements of other systems. Thus in bookkeeping the minus sign may mean that you owe the bank some money. And in geometry the minus sign can be interpreted as *rotation* through 180 degrees, so that negative numbers refer to distance in the direction opposite to that indicated by positive numbers (cf. Young, p. 114).

Again applying the principle of permanence (unconsciously perhaps) mathematicians introduced the *irrational numbers* into Western Europe in the sixteenth century (cf. Klein). Irrationals are necessary to the solution of equations like $x^2 - 2 = 0$. The solution, $\sqrt{2}$, is not a rational number like $\frac{2}{3}$ because it is not expressible as the ratio of two integers. But irrational numbers fit into arithmetic and pay their way as useful, law-abiding tenants of the realm.

Actually the Greeks were aware of the existence of incommensurable ratios. They knew that the diagonals of most right triangles are irrational—incommensurable with the sides—a discovery celebrated by Pythagoras with the sacrifice of a hundred

oxen. Furthermore the Greeks had a word for it—"unexpressible"—which tells us better than the Latin name that these ratios are not contrary to reason but merely undepictable by integers. But the Pythagoreans viewed the irrationals with mixed emotions. We are told that the members of the order were sworn to secrecy not to reveal to outsiders these "imperfections" in the number system, for number was supposed to rule the universe. Dantzig quotes Proclus: "It is told that those who first brought out the irrationals from concealment into the open perished in shipwreck, to a man."

As we have seen, the algebraic irrationals forced their way into the number domain, much as did the negatives, because they were useful in solving certain algebraic equations. An interesting question, one not settled until 1844, concerns the possibility that there exist irrational numbers that are not algebraic—that are the solution of no algebraic equation having rational numbers as coefficients. In 1873 Hermite astonished and delighted the mathematical world by proving that the number e , the base of the natural logarithms, whose value is 2.7182818 . . . , is the root of no algebraic equation of this sort, and in 1882 Lindemann did the same for π . These numbers belong to the category known as *transcendental*, for, as Euler put it, they "transcend the power of algebraic methods" (Courant and Robbins, p. 104). Transcendental numbers comprise some of our most useful devices, for they include most logarithms and trigonometric ratios—functions that might well be called the work horses of applied mathematics.

With this latest enrichment, the addition of transcendentals, the realm of number becomes fatter and fuller by far than primitive man could have imagined it would ever be. All the numbers thus far discussed belong to what is called the *real domain*, and in this domain we can perform rich and varied calculations. But there are still some simple things we cannot do. For example, we can-

not solve the equation: $x^2 + 1 = 0$, for a solution is $\sqrt{-1}$, which has the appearance of nonsense. For many centuries the impulse to write $x = \sqrt{-1}$ was inhibited by men's knowledge that there is no square root of a negative number. The Hindus and the Arabs resisted the temptation to write these numbers, although they were bold in other matters mathematical. It seems to have been the Italian, Cardan, who in 1545 first dared, albeit apologetically, to denote this "fiction" by a symbol. Once symbolized, however, these *imaginary numbers*, as we still call them, pushed their way to prominence. Denoted by the symbol i and combined with real numbers to make elements of the form $x + iy$, the imaginaries go to make up the complex numbers which are so essential to modern algebra. In fact it was with the aid of these numbers that the young Gauss was able, in his doctoral thesis in 1799, to prove what the mathematicians call the fundamental theorem of algebra, namely, that every algebraic equation in one unknown has a solution. And the prolific Euler had already in 1748 revealed the remarkable relation between integers, transcendentals, and imaginaries:

$$e^{\pi i} = -1$$

The creation of complex numbers is dramatic evidence of the validity of the distinction between the formal model and the empirical universe (cf. Stevens, 1939a). These numbers were originally developed from the purest of mathematical motives, and no application to concrete matters was even suspected when the rules for their addition and multiplication were first formulated. Complex numbers were simply abstract symbols, useless to the applied mathematician. True, there lurked an uneasiness in mathematical circles, for most men had not yet made peace with the notion that uninterpretable symbols need be no menace and that the justification of a formal system need not rest with its practical usefulness as a model of things

touchable. Nevertheless the formal system, the algebra of complex numbers, was born and elaborated in the vacuum of abstraction "without the approval, and even against the desires of individual mathematicians . . ." (Klein, p. 56).

As it turned out, these lingering doubts about the validity of complex numbers were set to rest early in the nineteenth century when a simple geometric interpretation of the operations with complex numbers was provided. Actually the fact that a geometric interpretation is possible proves neither the validity, nor the reality, nor the sanctity of complex numbers, but it does comfort the concrete-minded and the intuitionists, and it leads directly to the practical application of complex algebra in the physical sciences.

The geometric scheme consists simply in representing the number $x + iy$ as a point in the x, y plane. The abscissa of the point is x ; the ordinate is y . And the relations among the points in the "number plane" are reflected in the algebra of complex numbers, just as the relations among the points on a line are mirrored by the algebra of real numbers. Furthermore the symbol i can be thought of as a *rotation*. The minus sign, it was noted above, corresponds in geometry to a rotation of 180 degrees, and in analogous fashion the sign i corresponds to a rotation of 90 degrees. Thus we get to the real part, x , of our complex number by marching x paces out along the reference line, and the addition of the imaginary part, iy , means: make a right-angle turn and proceed y paces.

This isomorphism between geometry and complex numbers makes skill in complex algebra a must for the engineer. For example, in treating problems that involve alternating currents the engineer can let x stand for resistance, iy for inductive reactance, and $-iy$ for capacitive reactance. These are his semantical rules. He can then turn the crank of the algebraic machine and grind out formulas that depict measurable aspects of electric circuits. In other words he can use this formal system as a model for

the intricate theory of alternating currents. What began as an "empty play upon symbols" gets itself hitched by semantical rules to ohms, henries, and farads. And so well does it work that there are some electrical engineers, untutored in history, who think that complex algebra was invented expressly for the purpose of circuit analysis.

Not only were the inventors of complex numbers oblivious of electrical engineers and their practical problems; they were even convinced that no applications of these numbers would ever be possible. They were like a tailor in a compulsive fantasy who goes on designing garments for creatures whom he has never seen and can scarcely imagine. Occasionally a fellow shows up who fits one of the tailor's creations, and the world is filled with amazement and delight. But, as we noted near the beginning of this chapter, much of the mathematician's modern tailoring fits no known aspect of the physical world, and it seems certain that these symbolic tailors will go on creating new kinds of mathematics far faster than applications can possibly be found for them. Mathematics is not yet petrified in rigid completeness.*

This concludes our survey of numbers and how we came by them. Of course we could go on to show how still other kinds of numbers were added to the domain: numbers corresponding to points in space of three dimensions, quaternions, matrices, algebraic ideals, etc. It appears that once liberated from their fear of empty symbols the mathematicians produced a throng of new numbers, some useful, some useless. These new elements need not concern us here except in one particular: extensions of the domain beyond complex numbers call for a relaxation of the rules. The rule of the "permanence of the formal laws" must be shorn of its dominion if we are to add and multiply things like matrices — those "filing-cabinet" numbers

that consist of arrays of elements useful in factor analysis. For example, it was the revolutionary insight of Hamilton, the Irishman, that disclosed the necessity of revoking the commutative law of multiplication in order to extend complex algebra to "*n*-dimensional" numbers. The commutative law says what is intuitively so obvious, namely, that $a \times b = b \times a$, and it was a bold stroke when Hamilton proposed a system of quaternions in which *a* times *b* does not equal *b* times *a*.

If we are to point a moral in all this, it is that the rules and postulates of a formal system are arbitrary conventions. Under this conception of things, the "rule of permanence" turns out to be not so permanent. It has been demonstrated over and over again that the formal laws can be altered to the enrichment rather than the confusion of mathematics. Perhaps this is why Bell calls the rule of permanence a "notorious and discredited" principle. He sums up the modern attitude with an apt comparison: "In the same way that a novelist invents characters, dialogues and situations of which he is both author and master, the mathematician devises at will the postulates upon which he bases his mathematical systems" (1945, p. 330). Incidentally, Bell should know about the novelist. He writes science fiction under the name John Taine.

Summary of Number Domain

Leaving out the super complex numbers like quaternions, we can now summarize the number domain in a quotation and a table. The quotation is from Gauss, believed to be the greatest mathematician yet born, and is via Dantzig (pp. 189-190), the delightful expositor of number theory.

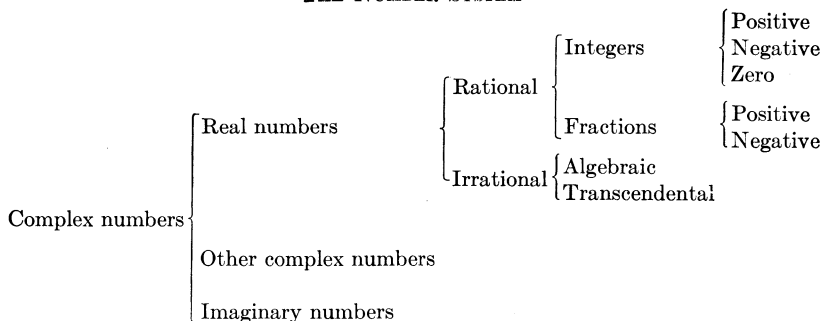

Wrote Gauss in 1831:

Our general arithmetic, far surpassing in extent the geometry of the ancients, is entirely the creation of modern times. Starting originally from the notion of absolute integers, it has gradually enlarged its domain.

* See Bell (1945, p. 21) for four other dramatic examples of the generation of mathematical principles under the drive of intellectual curiosity, with no prospect then apparent of any possible practical application.

TABLE 2

THE NUMBER SYSTEM

To integers have been added fractions, to rational quantities the irrational, to positive the negative, and to the real the imaginary. This advance, however, has always been made at first with timorous and hesitating steps. The early algebraists called the negative roots of equations false roots, and this is indeed the case when the problem to which they relate has been stated in such a form that the character of the quantity sought allows of no opposite. But just as no one would hesitate to admit fractions to general arithmetic, although there are so many countable things for which a fraction has no meaning, so we ought not deny to negative numbers the rights accorded to positive simply because innumerable things admit of no opposite. The reality of negative numbers is sufficiently justified, for in innumerable other cases they find an adequate interpretation. This has long been admitted, but the imaginary quantities—formerly and occasionally now improperly called impossible—are still rather tolerated than fully naturalized; they appear more like an empty play upon symbols, to which a thinkable substratum is unhesitatingly denied even by those who would not depreciate the rich contribution that this play upon symbols has made to the treasure of the relations of real quantities.

The table representing the number domain can be arranged as a breakdown of the complex number system into its subdivisions. This is possible because all real numbers are special cases of complex numbers, obtained

when the coefficient of i is zero. Similarly, when the real part of a complex number is zero we have a pure imaginary number.*

What this number system teaches us is that, given certain basic postulates or principles about relations within a formal system, the elements of the system generate themselves automatically. Or, as Dantzig says, "Arithmetic does not begin with numbers; it begins with criteria" (p. 208). These criteria (like one-to-one correspondence underlying the notion of cardinal number) existed only implicitly in the mathematics of a century or two ago, and the ferreting out of fundamental principles is a most modern phenomenon. The mathematicians are only lately becoming explicitly conscious of the rules that their predecessors followed unconsciously in their calculating.

Let us consider more fully some of these basic postulates that determine the nature of mathematics. And in doing so let us re-

* It should be pointed out, however, that Russell does not like this way of regarding the number domain. He says, "One of the mistakes that have delayed the discovery of correct definitions in this region is the common idea that each extension of number included the previous sorts as special cases" (1920, p. 63). To him negative numbers are relations, or instances of "relation-numbers," and are, therefore, not in the same universe with cardinal numbers, which are classes of classes. Nevertheless the "common idea," as he calls it, is a convenient if loose way of looking at the matter. "Although it is an error in theory, it is a convenience in practice" (p. 76).

member, as Young says, "that the starting point of any mathematical science must be a set of undefined terms and a set of unproved propositions (assumptions) concerning them. The science then consists of the formal logical implications of the latter" (p. 59). The elementary "objects" of mathematical inquiry, numbers, points, lines, etc., are not substantial "things in themselves," and they elude precise definition. The only relevant assertions concerning them are those that state their interrelations and the rules governing operations with them. Or, as Couturat put it:

A mathematician never defines magnitudes in themselves, as a philosopher would be tempted to do; he defines their equality, their sum and their product, and these definitions determine, or rather constitute, all the mathematical properties of magnitudes. In a yet more abstract and more formal manner he *lays down* symbols and at the same time *prescribes* the rules according to which they must be combined; these rules suffice to characterize these symbols and to give them a mathematical value. Briefly, he creates mathematical entities by means of arbitrary conventions, in the same way that the several chessmen are defined by the conventions which govern their moves and the relations between them. [From Bell, 1937, p. 565.]

The rules create the game of chess, whether we play with ivory pieces or with collar buttons.

The practical utility of our inquiry into the foundations of formal mathematics may not be immediately obvious to the psychologist, but we undertake it here for the light it throws on our most fundamental problem: the creation of scales of measurement.

Attributes of Relations

As we have seen, the gist of mathematics lies in the *relations* among its elements. The recognition of this fact has led to an intricate and specialized *theory of relations*, which constitutes an important branch of modern logic (cf. Tarski, Chapter 5; also Reichen-

bach, 1947). Logic, incidentally, is not something apart from mathematics. In the modern view of things mathematics is a branch of logic, and it turns out that the notion of number and all other mathematical concepts are definable in the field of logic. "It follows that all pure mathematics, in so far as it is deducible from the theory of the natural numbers, is only a prolongation of logic" (Russell, 1920, p. 25).

The technicalities of the calculus of relations need not concern us here, but certain special attributes of relations merit our understanding. For convenience we may arrange these attributes in four groups of three attributes each. Then all the relations we shall be interested in are typified by some combination of four attributes drawn one from each of these four groups (see Table 3).

The four categories have to do with reflexivity, symmetry, transitivity, and connectedness. Table 3 tries to define these notions by means of examples. Examples probably suffice to convey the meaning of the first three categories. The import of the fourth category is clarified by Russell's definition which runs as follows: "A relation is *connected* when, given any two terms of its field, the relation holds between the first and the second or between the second and the first (not excluding the possibility that both may happen, though both cannot happen if the relation is asymmetrical)" (1920, p. 33). In other words, a relation is connected if it holds between all pairs of items in a specified field. Connected relations are necessary (but not sufficient) to the arrangement of things in a series.

It is an interesting exercise to think up examples and to assign them their proper attributes. In so doing, remember that it is essential to specify the "field" of the relation, i.e. the class of things related, whether natural numbers, real numbers, all people, some people, triangles, etc., before a proper assignment can be made. (For the examples in Table 3 the field is usually left to implication, but sometimes it is stated explicitly.)

TABLE 3

SOME ATTRIBUTES OF RELATIONS

	Attribute	Examples
I	Reflexive	Equal to ($x = x$ for all values of x), similar to, includes
	Mesoreflexive	Reciprocal of (x may or may not be the reciprocal of x)
	Irreflexive	Greater than (it is not true for any x that $x > x$), older than, not equal to
II	Symmetrical	Equal to (if $x = y$ then $y = x$), not equal to, sibling of, proportional to, spouse of
	Mesosymmetrical	Not greater than (if $x \succ y$ then y may be equal to or less than x), angry at, includes, brother of
	Asymmetrical	Greater than (if $x > y$ then $y \not> x$), father of, successor to
III	Transitive	Equal to (if $x = y$ and $y = z$ then $x = z$), greater than, ancestor of
	Mesotransitive	Not equal to (if $x \neq y$ and $y \neq z$ then x may or may not equal z), angry at, in love with
	Intransitive	Father of (if x is father of y and y is father of z , then x is not father of z), successor to
IV	Connected	Greater than (in the series of natural numbers, if any two different items are selected, one of them is greater than the other), in telephonic link with (in the Bell system any subscriber can telephone each other subscriber)
	Mesoconnected	Ancestor of (given any two people, one may or may not be the ancestor of the other), successor to
	Unconnected	Alike (given any two fingerprints, neither is like the other)

Other attributes of relations are sometimes distinguished. For example, a relation may be *one-one* (square of, husband of); *one-many* (father of); *many-one* (relation of son to father, square root of); or *many-many* (grandparent of). For mathematics the one-one relation, which Russell sees as a special case of the one-many relation, is of great importance, because it is involved in all relations of the form, "the so-and-so of such-and-such," e.g. the king of Siam, the handle of the pump, the square of x , the log of y , etc. Relations of this sort are what Russell means by the term *function*. In the mathematical sense, the phrase "y is the so-and-so of x" defines a function in which x is the *argument* of the function and y is the *value*

of the function for the argument x. These are descriptive functions, and in this sense "the wife of Socrates" is as much a function as are the more mathematical formulations.

But confining our attention to the properties of relations listed in Table 3, we can single out certain combinations of attributes that are of especial moment. They are important because they characterize basic mathematical relations in the field of number. Thus the relation of *identity*, expressed by the sign =, is reflexive, symmetrical, transitive, and unconnected. The relation *successor to* is irreflexive, asymmetrical, intransitive, and mesoconnected.

One of the most interesting combinations of these attributes applies to relations that are irreflexive, asymmetrical, transitive, and connected. A little thought will show that a relation of this sort establishes a *serial order*. As a matter of fact, for the criterion of an ordering relation we would need to state only the three properties, *asymmetrical*, *transitive*, and *connected*, because if a relation is transitive and asymmetrical it is also irreflexive. (The properties of relations are not always independent.) Examples of relations having the three attributes that define order include such relations as *greater than* and *less than*.

The Postulates of Order

Since the business of setting things in rank order is important to many psychological inquiries, let us consider how we might characterize linear order by a set of *formal assumptions*. These assumptions, or postulates as they are often called, are due to Huntington (cf. Young, p. 68). When we make them we are laying down the conditions (the "demands") that any system must satisfy if it is to be classed as ordered. The word "postulate" is from the Latin *postulare*, meaning "to demand."

First we introduce a symbol, $<$, and we leave it completely undefined. It may stand for any one of a number of the relations, e.g. less than, precedes, older than, above, etc.

We also make use of the symmetrical relations expressed by the symbol \neq , meaning "is different from."

Then, given a class of elements, we let a , b , and c be any elements of the class. The relation $<$ is then assumed to obey the following rules:

O_1 If $a \neq b$, then either $a < b$ or $b < a$

O_2 If $a < b$, then $a \neq b$

O_3 If $a < b$ and $b < c$, then $a < c$.

These three demands are imposed upon the relations among the elements of an ordered series. If the three demands are met, the relations are of the sort that define what we mean by linear order. Now we have already seen that the relations defining order must have three attributes: they must be connected, asymmetrical, and transitive. And it is easy to see that these three attributes characterize the relations among elements that obey Huntington's three postulates.

Criteria for Postulates

Let us now digress a moment to discuss this business of postulation. Since postulates are merely the assumptions we make about relations, it is clear that initially they are very easy to come by. As Russell said when he was scolding those who postulate that an irrational number is the limit of the sequence of fractions that approach closer and closer to the irrational, "The method of 'postulating' what we want has many advantages; they are the same as the advantages of theft over honest toil" (1920, p. 71). But whether postulation is thievery depends upon circumstances. Russell objects to the process only when it is used to dodge a problem that honest toil could solve. In setting up the initial postulates of a mathematical system we are not trying to duck a difficulty; we are trying to pare away the irrelevant nonessentials in order to get a clear view of what constitutes the essence of the system. Generally we want to see how few notions we can leave undefined and still generate all the

propositions and theorems of the system. Consequently there are criteria that are applied to postulates in order to prove their fitness to serve. The most important of these criteria are *consistency*, *independence*, and *sufficiency*. The first of these is a must. The other two are in a sense optional.

Consistency is demonstrated if a system in which there are no known contradictions can be shown to fit the postulates. The postulates of order are consistent because systems like the natural numbers and the points on a line satisfy the postulates, provided, of course, that the proper interpretation is made of the symbol $<$. For the natural numbers this symbol may mean "less than"; for the points on a line it may mean "precedes."

Independence means that no one of the postulates can be derived from the others. The requirement of independence is not logically essential, because mere duplication or partial overlap among postulates does not invalidate the system they govern. But independence is economically and esthetically desirable. It furthers the cause of elegance.

The reader can test the independence of the postulates of order by thinking up interpretations of the symbol $<$ for which some one of the postulates is false while the others are true. Begin, for example, by letting $<$ mean "is the ancestor of."

Sufficiency is sometimes called *categoricity*. It is a property that may or may not be required of a set of postulates, depending on our purpose. Sufficiency refers to the ability of the postulates to determine a single system, as opposed to several systems that are not mutually isomorphic. Two systems are isomorphic if the elements of one system can be paired off one-to-one with the elements of the other system. It turns out that the postulates of order are not sufficient to determine a single system. These postulates can be satisfied by a finite set of integers, say the numbers from 1 to 10, and by the infinite set of all integers. Obviously,

these two sets cannot be put into one-to-one correspondence.

In contrast with the postulates of order, the fundamental postulates of algebra are sufficient to determine a single system. In this connection it is probably in order to call attention to a general principle: the negation of one of the postulates governing a system has the effect of making the system more general. In other words, it becomes easier to find instances that satisfy the postulates when their number is limited. Thus we have already seen how the suppression of the commutative law makes it possible to add quaternions to the number system. Another celebrated example is the creation of the numerous non-Euclidean geometries within the amplified elbow room of a curtailed set of postulates (e.g. a set in which the postulate of parallels is suppressed).

The Postulates of Algebra

It is a curious fact that, although the postulational method was applied to geometry two millenniums ago, only in modern times were the fundamental assumptions of algebra exhumed from the hodgepodge of rules by which algebraic manipulations are carried out. These basic postulates thus rep-

resent the distilled wisdom of more than 3000 years of algebraic juggling.

It should be pointed out at once that there is, strictly speaking, no one algebra—there are several. There is at least one for each major division of the number domain. In a certain sense all these algebras are included in the algebra of complex numbers, which is in many respects simpler than any of the more restricted algebras. The postulates of complex algebra as framed by Huntington are consistent, independent, and sufficient, and they are 27 in number, which means that we will not list them here. Instead we shall have a look at the postulates of ordinary algebra which Harkin sets forth in a scheme having a certain mnemonic merit. All that need be remembered is the word “scared,” which the student of algebra will find quite natural.

First we assume a class or set of elements, a, b, c, \dots . This class is ordered—it obeys the three postulates listed above. Next we assume two operations denoted by $+$ and \times , and finally we impose on these symbols the conditions listed in Table 4.

Out of the postulates we get the theorems of algebra. All the complicated propositions that fill the treatises on real algebra stem

TABLE 4
POSTULATES OF ORDINARY ALGEBRA

S (synthesis)	$a + b = c$ $a \times b = c$	The synthesis of any two elements produces another element that is in the set.
C (commutative)	$a + b = b + a$ $a \times b = b \times a$	The operations are commutative.
A (associative)	$a + (b + c) = (a + b) + c$ $a \times (b \times c) = (a \times b) \times c$	The operations are associative.
R (reversion)	$a + x = b$ $a \times x = b$	Reversion from a to b via some element x is always possible, provided $a \neq 0$ in multiplication.
E (existence)	$a + 0 = a$ $a \times 1 = a$	There exists an identity element for addition (0) and for multiplication (1).
D (distributive)	$a \times (b + c) = a \times b + a \times c$	Multiplication distributes over addition.

from this set of simple statements, and all the algebraic theorems can be reduced to the postulates S.C.A.R.E.D. Harkin shows how the elementary rules of cancellation, transposition, etc.—the rules we learn in high school—follow directly from these basic assumptions. These rules appear as *theorems*, derivable from Table 4.

Definitions, Postulates, and Theorems

It is helpful to distinguish among *definitions*, *postulates*, and *theorems*. In a formal system like algebra these distinctions are clear enough. By means of definitions we introduce new signs into the system, and the definitions relate the new signs to the older signs already explicated. Thus $a^n = a \times a \times a \times \dots$ (for n factors) is a definition used to introduce the exponential sign into the system. Postulates, then, are the statements we make, without proof, about the signs and operators and their relations. And theorems are the statements arrived at by combining the signs in a manner consistent with the postulates and definitions.

In an empirical science like psychology we have a situation that is in some respects analogous. What corresponds to formal definitions are the empirical definitions (semantical rules) invoked to relate words or symbols to objects or events. What corresponds to formal postulates are usually hypotheses—empirical statements relating terms previously defined. And what corresponds to theorems are empirical propositions deduced from the hypotheses.

Unlike the theorems of a formal system, which must pass only the test of consistency with the postulates and definitions of the system, the empirical propositions of science are subject to the additional test of empirical confirmation or refutation.

All this seems straightforward enough, but the fact of the matter is that these distinctions are not always preserved in our textbooks. Many statements have the appearance of empirical propositions when they are really definitions. And much confusion re-

sults. In the proper ordering of things we might set up the illustrative paradigm:

Definition: An instinct is a stereotyped mode of response.

Definition: A cat is a four-legged mammal.

Hypothesis: Cats have instincts.

Empirical verification: Do cats show instances of stereotyped behavior?

Here the definitions are semantical rules. They disclose an arbitrary convention concerning our use of words. Having arbitrarily defined the words "cat" and "instinct," it is in order for us to compose statements relating the two. These are empirical propositions, as distinct from formal theorems, and their validity is a matter to be tested by observation.

But consider what happens when an author begins with the statement, "Cats have instincts." What is he really putting forth, a definition or a proposition? It may be either, and unless the author tells us more we cannot be sure whether what he says is "true by definition" or whether he is proposing something that is amenable to operational test.

It is astonishing how frequently we generate pseudo-problems in our science by confusing definitions (semantical and syntactical statements) with empirical propositions. For an analysis of a concrete instance in which the scientist flounders in logomachy because he hides his syntactical and semantical rules in sentences that have the outward appearance of empirical propositions, see Stevens (1939a, pp. 251f.).

In further pursuit of the analogy between science and the postulational methods of algebra, let us consider the so-called *hypothetico-deductive method* of empirical inquiry, which has its vogue under the conviction that science should be pursued in the manner of Galileo rather than of Aristotle. In the scientific method at its neatest we set up hypotheses, we deduce consequences, and we confirm or refute. For this purpose we

choose a formal model — mathematical, logical, or simply linguistic. We draw from the model an array of symbols. By means of semantical rules we relate these symbols to observable events or objects, and we arrange the symbols in the form of an equation or proposition (the hypothesis). Then we avail ourselves of the *syntactical* rules of the formal system of symbols and proceed to deduce. That is to say, we apply syntactical rules of transformation and convert the original equation or proposition (the hypothesis) into some other equation or proposition (the deduction) consistent with the original. Finally we relate the terms of the deduction to observable events by means of semantical rules, and having done this we are ready to put the deduction to experimental test.

The main difference between the postulational method of algebra and the hypothetico-deductive procedure in science lies in the fact that empirical considerations enter the latter. In science we can test our deductions against nature. In mathematics the facts of the natural universe are irrelevant. We cannot prove algebra with test tubes.

But a point to be noted is that in the process of scientific deduction from empirical hypotheses the process of deducing is carried out at the formal level. A deduction consists in a transformation of a sentence in accordance with syntactical rules. When the hypothesis is an equation and the syntactical rules are the laws of algebra, there can be no doubt that the procedure is as outlined here. When the hypothesis is a sentence in English, where the rules of syntax are less explicitly stated, we often make deductions without being fully aware of the "logic" we are using. Nevertheless, if we are consistent, we are using a logic of some sort, and it is the carrying out of the rules of this logic that is the process we call deduction.

Fortunately for the future of theory building in the nonquantitative reaches of science, the formalization of logic into a symbolic calculus is presently proceeding apace. This modern logic "provides explicit techniques

for manipulating the most basic ingredients of discourse. Its yield for science may be expected to consist also in a contribution of rigor and clarity — a sharpening of the concepts of science" (Quine, p. 8). The well-read psychologist of the future may need to know both Russian and some universal language or pasigraphy like symbolic logic.

The Concept of Group

Let us return now to some further matters in what Russell likes to call the philosophy of mathematics, as opposed to its practice as an art. As we dig downward toward the lower strata of the subject in order to discover what notions are fundamental, we turn up, as we have already seen, some very simple but powerful ideas. The obviousness of some of these concepts does not detract from their importance. Rather we are reminded of what D'Arcy Thompson said of physics: "It behoves us to remember that . . . it has taken great men to discover simple things" (p. 13). The same can certainly be said of mathematics.

Two of the most fundamental concepts of mathematics have already been alluded to. They are the notion of a *class* of elements and the notion of one-to-one correspondence or *isomorphism*. A third concept is that of a mathematical *group*, and a fourth is the closely related concept of *invariance*. We shall first try to understand what the mathematician means by a group.

The theory of groups is little more than a century old, but it has already illuminated much of what goes on in geometry and algebra. Perhaps the theory is not the "Open sesame" it was thought to be in its heyday when the demonstration that a given theory obeyed the postulates of a group was considered a momentous accomplishment (cf. Bell, 1945, p. 445). Nevertheless the group is a very basic notion and one that we shall have use for when we consider the problem of devising scales of measurement.

A group in mathematics is a set of *operations*. The thing that makes these opera-

tions a group is the fact that one operation followed by another operation produces a result that is the same as what could have been produced by one or more different operations. This, of course, is a loose definition, and we will need to take up the slack as soon as we consider an example.

Take the batting order of a baseball team. There are nine players arranged in the sequence judged most effective by the divinations of the manager. Let the team lose a string of games, and the manager is apt to consult his oracle and shake up the batting order. Now, he operates on the order by interchanging (permuting) players. And it is plain that any one of the 362,880 possible orders could be achieved if, starting from any given order, the manager interchanged the players by successively substituting one for another in the order. He could put the lead-off man into the clean-up position (fourth place) by interchanging first and second, then second and third, and then third and fourth. That would get the lead-off man into fourth place. Then in order to move the clean-up man (now in third place) up to first place, the manager would interchange third and second, and then second and first. These five one-for-one substitutions produce the same batting order that would have resulted had the manager interchanged one and four in the first place. Hence we see that some combinations of operations are equivalent to other combinations of operations.

This always impresses the layman as a trivial and obvious matter, and he is astonished to learn that this simple notion, basic to the theory of *permutation groups*, was essential to Galois' solution of a long-standing riddle about the solvability of equations. These simple permutation groups even turn up in modern descriptions of atomic structure.

We generalize the group concept by doing what was just done for algebra: we lay down the postulates (demands) which a set

of operations must satisfy in order to merit the title "group."

First we assume a set of elements (operations) a, b, c, \dots and a symbol, \circ , denoting their combination. Then we impose the four postulates of Table 5 (cf. Harkin, p. 98).*

TABLE 5

POSTULATES OF A GROUP

Synthesis:	If a and b are members of the set of operations, then $a \circ b$ is also a member of the set.	(This postulate says that the group is closed.)
Associative:	For <i>any</i> three operations $(a \circ b) \circ c = a \circ (b \circ c)$.	(This postulate says that the group is associative.)
Existence:	There exists a unique "identity" operation, i , such that $a \circ i = i \circ a = a$.	(This postulate says that one of the operations must be the doing of nothing, or its equivalent.)
Reversion:	There is a unique "inverse" operation a' such that $a \circ a' = i$.	(This postulate says that we can always back-track and undo the effect of a given operation.)

In the special case when $a \circ b = b \circ a$ the group is commutative, or Abelian, named after Abel who was Norway's gift to mathematics. With the commutative postulate imposed we find Table 5 looking very much like Table 4 (the postulates of ordinary algebra). The D is missing from S.C.A.R.E.D. because the distributive law is not needed to determine a group, Abelian or otherwise.

Actually there are at least two interesting groups in Table 4. For example, the real numbers form a group with respect to the process of addition. The sign \circ in the group postulates becomes the $+$ sign in the addition group, and the numbers themselves may be regarded as the elements—the *opera-*

* The last two of these postulates are sometimes replaced by a single postulate in a different form, e.g. for every a, b there exist x, y such that $a \circ x = b, y \circ a = b$ (cf. Bell, 1945, p. 215).

tions. Thus $3 + 4 = 7$ may be interpreted to mean: if you first go 3 paces and then go another 4 paces, it is the same as going 7 paces; i.e. operations can be combined. In the addition group the identity element is 0, i.e. $a + 0 = a$, and the inverse element is $-a$, i.e. $a + (-a) = 0$. Since the commutative law (postulate C in Table 4) is in force, the addition group is Abelian.

Analogously, the real numbers (zero excepted) form an Abelian group under multiplication. In this case the identity element is 1, since $a \times 1 = a$ and the inverse element is the reciprocal, i.e. $a \times 1/a = 1$.

Curiously enough, some of the common operations of arithmetic do not form groups. Subtraction, for example, falls short of the demands listed in Table 5, because it is not associative. Division fails for the same reason. Had we only the positive numbers to work with, as in pre-Cartesian days, even the operations of addition would not form a group, for without the negatives reversion would be impossible.

Many different kinds of operations form groups (cf. Birkhoff and MacLane). There are groups of permutations on batting orders, on electrons hovering around an atomic nucleus, or on any other *arrangements* of things. There are rotations of objects in space, like those of a wheel with six spokes. Each operation of rotating by 60 degrees leaves the precise space occupied by rim and spokes unchanged (invariant), and these 60-degree rotations comprise a finite group in which a 360-degree rotation is equivalent to the identity operation of no rotation at all. On the other hand, all possible motions of a rigid body in space generate an infinite continuous group.

Perhaps the most interesting groups, from the point of view of measurement, are those whose sets of elements (operations) are algebraic transformations. The everyday process of multiplying by a constant, illustrated when we convert from inches to feet to yards to centimeters to miles, etc., is one of the simplest of these transformations. Such op-

erations belong to the *similarity* group, and we note that when it is applied to distances the property that is preserved invariant is the *ratios* among the distances. Other transformation groups will be listed when we come to scales of measurement.

In the meantime a word is in order concerning this term "operation." In the foregoing paragraphs it has carried two different meanings: it has stood both for a mathematical manipulation (e.g. multiplying) and for a concrete empirical act (e.g. rotating a wheel through 60 degrees). We call both enterprises operations, but obviously they belong to different realms: one concerns a formal matter, the other a physical procedure. Perhaps the use of two different words would set the issue to rights, but usage is toughly ingrained, and the best we can do is to remember that operations in mathematics can serve as a model for physical events, but they are not the same thing.

The Concept of Invariance

It has already been hinted that the important thing about a transformation is what it does not transform, i.e., what it leaves invariant. Within the last hundred years the basic importance of invariance has proved itself in algebra, geometry, and theoretical physics, and we occasionally hear of it in psychology. Bell gives it a forty-eight page chapter in his *Development of Mathematics* (1945), and he begins with this quotation from Keyser:

Invariance is changelessness in the midst of change, permanence in a world of flux, the persistence of configurations that remain the same despite the swirl and stress of countless hosts of curious transformations.

It took one of the greatest of self-taught mathematicians, George Boole, also a principal founder of symbolic logic, to call attention to the power of this simple principle (1841). It was with what is called *algebraic invariance* that Boole worked, and the gist of this stuff is a little beyond the grasp of

those of us who are not mathematicians. But not too much for our intuitions are the displays of invariance in other fields like geometry and physics.

Draw a figure made up of intersecting lines and curves on a rubber sheet, and then stretch or distort the sheet in any way imaginable. Areas, lengths, and angles are obviously not left invariant, but something is. However we torture the rubber, the order of the intersections we must pass in tracing a path from one given part of the figure to another and the communality of boundaries between different areas are two of the properties that stay put. The study of invariance in "rubber-sheet" geometry is part of the vast, vigorous inquiry known as *topology*. It is geometry without a metric, and the fact that it seems to deal with relations stripped of the encumbrance of magnitude has struck up the hope in some psychologists that topology may answer the need for a formal model to represent things unmeasurable. Topology might well find a usefulness here, but it may be that more than metrical nakedness is needed to clothe a social dynamics. In any case, if something empirically verifiable is to issue from the application of mathematics, something empirically known must be put in.

The importance of invariance as a tool of thought is exemplified by the classical notion of the conservation of energy. The total amount of energy in a system stays the same under transformations from one form, such as heat, into other forms, such as electricity. Similarly, what we mean by *shape* and *size* of a rigid object are the properties that do not change when we alter or transform the coordinate system in terms of which we describe the object. It may be said in general that the task of physics is the description of natural phenomena in terms that remain invariant when the frame of reference is changed.

An example will help here. Newton's second law equates force to the time derivative of momentum. The physicist verifies this

law in all sorts of reference systems and finds it true. The law would not be worth much if it worked only in Europe or only at sea level or only for circular motions or only for objects larger than elephants. The invariance of the law under a wide assortment of conditions is its source of power.

The scientist is usually looking for invariance whether he knows it or not. Whenever he discovers a functional relation between two variables his next question follows naturally: under what conditions does it hold? In other words, under what transformations is the relation invariant? The quest for invariant relations is essentially the aspiration toward generality, and in psychology, as in physics, the principles that have wide application are those we prize.

The conclusion, if we may venture one, is that the empirical scientist can emulate the attitude of the mathematicians who followed Boole and cultivate a love for invariance that leads him to seek uniformities in heterogeneity and to recognize invariance when he sees it.

Many psychological problems are already conceived as the deliberate search for invariances.* Perhaps all psychological problems ought to be so construed, at least when general principles are the goal. The "particularizing" mind may note that a visual stimulus has a threshold value, that two men look about the same size, and that flashing lights seem to move. The "generalizing" mind takes these matters into a wider frame and discovers (1) the luminosity or visibility curve — the threshold invariance under si-

* Note, for example, how explicitly Thurstone (1947, Chapter 16) makes "configurational invariance" a central issue in multiple factor analysis. And in a vastly different area, see how nicely the analysis of the determining factors in 'instinctive' behavior reduces to a problem of the invariance of a response under transformations of environmental conditions (cf. Chapter 12). For example, black-headed gulls continue to sit on the nest even though the eggs are painted a variety of colors or are replaced by wooden models of various sizes, shapes, and odors. Only if the 'eggs' have sharp contours does this invariant behavior break down.

multaneous transformations of frequency and intensity; (2) the size-constancy effect (the relative invariance of perceived size under transformations of distance, surrounds, etc.); and (3) the conditions for optimal phi phenomenon (the partial invariances of perceived movement known as Korte's laws).

In general, we enlarge the reach of invariance by exploring the effects of parameters. Thus we may start with a tonal threshold and find, for a given frequency, the intensity that can be heard as often as not. That is an invariant *point*. Then we change frequency and get the threshold *curve* for the whole audible range. That is the invariance under two parameters, frequency and intensity. Next we might vary another dimension, like the duration of the tone, and from the results we could construct in three dimensions the *surface* that gives the threshold invariance under three parameters. Age of the listener might be a fourth parameter, degree of the subject's training might be a fifth, and so on. In extending this process we encroach more and more on the no-man's land of what is usually pigeonholed in the catch-all called variability. Not that variability is ever banished from empirical science, but successive expansions of the domain of invariance can reduce the dominion of variance to tractable proportions.

As an illustration in another field, consider the intelligence quotient — the IQ. Why is this such a capital concept in psychology and education? Surely if the IQ bobbed about like female fashions it would be just another incidental phenomenon in psychology. The fact that it stays relatively constant throughout the growing years is the reason for the ferment it has engendered. In this respect the IQ is analogous to the concept of the somatotype — the designation of human morphology by means of three variables, or components, whose values determine the basic character of a given physique. It is the apparent invariance of the somatotype under the transformation we call

“aging” that makes this notion potentially useful in the characterization of human beings (cf. Sheldon, Stevens, and Tucker). *Absolute invariance* of the IQ and of the somatotype is not essential to the utility of these two concepts, but some degree of invariance seems requisite to their importance. The wider their limits of invariance, the more useful they become, for in his scientific account of humanity the scientist seeks measures that will stay put while his back is turned.

But, needless to say, the greater number of psychological studies seem not to result in the demonstration of significant invariance. It is obviously easy to say that the delineation of the conditions of invariance for any phenomenon would tell us all we want to know about the matter, but it is equally obvious that the experimental task itself is uphill work.

NUMERALS AND MEASUREMENT

Let us return now to the problem of measurement. Before the paraphernalia of mathematics can be of use to psychology, we must devise scales of measurement. I would spare the reader this platitude were it not for the fact that we sometimes talk the language of functional connections and speak in terms of “more” or “less” without seeming to diagnose the implications of our discourse. We might say, for example, that the more a man is frustrated the more aggressive he becomes. This is an easy sentence to translate into the language of proportionality, where it reads:

$$A = kF$$

i.e. aggression (A) is proportional (k) to frustration (F). This is an interesting notion and one we should like to test. The test would follow simply and automatically if we had a scale for the measurement of aggression and a different scale for the measurement of frustration. Each of these scales, as we shall see, would have to be a *ratio* scale

if a relation of *proportionality* is to hold. If a less restrictive relation is what we want to establish, *ordinal* or *interval* scales might suffice.

The requirements for measurement are easier to state than to realize. But this does not mean that the meaning of measurement has always been clear. We have it from one of their own distinguished number that "The most distinguished physicists, when they attempt logical analysis, are apt to gibber; and probably more nonsense* is talked about measurement than about any other part of physics" (Campbell, 1938). With this sharp warning before us, let us tread gingerly.

It seems safe enough to say that measurement involves the process of linking the formal model called the number system to some discriminable aspect of objects or events. This notion was expressed near the beginning of this chapter: "Measurement is the assignment of numerals to objects or events according to rules"—a paraphrase of Campbell himself (1940; cf. Stevens, 1946). Russell (1937) seems to go along with this conception: "Measurement of magnitudes is, in its most general sense, any method by which a unique and reciprocal correspondence is established between all or some of the magnitudes of a kind and all or some of the numbers, integral, rational, or real, as the case may be. . . . Measurement demands some one-one relation between the numbers and magnitudes in question—a relation which may be direct or indirect, important or trivial, according to circumstances" (p. 176). Campbell's and Russell's definitions are both excellent, provided we take them at their face value, and they seem both to be saying the same thing except that one uses the term "numeral" where the other says "number." Both definitions are liberal

* The reader who would like to sample some of this nonsense—to which Campbell seems to contribute his fair share—will find it in the deliberations of a committee appointed by the British Association for the Advancement of Science to consider the measurability of sensation (for reference, see Campbell, 1940). For a more sensible analysis of the issues raised by this committee, see Reese (1943).

and generous—in fact, they show an open-handedness that both authors seem later to go back on, each in a different way. But these defections need not concern us here.

In using two different words, "numeral" and "number," for what gets related to objects by means of semantical rules, Campbell and Russell probably both intend the same meaning. Elsewhere I have sided with Campbell's usage because the meaning of the term "number" is often ambiguous: among other things, it refers sometimes to a physical attribute of a collection of discrete objects (a number of peanuts), sometimes to Frege's class of isomorphic classes (cardinal numbers), and sometimes to Russell's relational expressions (relation numbers, of which the ordinal numbers are a subclass). My guess would be that the numbers Russell intends for measurement are the relation numbers.

The term "numeral" has the defect that it sometimes means the physical ink mark on a piece of paper and it sometimes means the essentially *logical* relation that a numeral may stand for. This second meaning is in line with the formalist's view of mathematics, according to which arithmetic is regarded as the rules of a game played with numerical symbols "whose shape is recognizable by us with certainty independently of place and time, of the particular conditions of their manufacture, and of trifling differences in their execution" (quoted from Hilbert by Weyl, p. 35). Campbell seems to have this second meaning in mind, which is probably also Russell's meaning. In any case, two facts are plain. (1) There is a need for some new and univocal terms for these various meanings.† (But, the inertia of usage being what it is, the need will most likely persist.) (2) Whatever terms may be chosen, the essence of measurement is the as-

† In an attempt to distinguish between the cardinality attribute of groups of objects (number in the layman's sense) and the "subjective" aspect or attribute that we observe when we look at, but do not count, a collection of objects, I used the terms "numerosity" and "numerousness" (Stevens, 1939b). Taves (1941) did an experiment relating the visual perception of numerousness to physical numerosity.

signment (to aspects of objects or events) of elements drawn from the formal system to which the postulates of algebra (Table 4) apply. These assignments are made according to one or another of the rules that we will now discuss.

Scales of Measurement

A rule for the assignment of numerals (numbers) to aspects of objects or events creates a *scale*. Scales are possible in the first place only because there exists an isomorphism between the properties of the numeral series and the empirical operations that we can perform with the aspects of objects. This isomorphism, of course, is only partial. Not *all* the properties of number and not *all* the properties of objects can be paired off in a systematic correspondence. But *some* properties of objects can be related by semantical rules to *some* properties of the numeral series. In particular, in dealing with the aspects of objects we can invoke empirical operations for determining equality (the basis for classifying things), for rank ordering, and for determining when differences and when ratios between the aspects of objects are equal. The conventional series of numerals — the series in which by definition each member has a successor — yields to analogous operations: We can identify the members of the series and classify them. We know their order as given by convention. We can determine equal differences, as $7 - 5 = 4 - 2$, and equal ratios, as $1\% = \%$. This isomorphism between the formal system and the empirical operations performable with material things justifies the use of the formal system as a *model* to stand for aspects of the empirical world.

The type of scale achieved when we deputize the numerals to serve as representatives for a state of affairs in nature depends upon the character of the basic empirical operations performed on nature. These operations are limited ordinarily by the peculiarities of the thing being scaled and by our choice of concrete procedures, but, once selected, the procedures determine that there will eventu-

ate one or another of four types of scale: *nominal*, *ordinal*, *interval*, or *ratio*. Each of these four classes of scales is best characterized by its range of invariance — by the kinds of transformations that leave the “structure” of the scale undistorted. And the nature of the invariance sets limits to the kinds of statistical manipulations that can legitimately be applied to the scaled data. This question of the applicability of the various statistics is of great practical concern to several of the sciences.

The principal facts about scales are summarized in Table 6.* It will be noted that the column listing the basic operations needed to create each type of scale is cumulative: to an operation listed opposite a particular scale must be added all those operations preceding it. Thus, an interval scale can be erected only provided we have an operation for determining equality of intervals, for determining greater or less, and for determining equality (not greater and not less). To these operations must be added a method for ascertaining equality of ratios if a ratio scale is to be achieved.

In the column that records the group structure of each scale are listed the mathematical transformations that leave the scale form invariant (see Fig. 1). Thus, any numeral x on a scale can be replaced by another numeral x' , where x' is the function of x listed in this column. Each mathematical group in the column is contained in the group immediately above it.

The fourth column presents examples of the type of statistical operations appropriate to each scale. This column is cumulative in

* A classification essentially equivalent to that in Table 6 was presented by the author before the International Congress for the Unity of Science, September 1941. (The present discussion follows Stevens, 1946.) The gist of this notion of relating scales of measurement to transformation groups is also contained in the recent book by von Neumann and Morgenstern on games and economic behavior (pp. 22–23). They omit mention of the group corresponding to the nominal scale, and they call attention specifically to the group in which no transformation would be tolerated, i.e. where, under the similarity group, a would be limited to unity.

that *all* statistics listed are admissible for data scaled against a ratio scale. The criterion for the appropriateness of a statistic

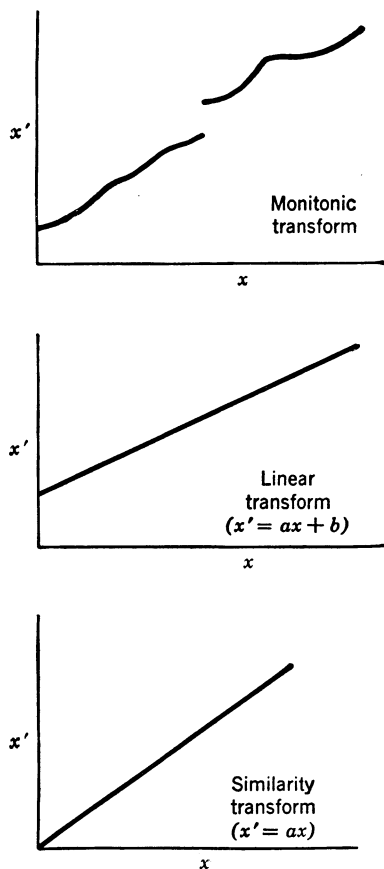

FIG. 1. Graphical examples of three groups of transformations. The increasing monotonic function, which may have discontinuities of the type shown, belongs to the isotonic group and is a transformation applicable to ordinal scales. The linear transformation, intersecting the ordinate at the value b , is applicable to interval scales. Ratio scales allow only the similarity transformation (multiplication by a constant).

is *invariance* under the transformations in column 3. Thus the case that stands at the median (midpoint) of a distribution maintains its 'middleness' under all transformations that preserve order (isotonic group),

but an item located at the mean remains at the mean (retains its 'meanness'!) only under transformations as restricted as those of the linear group. The ratio expressed by the coefficient of variation remains invariant only under the similarity transformation (multiplication by a constant).

We note that there are two kinds of invariance involved here. If the statistic in question is dimensionless* (e.g. product-moment correlation coefficient, coefficient of variation, etc.), the numerical value of the statistic remains fixed when the scales are subjected to their permissible transformations. But when the statistic has a dimension (e.g. mean, median, etc.) its numerical value changes in accordance with the transformations applied to the scale. Thus the height of the *average man* in centimeters is numerically different from his height in inches. On the other hand, the man (or men) whose height is average remains the same man (or men) whether the measurements are made in inches or in centimeters. The invariance required of those statistics that have dimensions, then, is the identity of the object or event to which the given statistic corresponds.

The numerical value that a statistic assumes depends, of course, upon the statistic and upon the transformation. For example, a linear transformation, $x' = ax + b$, operating on the original scale values, produces for the mean $m' = am + b$, for the standard deviation $\sigma' = a\sigma$, and for the variance $\sigma'^2 = a^2\sigma^2$.

* Dimensions and the lack thereof figure prominently in the formulas of physics. The dimensionless factors are generally those that are formed of ratios in which the dimensions of the numerator cancel those of the denominator, as in the case of decibels. Measures having dimensions are those like velocity (having the dimensions of length divided by time), area (length times length), etc. In his *Dimensional Analysis*, Bridgman (1931) created a kind of algebra of dimensions which proves helpful in the investigation of physical relations. The basic notion is that the two sides of an equation must be dimensionally equivalent, and a discrepancy in dimensions may reveal an error that might be hard to detect by other means.

The last column in Table 6 lists some typical examples for each type of scale. It is an interesting fact that the measurement of many physical quantities has progressed from scale to scale. When men knew temperature only by sensation, when things were only "warmer" or "colder" than other things, temperature belonged to the ordinal class of scales. It became an interval scale with the development of thermometry, and after thermodynamics had used the expansion ratio of gases to extrapolate to zero it became a ratio scale.

Let us now consider each scale in turn.

Nominal Scale

The *nominal scale* represents the most unrestricted assignment of numerals. The numerals are used only as labels or type numbers, and words or letters would serve as well. Two types of nominal assignments are sometimes distinguished, as illustrated (type A) by the 'numbering' of football players for the identification of the individuals, and (type B) by the 'numbering' of types or classes, where each member of a class is assigned the same numeral. Actually, the first is a special case of the second, for when we label our football players we are dealing with unit

TABLE 6

SCALES OF MEASUREMENT

The basic operations needed to create a given scale are all those listed in the second column, down to and including the operation listed opposite the scale. The third column gives the mathematical transformations that leave the scale form invariant. Any numeral x on a scale can be replaced by another numeral x' , where x' is the function of x listed in column 3. The fourth column lists, cumulatively downward, some of the statistics that show invariance under the transformations of column 3.

Scale	Basic Empirical Operations	Mathematical Group Structure	Permissible Statistics (invariantive)	Typical Examples
Nominal	Determination of equality	Permutation group $x' = f(x)$ [$f(x)$ means any one-to-one substitution]	Number of cases Mode Contingency correlation	"Numbering" of football players Assignment of type or model numbers to classes
Ordinal	Determination of greater or less	Isotonic group $x' = f(x)$ [$f(x)$ means any increasing monotonic function]	Median Percentiles Order correlation (type O)	Hardness of minerals Quality of leather, lumber, wool, etc. Pleasantness of odors
Interval	Determination of equality of intervals or differences	General linear group $x' = ax + b$	Mean Standard deviation Order correlation (type I) Product-moment correlation	Temperature (Fahrenheit and centigrade) Energy Calendar dates "Standard scores" on achievement tests (?)
Ratio	Determination of equality of ratios	Similarity group $x' = ax$	Geometric mean Coefficient of variation Decibel transformations	Length, weight, density, resistance, etc. Pitch scale (mels) Loudness scale (sones)

classes of one member each. Since the purpose is just as well served when any two designating numerals are interchanged, the structure of this scale remains invariant under the general substitution or permutation group (sometimes called the symmetric group of transformations). The only statistic relevant to nominal scales of type A is the number of cases, e.g. the number of players assigned numerals. But once classes containing several individuals have been formed (type B) we can determine the most numerous class (the mode), and under certain conditions we can test, by the contingency methods, hypotheses regarding the distribution of cases among the classes.

The nominal scale is a primitive form, and quite naturally there are many who will urge that it is absurd to attribute to this process of assigning numerals the dignity implied by the term measurement (cf. Campbell, 1938, p. 122). Certainly there can be no quarrel with this objection, for the naming of things is an arbitrary business. However we christen it, the use of numerals as names for classes is an example of the "assignment of numerals according to rule." The rule is: do not assign the same numeral to different classes or different numerals to the same class. Beyond that, anything goes with the nominal scale.

The formation of *classes* of objects or events is based on the demonstration of *equality* in respect of some trait or other. As an empirical problem the forming of classes is by no means trivial, and endless arguments have ensued over taxonomic standards. The definition of any common noun, like "horse," raises problems of classification—what animals are included, what excluded? (Cf. Stevens, 1939a, p. 233.) At the formal level, the logical (mathematical) definition of classes and of equality is the subject of much writing and arguing. Curiously enough, the relation of equality, which was described above as reflexive, symmetrical, and transitive, is so "obvious" that not until the 1930's did it become customary in

books on logic to include the postulates governing this basic relation (cf. Bell, 1945, p. 578). Mathematics has learned to pay attention to the obvious, and the empirical sciences need never apologize for following suit.

Ordinal Scale

The *ordinal scale* arises from the operation of rank ordering. Since any 'order-preserving' transformation will leave the scale form invariant, this scale has the structure of what may be called the isotonic or order-preserving group. This, of course, is a big group, for it includes transformations by all increasing monotonic functions, i.e., functions that never decrease and therefore do not have maxima. Thus the positive scale values on an ordinal scale may be replaced by their square or their logarithm or by a host of other functions, including in particular the "normalizing" transformation used in factor analysis (Thurstone, 1947, p. 368). All these transformations leave invariant the relation of "betweenness" for a given value with respect to its neighbors.

As a matter of fact, most of the scales used widely and effectively by psychologists are ordinal scales. In the strictest propriety the ordinary statistics involving means and standard deviations ought not to be used with these scales, for these statistics imply a knowledge of something more than the relative rank order of data. On the other hand, for this 'illegal' statisticizing there can be invoked a kind of pragmatic sanction: in numerous instances it leads to fruitful results. Although the outlawing of this procedure would probably serve no good purpose, it is proper to point out that means and standard deviations computed on an ordinal scale are in error to the extent that the successive intervals on the scale are unequal in size. When only the rank order of data is known, we should proceed cautiously with our statistics, and especially with the conclusions we draw from them.

Even in applying those statistics that are normally appropriate to ordinal scales, we

sometimes find rigor compromised. Thus, although it is indicated in Table 6 that percentile measures may be applied to rank-ordered data, it should be pointed out that the customary procedure of assigning a value to a percentile by interpolating linearly within a class interval is, in all strictness, wholly out of bounds. Likewise, it is not strictly proper to determine the midpoint of a class interval by linear interpolation, because the linearity of an ordinal scale is precisely the property that is open to question.

Another matter also needs comment. In earlier discussions (e.g. Stevens, 1946) I expressed the opinion that rank-order correlation does not apply to ordinal scales because the derivation of the formula for this correlation involves the assumption that the differences between successive ranks are equal. My colleague, Frederick Mosteller, convinces me that this conservative view can be liberalized, provided the resulting coefficient (e.g. Spearman's ρ , or Kendall's τ) is interpreted only as a test function for a hypothesis about order. On the other hand, the interpretation of the coefficient as equivalent to r (the product-moment coefficient) would assume an underlying interval scale, and a bivariate normal distribution as well. In Table 6 I have allowed for these two interpretations by placing order correlation under both headings: type O for ordinal, type I for interval.

Interval Scale

With the interval scale we come to a form that is "quantitative" in the ordinary sense of the word. Almost all the usual statistical measures are applicable here, unless they are the kinds that imply a knowledge of a 'true' zero point. The zero point on an interval scale is a matter of convention or convenience, as is shown by the fact that the scale form remains invariant when a constant is added.

This point is illustrated by our two scales of temperature, centigrade and Fahrenheit. Equal intervals of temperature are scaled off

by noting equal volumes of expansion; an arbitrary zero is agreed upon for each scale; and a numerical value on one of the scales is transformed into a value on the other by means of an equation of the form $x' = ax + b$. Similarly, energy is measured on an interval scale, for, as von Neumann and Morgenstern assert, "there is nothing in mechanics to fix a zero or a unit of energy" (p. 22). Our scales of *calendar time* offer another example. Dates on one calendar are transformed to those on another by way of this same equation. On these scales, of course, it is meaningless to say that one value is twice or some other proportion greater than another.

Periods of time, however, can be measured on ratio scales, and one period may be correctly defined as double another. In like manner, *differences* in energy (which is what we mean by *work*) may be considered ratio magnitudes, measurable on ratio scales. *Differences* between values on an interval scale become ratio scale measures for the simple reason that the process of determining a difference (i.e. subtraction) gets rid of the additive constant b .

Most psychological measurement aspires to create interval scales, and it sometimes succeeds. The problem usually is to devise operations for equalizing the units of the scales — a problem not always easy of solution but one for which there are several possible modes of attack. The determination of what we call equal sense distances is one obvious procedure. Only occasionally in psychological scaling is there concern for the location of a 'true' zero point. Intelligence, for example, is usefully assessed on ordinal scales that try to approximate interval scales, and it is not necessary to define what zero intelligence would mean. (Both Thorndike and Thurstone have tried it, however.)

The variability of a psychological measure is itself sometimes used to equalize the units of a scale. This process smacks of a kind of magic — a rope trick for climbing the hierarchy of scales. The rope in this case is the

assumption that in the sample of individuals tested the trait in question has a canonical distribution (e.g. "normal"). Then it is a simple matter to adjust the units of the scale so that the assumed distribution is recovered when the individuals are measured. But this procedure is obviously no better than the gratuitous postulate behind it, and we are reminded of what Russell said about the larcenous aspects of postulation. There are those who believe that the psychologists who make assumptions whose validity is beyond test are hoist with their own petard, but the fact remains that the assumption of normality has the advocacy of a certain pragmatic usefulness in the measurement of many human traits. Forced to live up to certain criteria of internal consistency, as in the method of paired comparisons (cf. Thurstone, 1948), such assumptions make it possible to lay hold on problems of preferences and the like, which seem recalcitrant to other treatments.

Ratio Scale

Ratio scales are those most commonly encountered in physics, and they are possible only when there exist operations for determining all four relations: equality, rank order, equality of intervals, and equality of ratios. In the practical instance the determination of the last of these four relations—equal ratios—may take the form of the determination of successive equal intervals beginning at the zero value of the scale. This is *one* of the procedures by which we can assign numerals in such a way that equal ratios among them correspond to equal ratios of some attribute or other.

Once a ratio scale is erected, its numerical values can be transformed (as from inches to feet) only by multiplying each value by a constant. An absolute zero is always implied, even though the zero value on some scales (e.g. absolute temperature) may never be produced. All types of statistical measures are applicable to ratio scales, and only with these scales may we properly indulge in

the kind of transformations involved in the use of decibels where we take the logarithm of the ratio of two amounts of power.

Foremost among the ratio scales is the scale of "number" itself—number in the empirical sense—the scale we use when we count such things as eggs, pennies, and apples. This scale of the numerosity of aggregates is so basic and so common that it is ordinarily not even mentioned in discussions of measurement. This neglect might surprise us had we not already learned, in connection with the notion of equality, that it is often the most common and obvious things that are longest overlooked!

On the scale of numerosity we ordinarily admit only the transformation that involves multiplication by unity—the identity element of the similarity group. In other words we ordinarily count by ones. But it is plain that we could equally well count by twos, threes, tens, etc. We could assign numerals to collections of objects by the rule that would lead us to say that the numerosity of our toes is two and a half, in which case we would be counting by fours.

It is conventional in physics to distinguish between two types of ratio scales: *fundamental* and *derived*. Fundamental scales are represented by length, weight, and electrical resistance (and we should add numerosity), whereas derived scales are represented by density, velocity, and elasticity.

These latter are *derived* magnitudes in the sense that they are mathematical functions of certain fundamental magnitudes. They are actually more numerous in physics than are the fundamental magnitudes, which are commonly held to be basic because they permit a physical operation of addition analogous to the mathematical operation of addition. Weights, lengths, and resistances can be added in the physical sense, but this important empirical fact is generally accorded more prominence in the theory of measurement than it deserves. The so-called fundamental scales are important instances of ratio scales, but they are only instances.

As a matter of fact, it can be demonstrated that the fundamental scales can be set up even if the physical operation of addition is ruled out as impossible of performance. As an example, consider the scale of weight, and assume that we live in a world of explosive stuff, such that if we ever separate two blobs of it and then put them together in the same scale pan they will blow up. (There are such materials, we now know.) We will require three balances as follows: (1) a balance like the standard variety of the laboratory, (2) one like the standard variety (fulcrum at the center of the horizontal arm) but on which one pan hangs below the other when the pans are empty, and (3) one like the standard variety except that the fulcrum is not at the center of the arm. The first balance will suffice to determine equality and order, the second will determine equal differences, and the third equal ratios. We can then measure out with the second balance any required number of samples separated by equal intervals. Call these samples $a, b, c, d \dots$. With the first balance we can find the order of this series from least to greatest. Then with the third balance we can get samples (A, B, C, D \dots) related by equal, but unknown, ratios. At this point we apply the first balance to find which members of the one series are equal to which members of the other. Suppose it is

$$C = d, \quad D = j, \quad R = h, \quad S = p$$

Then $C/D = R/S$, and we can replace the capital letters by the letter d , plus the number of equal intervals between d and the other lower case letters corresponding to the appropriate capital letters. Then $C/D = R/S$ becomes

$$\frac{d}{d+6} = \frac{d+4}{d+12}$$

Solving, we find $d = 12$. Then, since the intervals $a-b-c-d-e \dots$ are equal, it follows that $c = 11, b = 10, a = 9$, and $e = 13, \dots h = 16, \dots, j = 18, \dots, p = 24$, etc. These

values form a true ratio scale, and the weights they attach to could serve as "standard" weights for measuring other things.

By this procedure we could achieve a set of weights whose properties would be completely isomorphic with the properties of a set determined by what the physicist calls fundamental measurement—built on the process of equating weights and of "adding" them.

This highly condensed description of a possible procedure is given here simply to show that *physical* addition is not necessarily the basis of all measurement. Valid measuring goes on where resort can never be had to the process of laying things end to end or of piling them up in a heap.

. . . .

We conclude, then, that the most liberal and useful definition of measurement is the assignment of numerals to things so as to represent facts and conventions about them. The problem of what is and what is not measurement then reduces to the simple question: what are the rules, if any, under which numerals are assigned? If we can point to a consistent set of rules, we are obviously concerned with measurement of some sort, and we can then proceed to the more interesting question: what kind of measurement is it? In most cases a formulation of the rules of assignment discloses directly the kind of measurement and hence the kind of scale involved. If there remains any ambiguity, we may seek the final and definitive answer in the mathematical group structure of the scale form: in what ways can we transform its values and still have it serve all the functions previously fulfilled? We know that the numerical values on all scales can be multiplied by a constant, which changes the numerical size of the unit (unless the multiplier is itself unity). If, in addition, a constant can be added (or a new zero point chosen), it is proof positive that we are not concerned with a ratio scale. Then, if the purpose of the scale is still

served when its values are squared or cubed, it is not even an interval scale. And finally, if any two values may be interchanged at will, the ordinal scale is ruled out and the nominal scale is the sole remaining possibility.

This proposed solution to the problem of classifying scales is not meant to imply that all scales belonging to the same mathematical group are equally precise or accurate or useful or "fundamental," or even that in the practical instance it can always be decided into which category a given scale falls. Measurement is never better than the empirical operations by which it is carried out, and operations range from bad to good. Any particular scale, psychological or physical, may be objected to on the grounds of bias, low precision, restricted generality, and other factors, but the objector should remember that these are relative and practical matters and that no scale used by mortals is perfectly free of their taint.

PSYCHOPHYSICS

Scales of measurement find application in all domains of psychology, but in few quarters of the subject is the resort to measurement as deliberate as it is in psychophysics. There the formulation of the basic problems may be so worded that they read for all the world like the list of empirical operations in column 2 of Table 6. This follows from the fact that psychophysics, at least as it was conceived by its creator, is the exact science of the functional relations between "body and mind." It is beside the point that founder Fechner aimed to philosophize us into a panpsychism in which the distinction between mind and matter would be banished, or that his *Elemente der Psychophysik* of 1860 confined itself to the myopic view that sensation can be measured only "indirectly" (cf. Boring). What matters is that psychophysics was fashioned by an inventor who knew both the meaning of experiment and the essence of measurement.

Psychophysics, like mathematics, has had a curious history. Vastly younger than the "queen of the sciences," psychophysics has already stood long enough to contribute valid testimony to the invariance of human nature. Fechner, like his fellow mystic Pythagoras, advanced a science by trying to prove a theology. There followed a contentious clamor of complaint against the notion that sensations have units and magnitude. This clamor was no greater, and very little less, than the disquiet in the ranks when it was proposed that numbers may be incommensurable, or less than nothing, or the square roots of less than nothing. The sterility of the subtle wars occasioned by minutiae of method and interpretation in psychophysics is easily matched by the futility of the "vacuous logomachy" (to use Bell's name for it) that raged over such issues as the existence of points and lines and their role in geometry.

Both psychophysics and mathematics have been periodically enlivened by the clashes of those two polar temperaments—the analyzers and the synthesizers, the rigorous and the loose, the logicians and the geometers, the formalists and the intuitionists—call them what you will—there are dozens of names for them. The one is addicted to rigor and scorns what William James called the "more nutritious objects of attention." The other is irked by the demands of precision and seeks a swift road to the heart of things. Poincaré, the best psychologist among the great mathematicians, insists (pp. 210ff.) that every age has produced these two types of mind in mathematics. And the apparent victory has been now to the one, now to the other. In psychology it is the same, with the same pendular swings in ascendancy.

Perhaps this explains a lot about the pulling and hauling of the past ninety years in psychophysics. James, the intuitionist, could assess the published bickerings of the punctilious methodologists as a "dreadful literature" without in the least discouraging the

invention of new methods and procedures and adhibitions. But, as with all such scientific tempests, the epithets are forgotten in the subsequent calm, and what lasts out the storm is the substantial residue of useful tools with which oncoming workers can build. That the tools of psychophysics have their uses is amply attested by the substance of many chapters of this handbook. And in the middle of the twentieth century psychophysics, like mathematics, finds itself incorporated into the applied disciplines of science, industry, and government.

Here we are viewing psychophysics in its broader aspects—as the science of the response of organisms to stimulating configurations. There are narrower ways of looking at it, and the parochial view is perhaps the more traditional.* The trouble with the narrow conception of psychophysics is that it mistakes procedures for problems, and precision for goals. Psychophysics then becomes synonymous with a few methods of determining thresholds, and the more meaty issues are lost in a concern for what amounts to a mere matter of sampling error. But the narrow view is fast fading as the applications of psychophysics are extended to such varied problems as telephone engineering and the assessment of attitudes.

We need belabor the narrow view no longer. Rather let us see what psychophysics is currently up to in the area of measurement and quantification. A factual inventory of current research would be one way of approaching this matter, but a better way perhaps is to search out the basic problems and methods.

We may confine our illustrations to the field of sensation. Not that sensory psychology is coextensive with psychophysics:

* As an example of a straitened definition of psychophysics, consider the ruling of the Colorimetric Committee of the Optical Society of America (Report of 1943-44), which reduces psychophysics to the employment of a human observer as a null instrument under a set of strictly specified conditions. See also H. Helson's complaint about the narrowness of this definition (*Psychol. Bull.*, 1949, **46**, 167-168).

it is merely a convenient backdrop against which to exhibit the sharper contours of the problem. If we succeed in delineating the generalities in one area, it should be a simple matter to transpose them to other areas. For example, Mosier (1940, 1941) elaborates a suggestive scheme for restating the theorems of psychophysics in the language of psychometrics (mental testing) by means of an appropriate transposition of the postulates and definitions. This is possible because both disciplines study the responses of individuals to stimulus situations. Psychophysics sees the response as an indicator of an attribute of the individual—an attribute that varies with the stimulus and is relatively invariant from person to person. Psychometrics regards the response as indicative of an attribute that varies from person to person but that is relatively invariant for different stimuli. Both psychophysics and psychometrics make it their business to display the conditions and limits of these invariances.

There is a kind of binary relation here—a relation between *responses* (sensations, perceptions, attitudes, judgments, preferences, and the like) and *organisms* (people and animals). On a given scale we can, for a single organism, or for a class of similar organisms, measure an aspect of a response. On the same scale we can also measure organisms. To take a simple example: in the laboratory we establish on a given scale the threshold for the response called hearing in a group of "normal" ears. In the hearing clinic we use the same scale to measure people—to sort them out in terms of their ability to hear.

Problems of Psychophysics

In a sense there is only one problem of psychophysics, namely, the definition of the stimulus. In this same sense there is only one problem in all of psychology—and it is the same problem. The definition of the stimulus is thus a bigger problem than it appears to be at first sight. The reason for equating psychology to the problem of de-

fining stimuli can be stated thus: the complete definition of the stimulus to a given response involves the specification of all the transformations of the environment, both internal and external, that leave the response invariant. This specification of the conditions of invariance would entail, of course, a complete understanding of the factors that produce and that alter responses. It is easy enough, of course, to decide upon arbitrary definitions of "stimulus objects" (e.g. a given pattern of lines, a quantity of luminous flux, an acoustic waveform, etc.), but the question is: what properties of these objects do the stimulating? Viewed in this fashion, it is evident that for no response have we yet given a complete definition of the stimulus. At best we have only partially determined the conditions and limits of invariance.

Take, for example, a field like hearing, in which we think we know a lot. Under what transformations is the perception of a given pitch invariant? Can we change frequency? Yes, within limits, provided an appropriate change is made in intensity. Can we change phase? Yes, again, within limits. But we do not know precisely within what limits. What about waveform, power spectrum, duration, preceding stimuli, etc.? Actually we know only a little about the stimulus to pitch.

Consider next the perception of a given smell. Here it is probably safe to say that we can scarcely begin even to name the properties of gases that govern the invariance of odor. One theory suggests that the only transformation that will alter a smell is a change in the infrared absorption of a vapor, but this is far from settled.

When it comes to such complicated responses as hallucinations, attitudes, preferences, and the like, our ignorance of causes is even more impressive. Knowledge of the conditions and limits of invariance in these matters is only a remote aspiration.

These examples suffice to show that it is not unreasonable to subsume the problems of psychophysics under the quest for a defi-

inition of the stimulus, but they also reveal the practical futility of all-inclusive definitions. In order to get on with science we must break its problems into manageable sections. We cannot solve the universe at a stroke.

One manner of classifying the problems of psychophysics results in seven categories (Stevens, 1948). We may list them as follows:

1. *Absolute thresholds.* What are the stimulus values that mark the transition between response and no response on the part of an organism?

2. *Differential thresholds.* What is the resolving power of the organism; i.e. what is the smallest detectable change in a stimulus?

3. *Equality.* What values of two different stimuli produce the same response (e.g. appear equal on the scale of some attribute)?

4. *Order.* What different stimuli produce a set of responses or psychological impressions that can be set in serial order?

5. *Equality of intervals.* What stimuli produce a set of responses successively equidistant on the scale of some attribute?

6. *Equality of ratios.* What stimuli produce a set of responses bearing constant ratios to one another on the scale of some attribute?

7. *Stimulus rating.* With what accuracy (validity) and precision (reliability) can a person estimate the "physical" value of a stimulus?

These seven problems of psychophysics call for some additional comments. These comments must be brief, but we shall try to single out a few of the more interesting features of the psychophysical problems, especially as they relate to sensation. These are empirical issues. They are the working problems of the psychophysicist. Relative to the matters discussed in the early sections of this chapter they are practical problems. Relative to human engineering they are theoretical problems. Which proves the relativity of practicality.

Absolute Thresholds

The absolute threshold is a familiar notion to the psychologist. He is impressed by the fact that thresholds are universal among living organisms and that for each animal reaction there is a finite value of the stimulus below which nothing happens. The threshold is the value that divides the continuum* of stimuli into two classes: those to which the organism reacts and those to which it does not. Thus the threshold may be regarded as a 'cut' in the continuum of stimuli. This way of saying it is reminiscent of Dedekind's definition of an irrational number as the kind of "cut" in the domain of rational numbers that divides the domain into two classes, neither of which has a terminus in the region of the cut (see Young, p. 104).

One of the practical problems of psychophysics is to define the properties and limits of the two classes of stimuli into which the threshold cuts the energetic configurations of the environment. In solving this problem the psychophysicist addresses himself explicitly to the problem of invariance. Thus for any given attribute of sensation he asks what combinations of stimulus values (e.g. of frequency and intensity) will produce the threshold cut. In general the cut is invariant under the simultaneous transformation of several stimulus dimensions. The plot of the threshold contour, such as an "audiogram," is a common device for depicting an aspect of this invariance.

* Applied to the stimulus, the word "continuum" refers to a property of the various dimensions in terms of which stimuli may be ordered. Along these dimensions it is ordinarily possible to produce gradations that are small compared to the discriminative capacities of organisms. In this sense the dimensions of stimuli are continuous. Under certain special conditions, however, the ultimately discontinuous (quantal) nature of physical events may assert itself, e.g. when the visual threshold is made to appear dependent upon the absorption by the retina of a half-dozen light quanta. Unlike the continua of mathematics, physical continua are not infinitely divisible. Nevertheless, the mathematical continuum, although not perfectly isomorphic with the physical continuum, serves as a useful model for it.

In expounding the psychophysics of thresholds it is customary to bear down hard on the matter of variability. Ordinarily the threshold is not invariant with time. Rather it shifts about from moment to moment in a restless fashion, and we are forced to catch it on the fly. We manage this by procedures that are vaguely analogous to what the mathematician does when he traps the value of an irrational number by narrowing the gap between two rational numbers, one larger and one smaller than the irrational in question. We trap the threshold value of a stimulus by means of statistical devices for interpolating in the gap between stimuli that are definitely below threshold and stimuli that are definitely above threshold. What gets recorded as the threshold is then an arbitrary point within a range of variability.

This variability is a function of time. And, since we are forced to take time samples of it, the threshold takes on a fuzzy-edged appearance—as though the stimulus continuum had been cut with a wooden spoon. Nevertheless, there is reason to believe that at any instant the position of the threshold on the stimulus continuum is fixed, definite, and precise, and that adequate procedures would reveal the sharpness of the threshold 'cut.' Methods adequate to this revelation have not as yet been forthcoming for absolute thresholds, but for differential thresholds the outlook is more encouraging.

Differential Thresholds

Here the problem is to locate on the continuum of *stimulus increments* the point that divides the increments into two classes: those to which the organism reacts and those to which it does not. Thus the differential threshold, like the absolute threshold, is a cut that divides a physical continuum. And here again the location of the cut is obscured by its variability in time, so that resort must be had to sampling techniques and to interpolation. The traditional "psychophysical methods" are just such procedures for sampling and interpolating.

The fact that the discriminations of organisms depend on neural processes that are all-or-none in character suggests that the just noticeable difference between two stimuli ought, at a given instant, to be finite and definite, as we have assumed the value of the absolute threshold to be. This suggestion bore fruit when Békésy showed how the stimulating and the sampling of responses might be carried out so as to reveal the "quantal" nature of discrimination. Békésy's procedure was modified by Stevens and Volkman (1940a) into a form that eliminated the "time error" and revealed more directly the size of the "neural quantum." This quantum has other theoretical implications, but our present interest in it stems from the lesson it teaches about mathematical models and their uses. Let us consider this matter more closely.

There are two basic models applicable to time samples of sensory discriminations of the type obtained when a subject tries to detect an increment added to a stimulus (cf. Stevens, Morgan, and Volkman). Call them the 'normal' model and the rectangular model, in honor of the types of distributions into which the data are assumed to fall. The 'normal' model is invoked when it is assumed that the response to a stimulus increment depends upon the operation of a multitude of minute factors combining in random formation to help or hinder discrimination as chance might have it. This model makes use of an infinite, continuous mathematical function, the "normal curve," whose integral (the phi function of gamma) we fit to a plot of data: number of responses versus size of increment. This plot we call the *psychometric function*.

The rectangular model is used under the assumption that discrimination is discontinuous and proceeds by finite quantal jumps. The integral of the rectangular distribution is a straight-line function between two finite limits, and this integral we fit to the data as before.

Now we ask which of these two models fits the data on differential thresholds. The answer is that within reasonable limits of error both of them can be shown to fit. Which, if either, will fit a *given* psychometric plot depends upon the experimental procedure—upon the method used to collect the time sample of responses (see Fig. 2). As a matter of fact, several forms of psychometric function can be predictably obtained by various procedural devices (cf. Miller and Garner).

As is often the case, therefore, we cannot choose between two mathematical models simply by inspecting the fit of the data. Poincaré's famous dictum suggests itself in this connection: "If, then, a phenomenon admits of a complete mechanical explanation, it will admit of an infinity of others that will render an account equally well of all particulars revealed by experiment" (p. 181). We are not here concerned with a "mechanical phenomenon" or with the equations of which Poincaré spoke, but the ever-present possibility of alternative explanation—alternative models—is not something the psychologist can afford to lose sight of.

For the singling out of a preferred model the scientist likes to invoke the criteria (rationalizations?) of simplicity and power. Applied to the problem of sensory discrimination, these criteria would seem to favor the rectangular model—the quantal theory—because (1) another parameter than the mere form of the function is predicted by the theory, namely, the slope of the psychometric line, and (2) the phi function of gamma emerges as a special case of the quantal hypothesis: the phi function of gamma is commonly obtained when the experimental procedure leaves time for the organism to change its sensitivity between the presentations of the standard and the comparison stimuli.

One more point about differential thresholds.

The relation of the just noticeable difference to the size of the initial stimulus stands

as a law of relativity in psychology: what must be added to produce a detectable difference is relative to what is already there. Weber proposed the principle that the ratio between the stimulus and the increment that

constancy fails.) The early psychophysicists, Fechner and Helmholtz, and others, knew about this small range of inconstancy, and they proposed to salvage "Weber's law" by a suggestion recently revived by G. A. Miller.

FIG. 2. Psychometric functions obtained with two different procedures. The two upper plots (for two different listeners) show the rectilinear functions obtained with the "quantal" procedure. Each point is based on 100 judgments of a brief increment added every 3 seconds to a 1000-cycle tone. The size of the quantum for R.R. is 2.8 cycles per second. For M.J. it is 1.1 cycle per second. Note that the slope of the line changes with the size of the quantum and reaches 100 per cent at the value of two quanta. (From Stevens, Morgan, and Volkman, 1941.)

The lower plot is for the 11 best subjects out of 95 that were given the Seashore Test of pitch discrimination. This test employs the method of constant stimuli, with a short time interval between the standard and the comparison tone. If the 75-per-cent point is taken as the difference limen, its value for these 11 subjects is about 2 cycles per second. The psychometric function for the rest of the 95 listeners was even less steep than this one (cf. Stevens, 1948).

must be added to it is invariant with intensity, and to a good approximation he was right. It is fashionable to say that he was wrong, but in vision and hearing, where the measurement of these things is probably most satisfactory, the "Weber fraction" is apparently constant over more than 99.9 per cent of the usable range of stimulus intensities. (The customary plotting of this ratio against the logarithm of the stimulus magnifies the minute range of stimuli in which

Instead of saying $\Delta I = kI$, as Weber would have it, these gentlemen write

$$\Delta I = k(I + I_r)$$

where ΔI is the increment corresponding to a jnd, I is the stimulus intensity, I_r is a small addition to I , and k is a constant. Miller finds that this equation fits the data for the intensitive jnd measured with "white noise" when the procedure is such that the quantum of sensory discrimination can be assessed over

a wide range of intensities. This modified equation reduces to Weber's law at high intensities, because I_r then becomes negligible, and at low intensities it makes the reasonable assumption that not all the effective stimulation is due to the "stimulus" that the experimenter measures. Some of it seems to be there as a residual background, and it is represented by the additive term in the equation, I_r .

If we now proceed one step further and write the modified equation in the form

$$\frac{\Delta I}{I + I_r} = k$$

we see that the invariant ratio between the increment and the stimulus is reestablished, provided we add a small residual I_r to the measured intensity I . This conception, if it can be made to stand up, is of prime interest to psychophysics, precisely because it hints at a basic invariance in sensory discrimination. These basic invariances are too precious few to be taken lightly.

Fechner, as we all know, used Weber's law to derive what he thought was a measure of the magnitude of a sensation. His procedure need not concern us here except for one particular. In order to make it come out, Fechner had not only to assume the validity of Weber's law, he had also to *postulate* the subjective equality of jnd's. This means that a stimulus 20 jnd's above threshold should produce a sensation twice as big as a stimulus 10 jnd's above threshold. Now Russell's words about postulation have already been quoted in this chapter, but here they are again: "The method of 'postulating' what we want has many advantages; they are the same as the advantages of theft over honest toil." Reasonably honest toil in several different laboratories has lately revealed that a tonal stimulus 20 jnd's above threshold sounds far more than twice as loud as a stimulus 10 jnd's above threshold (cf. Stevens and Davis, pp. 148ff.). Fechner's postulate has had to go, but its failure does not invalidate the notion that sensation is

measurable. Instead we now proceed to its measurement by a more direct route, forsaking Fechner's indirection.

It turns out, as we have seen, that the jnd's for loudness are unequal in subjective magnitude. The same appears to be true of other intensive attributes like subjective weight, brightness, and taste. On the other hand, for pitch, and possibly for saturation, the jnd's are subjectively equal; i.e. Fechner's postulate is apparently verified. Now the fact that there are two classes of jnd's, the equal and the unequal, suggests the hypothesis (Stevens, 1939b) that there may be two basic mechanisms of discrimination, illustrated by the mechanisms underlying our perception of loudness and of pitch. Presumably we discriminate an increase in loudness when neural excitation gets *added* to excitation already present, whereas we detect an increase in pitch when there is a change in the distribution of excitation—when new excitation gets *substituted* for old. The suggested generalization, then, is that for the *additive mechanism* the jnd's are subjectively unequal in size; for the *substitutive mechanism* they are equal. In this latter case it would seem legitimate to number the jnd's successively and to use them for an interval scale of the attribute in question.

In both cases, of course, the counting off of just noticeable differences produces at least an ordinal scale.

The Determination of Equality

The problem of equality (or of *equivalents*, as it has been called) is precisely the problem of finding alternative stimulus configurations for which some attribute of a response remains invariant. This problem shows up in many forms and in many fields of inquiry. As a matter of fact, an inventory would probably show it to be one of the commonest problems tackled by psychologists. An early and simple example of it is Weber's determination that a pressure of 4 ounces on the forehead feels approximately equal to a pressure of 1 ounce on the lips.

A later and not so simple example is Bruner and Postman's study of the apparent size of objects having different "symbolic values." Their observers found that a larger circle of light was needed to match a 1-inch disk with a dollar sign on it than to match a 1-inch disk bearing a neutral design. In this experiment the physical diameter of the circle of light provides an arbitrary yardstick for measuring the effect on perception of different symbolic values.

Other common examples of the determination of equivalents are the various isophonic contours: equal loudness, equal volume, etc.; and the isophotic contours: equal brightness (luminosity curve), equal hue (Bezold-Brücke phenomenon), etc. All these contours show the combinations of frequency and intensity for which the attribute in question is constant. A threshold contour, incidentally, may be regarded as a special case of equivalents; e.g. an audiogram may be thought of as the "highest" contour along which loudness is zero.

The problem of equality is ever with us, because it is in this problem that we most often land when we try to measure things for which there are no interval or ratio scales. My own induction into these mysteries was via the humble color mixer (Stevens, 1934). A combination of a red and a blue-green mixed to match a gray composed of black and white no longer matches the gray when we change the size of the field. Enlarge the field, and the mixture turns blue-green; narrow it, and the mixture turns red. For various changes in field size, then, how great is the change in saturation? With no scale to measure saturation, an alternative is to change the area and then to restore the match by inserting into the black-white mixture a sector of the necessary color. The size of this sector needed to restore equality then becomes an arbitrary "measure" of the change in saturation produced by the areal alteration.

Examples like this could be multiplied almost indefinitely. What we obtain from

this procedure of mapping invariances is the chance to assess the change in a perception in terms of the stimulus configuration required to undo the change. The observer is used as a *null instrument*, and this is the way psychologists most often work with "illusions," so called. Sometimes this is the only practicable procedure, and often it gives results of major usefulness.

The Determination of Order

The setting of things in rank order is another pandemic activity among psychologists. This process presents itself explicitly as a problem whenever we confront a heterogeneous collection of stimuli having no obvious physical dimension that orders the stimuli in monotonic relation to the response in question. This sounds like a difficult notion; let us try to restate it. We usually resort to rank ordering when the psychological attribute connected with a group of stimuli is not a single-valued function of some measurable dimension of the stimuli.

Perhaps an example will help.

Consider the stimuli to be samples of handwriting, and the attribute of the observer's response to be his judgment of pleasingness. Admittedly there are many physical dimensions to handwriting, and against any one of them the handwriting could be "objectively" scaled: height of letters, length of words, width of lines, etc. But pleasingness is not a monotonic function of any of these physical measures in the same obvious way that pitch is a monotonic function of frequency. Consequently in order to set up an ordinal scale of pleasingness we resort to one or another of the several methods of ordering: paired comparisons, order-of-merit, rating scale, etc.

Once having set the specimens in a rank order, we may or may not find it possible to devise some physical measure, or a combination of measures, that correlates with the subjective order. If we find such a measure, we have probably advanced our understanding of the essential ingredient of pleasingness

in handwriting. If not, we at least have an ordered set of examples against which to test various hypotheses.

It is interesting to note that in many practical problems of ranking we do not achieve a result that is completely isomorphic with a formal model obeying the three postulates of order listed in an earlier section. This is because two or more items are often tied for the same rank. In other words the relation in question (e.g. more pleasing than) is not always a *connected* relation in the field of samples under consideration. The result is what the mathematician would call a *partially ordered* system, a concept that figures prominently in lattice theory — the theory of structure — which is built on the relation “includes” or “is part of.”

Whenever, as often happens, we try to order stimuli having multidimensional qualities, we are thrust into interesting problems of a different sweep. Given a large sample of odors, for example, the problem of ordering them may land us in the related problem of finding the dimensions or attributes along which olfactory sensations can vary. In general, the number of these attributes is the number of consistent orders in which the observer can set the stimuli. Normally the observer achieves these different orders by adopting for each ordering task a different “set,” or attitude, and with the aid of this analytic approach the various attributes of sensation have been sorted out: hue, brightness, and saturation for vision; pitch, loudness, volume, and density for tones, etc. For odors there is in wide commercial use a set of four scales, each for a separate attribute, by means of which experienced judges are able to characterize an odor by assigning it a value on each scale separately (cf. Crocker and Henderson; also Beebe-Center). An analogous problem was faced by Sheldon in the initial phases of the somatotype development. For each of the three most obvious “components” of human physique, judges sorted photographs of 4000 individuals into three separate rank orders, one for each

of the visually distinguishable components: endomorphy, mesomorphy, and ectomorphy (cf. Sheldon, Stevens, and Tucker).

It is not always possible, of course, for subjects to analyze out a single subjective dimension, e.g. when they are asked to rate the *seriousness* of various criminal offenses. This means that different subjects will then produce incompatible rank orders that cannot be plotted on a single ordinal scale without resort to more than one dimension. When such judgments are made on the basis of multidimensional criteria, it is sometimes possible, under the method of paired comparisons, to infer the number of dimensions the subjects have used and to “scale” these dimensions in the appropriate number of “spaces” (cf. Gulliksen).

As a rule the psychophysicist does not feel obliged to undertake the rank ordering of stimuli that have convenient physical dimensions when one of these dimensions is clearly a monotonic function of the attribute under investigation. He skips the issue because the rank order is obvious and he takes it for granted. Thus he does not bother to rank-order a series of luminous stimuli in terms of subjective brightness because the order is readily apparent and his interest is in more fertile tasks. But the neglect of the obvious has its hazards, and some relations that are assumed to be monotonic might, under closer scrutiny, reach a maximum and double back on themselves. The possibility at least demands our alertness. In any case, it is clearly impossible to set up any scale above the nominal unless the order of the items scaled is determinable.

One further point. The fact that we most often resort to rank ordering when the stimuli have no common dimension that is a monotonic function of our responses to them does not mean that we are limited to rank ordering. Not at all. We might in addition select from the stimuli those that are separated by equal-appearing intervals or even by equal-appearing ratios, if such proves practicable. No logic forbids it. It is sim-

ply an observable fact that in such cases the psychologist usually determines rank orders and stops. Quite possibly he ought to go on. For, as Reese points out, "the operations for measurement in psychology do not necessarily depend upon the prior measurement of any other magnitude." What is required is that we have some means of *identifying* the objects, situations, or events that we are trying to scale. When physical scales exist, they usually provide the most convenient means of identifying stimuli, but any other identification would serve as well.

The availability of a physical scale enables us to determine the functional relation between it and the subjective scale — which relation is mighty interesting by itself — but, theoretically at least, we could deposit with the National Bureau of Standards the appropriate samples of handwriting that would define known values on a ratio scale of pleasantness without ever having measured the handwriting on any physical scale.

Equal Intervals

The equalizing of differences is the next step beyond ordering. The determination of equal intervals becomes a problem in psychophysics whenever we aspire to measurement of the sort that makes the mean a meaningful measure — whenever it is a question of *units* in the ordinary sense of the term.

This problem got its first explicit recognition in psychology when Plateau provided a group of artists with a black and a white piece of paper and had each of them paint a gray that seemed to lie halfway between (cf. Boring, p. 42). This determination of two equal sense distances, as Titchener called them, by the procedure of bisection is probably the easiest approach to equal intervals. The operation of "halving," as we noted when we considered base-eight arithmetic, is apparently one of the simplest of psychological operations. The 'simultaneous' adjustment of several stimuli to produce more than two equal intervals is possible, but harder. Stevens and Volkman (1940b)

used five stimuli to produce four equal intervals of pitch. Their experiment confirmed, incidentally, the results of Münsterberg, who equated two pitch extents that were not adjacent, i.e. intervals that had no point in common.

These examples suffice to show that the equalization of sense distances has had its uses in psychophysics.* Other instances could be cited, but it is fair to state that the procedure has not been vigorously exploited by psychologists, despite the fact that it is essential to the creation of equal units on sensory scales. True, the solution of the problem of equal intervals is not in itself sufficient to determine the zero point of a psychological scale, but in the strict logic of the matter the equalizing of differences is a prerequisite to the erection not only of an interval scale but of a ratio scale as well. We shall return to this matter in a moment.

Meanwhile it is of interest to note that the problem of equalizing intervals gets a bigger play from the mental testers and other psychometricians than it does from the sensory psychologists. In psychometrics the need for equal units is distressingly acute, because the paraphernalia of metric statistics (means, standard deviations, coefficients of correlation, etc.) seem to be essential tools of the trade. The assessor of human abilities is usually knee deep in statistical problems to which most statistics do not apply unless his units can be equalized. Out of this quandary he hoists himself by an act of faith in the "normal distribution" of nature's errors. If this faith is firmly founded — if in truth it is legitimate to use the distribution of scores as a criterion for the sizes of units — then the equalization of units is pos-

* The meteorologists and other students of climate have experimented rather extensively with scales of subjective temperatures, humidity, and general climatic excellence. They have based these scales on equal-appearing intervals as well as on other psychophysical measures. As Titchener pointed out in 1909, here is rich sod for the cultivation of an applied branch of psychophysics.

sible. It is certainly not unreasonable to believe that this faith is often justified. What haunts us is the difficulty of knowing when it isn't.

Equal Ratios

The problem of determining equal ratios has had a long but spotty history in psychophysics. As early as 1888 Merkel tried setting visual intensities so that they appeared to be in the ratio of two to one. He seems not to have advanced, however, to the creation of a workable ratio scale, which is the *raison d'être* for equalizing ratios. And it was not until the 1930's that a full-dress ratio scale for a sensory attribute (loudness) was achieved. Since then ratio scales for subjective magnitudes have blossomed out in startling profusion. Scales have been attempted for:

Loudness (several workers; cf. Boring, p. 44).

Pitch (Stevens and Volkman, 1940b).

Visual numerosness (Taves, 1941).

Warmth (Herget, Granath, and Hardy, 1941).

Visual flash rate, subjective difficulty of digit memorization, subjective difficulty of words in a vocabulary test (all three by Reese, 1943).

Pain (Hardy, Wolff, and Goodell, 1948).

Sweetness, sourness, saltiness, bitterness (all four by D. R. Lewis, 1948).

Subjective weight (Harper and Stevens, 1948).

Visual brightness (Hanes, 1949).

Of all these scales only the first two, loudness and pitch, have thus far been subjected to the kind of cross-checking that might justly be demanded by the skeptic. The pitch scale, of which the unit is called a *mel*, has been determined by "fractionation" judgments, in which the listener adjusts one tone until it sounds half as high in pitch as some standard tone, and by judgments of equal sense distances, in which the listener equalizes a series of adjacent pitch extents, or

pitch differences. The pitch scale also agrees with the prediction that we would make if we assumed that pitch is 'spread' evenly along the basilar membrane, in such a manner that the pitch that bisects the audible range corresponds to the frequency that stimulates the midpoint along the basilar extent.

The loudness scale, based on fractionation judgments and measured in *sones*, has been tested against equal sense distances only to a very limited extent, but it has been shown to agree with a number of other reasonable assumptions. (1) It confirms the prediction that, for a given sound, the loudness heard with two ears is just twice the loudness heard with one ear. (2) It endorses the assumption that the loudness of two or more equally loud tones equals the sum of the loudnesses of the individual tones, provided the tones do not stimulate overlapping regions of the basilar membrane (cf. Howes). These are perhaps the most important checks. There are others.

Curiously enough, however, in all this work on ratio scales the psychophysical problem of equating sense ratios has not been faced. It has been dodged by what appears to be a happy expedient (until someone shall prove it a sad one). Instead of adjusting pairs of stimuli until the members of each pair appear to stand in some fixed (but unknown) ratio to each other, the subject adjusts the stimuli until they appear to stand in some *prescribed* ratio, usually two to one. Or, alternatively, a pair of stimuli are given, and the subject estimates the numerical value of their apparent ratio. (More properly stated, he estimates the numerical ratio between the two magnitudes of an attribute of the sensation aroused by the two stimuli, but for the sake of brevity we say simply that he estimates the apparent ratio of the stimuli.) These are the procedures we label "fractionation."

When we proceed in this fashion, we make an assumption that calls for scrutiny. We postulate, among other things, that the sub-

ject knows what a given numerical ratio is and that he can make a valid judgment of the numerical relation between two values of a psychological attribute. If this postulate is thievery, it is certainly no petty larceny, for among the precious loot we find all the relations that we need in order to proceed directly to the construction of a ratio scale. This looks like larceny in the grand manner. If a series of items have been found that stand in a *known* ratio, each to its neighbor, it is a straightforward matter to assign a numeral to one of the items and then to assign to the other items numerals exhibiting the appropriate ratios to the first numeral. If the assumption is valid, the result is a ratio scale.

Actually there is persuasive evidence to attest the empirical validity and reliability of the judgment of ratios, especially of the ratio two to one. Halving, as we have already noted twice, is a wonderfully simple psychological operation. If we are to build a structure on psychological operations, this looks like a sturdy stone for the foundation.

Reese expounds the defensible opinion that this operation of finding a stimulus that appears half as great as a standard stimulus is merely a special case of the bisection of an interval, one end of which has the value zero. This view of the matter gets added support from the discovery of Stevens and Volkman (1940*b*) that the subject does better when he is allowed to experience a stimulus that is very near zero. Apparently he can then tie the lower end of the interval to an anchor more solid than an imagined zero.

Needless to say, however, for the problem of scaling it matters little whether the subject bisects the interval between some value and zero, or whether he sets two stimuli to produce a known sensory ratio. In either case the empirical outcome is isomorphic with what we might call the ratio properties of the number system.

But it is important, theoretically at least, to consider what happens if we forsake the

assumption that the subject can interpret a given numerical ratio in terms of relations between experiences, or that given two experiences he can name the numerical ratio between them. Having denied this postulate, we would need to retain the assumption that the subject can judge equality and order (e.g. greater than). We would also need to assume that he can determine the equality of two intervals, or sense distances, and the equality of two sense ratios. On the basis of these postulates we could then proceed precisely as we did in the example cited earlier (p. 29), where the problem was to erect a scale of weight without resort to "addition." This construction of a weight scale is an adequate paradigm for the building of a ratio scale when the empirical operations are limited to the determination of equality, rank order, equal intervals, and equal ratios.

This paradigm reveals in explicit fashion the full logic of ratio-scale measurement. In practical instances short cuts of one sort or another are usually possible, but the by-passing of any step in the procedure implies assumptions that need to be probed. Consequently it would be interesting, at least as an essay in method, to construct a psychological ratio scale by requesting a subject to equate intervals of arbitrary extent and to equate ratios of arbitrary size. This procedure ought to corroborate the scale gotten by fractionation, although I should predict that it would show less precision (reliability) than the short-cut method of "fractionation" displays.

Stimulus Rating

In this world of gadgets and gimmicks we are often more interested, as a practical matter, in the correct judgment of the physical measures of things than we are in the nature of subjective scales. The policeman tries to assess correctly the objective speed of passing cars; the aviator tries to judge his altitude in feet above the ground; the grocer tries to estimate the weight of a bag of beans; and the tailor tries to guess the size of the

coat that will fit the customer. The common problem in these activities and the thousands like them is the utilization of a subjective impression to predict the result that would be obtained by an objective measurement. To perceive the stature of a man is one thing; to measure him with a yardstick is another. It is the business of many of us to correlate "subjective" and "objective" operations such as these and to predict the second from the first. In one way or another, we are constantly guessing at the physical values or relations of stimuli. We are doing deliberately what we just as deliberately try not to do when we study our sensations and perceptions: we are committing what Titchener called the "stimulus error." It would seem that more of the world's business depends on the successful commission of this "error" than on its successful avoidance.

Especially in military combat, where shells and missiles are hurled about by men who have no time for measurement, is the estimation of stimulus values a matter of great issue. There the gravity of the problem calls for programs of systematic training and procedures for gauging expertness. The excellence of an individual's performance in "free gunnery" and the like, where the close estimation of objective relations is vital, turns out to be compounded, as we might expect, of native ability and learning.

In distinguishing the problem of stimulus rating as a separate problem of psychophysics, we probably impute to it a dignity that its general untidiness belies. Actually it is a jumble of separate problems, each solvable *ad hoc*, perhaps, but no net of principles seems to bind these problems together. Conceivably, future insights might change all this, but for the present, at least, we must seek out the separate facts as we need them.

It can even be argued that the problem of stimulus rating, except for what it might teach us about individual skills in the matter, and the manner of their acquisition, is logically reducible to the other six problems we have discussed. If, for example, the

policeman tends to make a systematic error in naming the speed of a Sunday driver, this fact reveals something about the relation between his psychological scale of apparent speed and the objective scale of miles per hour. Presumably the form of the subjective scale is the primary fact, and the policeman's skill at committing the "stimulus error" is merely a measure of his ability to compensate for the nonlinearity of his subjective scale.

On the other hand, the problem of stimulus rating assumes major dimensions if we see it as including the problem of the rating or judging of stimuli for which there are no objective measures, e.g., such elusive complexes as human traits. When we use one human being as an 'instrument' for the assessment of qualities in other human beings, we hope that the 'instrument' will commit the stimulus error 100 per cent and not return a verdict that tells us more about the 'instrument' than it does about the 'stimulus.' This hope, we know, is partly vain, but its degree of fulfillment is adequate to put rating-scale procedures in the category of the indispensable in some parts of psychology (cf. Guilford, Chapter 9). Perhaps there seems to be little in common between the judging of velocity on the highway and the rating of traits of leadership, but, if there are any common principles governing the estimation of the objective qualities of things, they ought to apply to both these instances.

But we are wandering far into speculation. Let us return to problems of exactitude.

PSYCHOPHYSICAL METHODS

With the seven problems of psychophysics before us, it is time to worry about methods for solving them. We shall not worry long, however, for methods have a way of being tedious. Moreover, the prescription of method is as antiscientific as the scientific method is receptive of innovation. When better psychophysical methods are devised,

psychologists will use them, regardless of historical precedents.

Some of the psychophysical methods have already had incidental mention in previous sections. Here we shall try to call their roll in a more complete but still far from exhaustive fashion. The unabridged listing of methods is at best a fugacious goal, because for any method invented for one problem variations on it promptly suggest themselves for others. Three of the methods we shall list are styled "classical" (1, 2, and 4 in Table 7), but there is no reason to suppose that these, or any others, are better or worse than what may be devised by tomorrow's genius.

The reason for the traditional emphasis on method in psychophysics is simple enough: the responses of organisms vary from moment to moment. Forced to take time samples of a fluctuating process, we find ourselves thrown on the tender mercies of statistical procedures whenever we try to draw stable conclusions. It is a frustrating business. And in order to temper their frustration the psychophysicists have elaborated subtle measures that try to transcend the inconstancy of the mercurial response.

Seven of these methods are listed in Table 7. The listing of seven methods is sheerly arbitrary. We could easily list many more. But these are the main species of which most

TABLE 7
SOME METHODS OF PSYCHOPHYSICS

Method	Brief Characterization	Usual Statistical Index	Problems to Which Most Applicable
1. Adjustment (average error)	Observer adjusts stimulus until it is subjectively equal to or in some desired relation to a criterion.	Average of settings (average error of settings measures precision).	Absolute threshold Equality Equal intervals Equal ratios
2. Minimal change (limits)	Experimenter varies stimulus upward and/or downward. Observer signals its apparent relation to a criterion.	Average value of stimulus at transition point of observer's judgment.	All thresholds Equality
3. Paired comparison	Stimuli are presented in pairs. Each stimulus is paired with each other stimulus. The observer indicates which of each pair is greater in respect of a given attribute.	Proportion of judgments calling one stimulus greater than another. (These proportions are sometimes translated into scale values via the assumption of a normal distribution of judgments.)	Order Equal intervals (under 'distribution' assumption)
4. Constant stimuli	Several comparison stimuli are paired at random with a fixed standard. Observer says whether each comparison is greater or less than the standard. (A special case of paired comparisons.)	Size of difference limen equals stimulus distance between 50- and 75-per cent points on psychometric function.	All thresholds Equality Equal intervals Equal ratios
5. Quantal	Various fixed increments are added to a standard, with no time interval between. Each increment is added several times in succession. Observer indicates apparent presence or absence of the increment.	Size of sensory quantum equals distance between intercepts of rectilinear psychometric function.	Differential thresholds
6. Order of merit	Group of stimuli, presented simultaneously, are set in apparent rank order by the observer.	Average or median rank assigned by observers.	Order
7. Rating scale (single stimuli)	Each of a set of stimuli is given an "absolute" rating in terms of some attribute. Rating may be numerical or descriptive.	Average or median rating assigned by observers.	Order Equal intervals Stimulus rating

others are varieties. For a fuller discussion of all but method 5, see Guilford. For method 5, see Stevens, Morgan, and Volkmann.

The last column of Table 7 suggests that more than one method may be applicable to the solution of a given problem. Generally speaking, the empirical nature of the stimulus and the manner in which it can be manipulated will decide the method, but other considerations may well arise. Thus it has been rightly urged that of two alternative procedures the more direct is the better.

Now all the psychophysical methods give a distribution of scores from which may be obtained a measure of location (sometimes ill-advisedly called central tendency) and a measure of dispersion. Use might be made of either or both of these measures, but, other things being equal, the measure of location is the more solidly rooted in reality. It would seem defensible to argue, therefore, that the best method to use in a given instance is the one that gives the location of the observer's responses to the aspect or attribute in question. Then the measure of dispersion can be used to assess the precision of the observer's judgment. In general, we do well to keep clear of indirect measurements when direct measurements are possible.

A single example will suffice to illustrate this principle. The method of adjustment, which permits the observer to set the stimulus directly to the value that meets the criterion of his task, is the favored method for determining equivalents. But it is not so suitable for differential thresholds, because it forces us to estimate the limen by way of some arbitrary measure of dispersion.

This criterion of directness is not, however, the sole guide in these matters. Far from it. Considerations both practical and theoretical interact to mold our choice of method, and the manner of their give-and-take is too intricate to untangle here. An example of the problem of method as it applies to the hypothesis of the "neural

quantum" has already been discussed above. For a discussion that makes a distinction between mean jnd's determined by the method of minimal changes, and jnd's derived as "variational indices" from dispersions of judgments, see Holway and Pratt.

PROBABILITY

In the foregoing sections the concept of probability has been latent in much of the discussion. The superstructure of statistics has the theory of probability in its basement, and without statistics there would be little measurement in psychology. As a matter of fact, the problem of quantification in most of the biological sciences has two chief facets: measurement and sampling. And the problem of sampling is one aspect of probability.

Now, everyone talks about probability, but no one explains it to the satisfaction of everybody else.* This is not the place nor is your author the person to rectify the cross-currents of contention in this field, but two points ought to be made here—points that suggest themselves as lessons to be learned from the history of mathematics and from the theory of signs (syntactics, semantics, and pragmatics). These two points concern (1) the meanings of the word "probability" and (2) the formal-empirical dichotomy.

For the substance of probability theory in its modern technical forms the reader must go to the texts and treatises of the mathematicians. Perhaps a good place to start is with Wilks. And for an up-to-date sampling of the philosophical furor over basic issues and interpretations the reader should go to the *Journal of Philosophy and Phenomenological Research*, where a distinguished galaxy of scholars produced papers and counter-papers in "A Symposium on Probability," beginning in 1945. The two points

* Russell once told his lecture audience that "probability is the most important concept in modern science, especially as nobody has the slightest notion what it means" (see Bell, 1945, p. 587).

that follow may help the reader steer an orderly course through this symposium.

First of all there is the semantical problem: to what kinds of phenomena shall we apply the word probability? Ample precedent exists for many different semantical rules, and, theoretically at least, we could keep the record straight by using different words or, as is sometimes done, by appending subscripts.

Thus we might define probability₁ as degree of belief—what a man is willing to wager. This is the psychological or subjective feeling of probability known to all of us who make guesses before the fact.

Probability₂ could stand for the degree of confirmation of a proposition or hypothesis—the likelihood that an empirical statement is true in the operational sense. This is the concept for which Carnap tries to develop an inductive logic (see Carnap, 1947).

Probability₃ could be the a priori notion of probability: the probability induced from the “principle of indifference” which says that if we have no means of choosing among several alternatives then they are regarded as being equally likely. This is the principle we invoke when we assign the probability of $\frac{1}{6}$ to the upturn of a given face on the symmetrical die that is thrown on the carpet.

Probability₄ could stand for the frequency theory of probability—the notion that the probability of an event is the relative frequency of its occurrence in a large sample. This is the concept of probability that underlies most of statistics. And it is rightly argued that probability₄ is the operational test of probability₃. If without the one we could never know about the other, perhaps the two reduce to the same thing.*

These, then, are four possible kinds of probability. There are others, but these are sufficient to apprise us of the diversity of notions to which the word probability is linked. These are four semantical rules for relating this term to some aspect or other

of the empirical world. Quite naturally, therefore, there is no one theory of probability: there are as many as there are meanings for the word.

The second point to be made in this discussion concerns mainly the last two of these four varieties, because it is for them that the elaborate models of mathematical probability have been invented, and they are what we talk about in statistics.

Part of the cure (if there is one) for the confusion about the nature of statistical probability ‘probably’ lies in a strict adherence to the formalistic conception of mathematics. It behooves us to keep solidly in mind the distinction between a formal system that we might use as a model and the empirical reality for which the model might serve as a more or less isomorphic map. Consistent devotion to this distinction is hard enough to maintain in ordinary mathematical discussion. In talk about probability theory it seems to be doubly difficult. But it is precisely when we argue about chance expectations that it is most misleading to reason from the relations within the *mathematical model* of probability to the *necessity* of physical events. Under certain empirical conditions the mathematical model appears to “fit” the collection of empirical events, but the isomorphism is seldom if ever perfect, point for point.

The records compiled through the years at the Casino of Monte Carlo display a remarkable agreement between the properties of the frequency distributions of the winning numbers on the roulette wheels and the predictions of combinatorial analysis—the so-called laws of chance. But even here the coincidence between model and reality is not perfect. We are told that an English engineer patiently tabulated thousands of winning numbers for a particular wheel, and then alarmed the management by running up a long series of wins. In desperation the Casino spoiled his game by interchanging the parts from one wheel to another. This interchange is still a daily precaution. And most

* For a modern elaboration of the frequency theory of probability, see Reichenbach (1949).

likely it helps to insure the futility of any gambling rule that the persevering system makers concoct.

Given a roulette wheel that is "mechanically perfect" — one with no physical irregularities — we get from it a *random* series of numbers fitting the mathematical expectation only provided we put this randomness into the throw of the ball. This the experienced croupier seems to manage. In much the same way we get the runs of heads predicted by the binomial expansion provided we put the right kind of randomness into the flip of a coin. But there is nothing in the pure mathematics of the binomial expansion that determines the behavior of the coin. In fact, it would not be particularly difficult to build a mechanical coin-tosser that would flip heads almost every time.

Our tendency to confuse a formal calculus of probability with the empirical properties of certain kinds of events is partly determined by the fact that, like most of the rest of mathematics, this formal calculus had its beginnings in empirical problems (cf. Bell, 1937, p. 86). It was originated by Pascal and Fermat to answer the query of a professional gambler, and never since that time have we entirely succeeded in separating the empirical and the formal aspects of the issue.

The trouble usually begins on the first page of the chapter on probability in any textbook on college algebra, where we find it duly recorded that the probability p of a success s is the ratio of the number of ways in which an *event* can succeed to the total number of ways in which it can happen, $s + f$. This gives the formula

$$p = \frac{s}{s + f}$$

So far so good, for the word "event" is undefined, as it should be in a purely mathematical statement, and what we have is a formula that is true by definition — a postulate, as it were. But, before the paragraph is out, s has been identified with a face on

an "unbiased" die, or with one side of a symmetrical coin, or with a white ball in a bag with some black ones. From then on we seldom know whether the author is talking about mathematics or about the actual tosses of actual coins. We even get the impression that it might be possible to *test* the mathematical model by empirical manipulations, as the ancients once thought they could test the rest of arithmetic.

If the history of mathematics teaches anything, it is that all we can ever test is the degree of isomorphism between the formal model — the calculus of probability — and some particular collection of empirical events. That the isomorphism is often good is a fortunate circumstance, for it permits us to predict the behavior of molecules and death rates and election votes. But the existence of this isomorphism proves nothing more than our good fortune. It certainly proves nothing about the necessity of things, nor does our belief in any particular variety of necessity guarantee that the formal model will fit the resulting events.

Let us consider, as an example of a formal system, the mathematical model proposed by von Mises for the frequency theory of probability. In the English edition of his book von Mises does not always make explicit the formal-empirical distinction, but some of his oral statements lead me to conclude that he believes in it. Central to von Mises' formal system is the concept of the "collective," which he defines by two postulates: (1) the ratio of one kind of element to the total number in the collective approaches a limit as the number becomes infinite; and (2) every "place selection" (the drawing of elements according to any fixed rule) results in another collective having the same limit. This second postulate is equivalent to saying that, by definition, there is no gambling rule that will guarantee success if a true collective is involved. From these two postulates a formal calculus is derived, and, as is always the case, the question whether physical systems will be found that

fit these postulates is a matter for empirical test to decide. The roulette numbers of our earlier example approximate a collective, as is attested by the perennial solvency of the Prince of Monaco, and throughout many interesting pages von Mises examines still other concrete cases in which his calculus of collectives suffices for the statistical dissection of natural phenomena.

It is of incidental interest to us that Fechner, the psychophysicist, invented what von Mises calls the "useful concept of the 'Kollektivgegenstand'" (p. 98). Fechner did not go on, however, to develop a theory of probability on the basis of this notion of a "finite collective." Instead he developed, in what became posthumously a book, his theory of finite populations (Kollektiv-masslehre) which is closely related to the frequency theory of probability, and which von Mises acknowledges as a "stimulus" to his own developments (p. 123). The missing notion in Fechner's treatment of the collective is the concept of randomness—the notion covered by the second postulate of von Mises.

One virtue of this frequency theory of probability is that it sets us straight about which comes first, the properties of the collective or the probability of the event. The collective is the prior concept, and events get their probabilities by belonging to collectives. Then the assignment of a probability to a single event is one of two things: either it is a meaningless procedure, or it is a back-handed way of saying that the event belongs to a particular collective.

It follows from this conception of probability that one of the first tasks in mathematical statistics is to determine whether a given collection of statistical data forms a collective. If it does not, then von Mises' formal calculus of probability is not the proper model for it. But the quality of probability that balks and baffles us lies in just this feature of it: for no *finite* set of data can we ever be quite sure either that the model fits or that it does not. In the

strict sense this difficulty plagues every scientific indagation, but in matters of probability it founders our intent with a distressing regularity.

MEASURES AND INDICANTS

One final point and we are through.

Although psychologists devote much of their enthusiasm to the measurement of the psychological dimensions of people, they squander more of it in an effort to assess the various aspects of behavior by means of what we may call *indicants*. These are *effects* or *correlates* related to psychological dimensions by *unknown* laws. This process is inevitable in the present stage of our progress, and it is not to be counted a blemish. We know about psychological phenomena only through effects, and the measuring of the effects themselves is a first trudge on the road to understanding.

The end of the trail is measurement, which we reach when we solve the relation between our fortuitous indicants and the proper dimensions of the thing in question.

In the meantime we take hold of our problems by whatever handles nature provides. We count the number of pellets hoarded by a rat in order to assess its hoarding drive. We count the number of trials required for a man to learn a task, and use this number as an index of his ability. We measure changes in the resistance of the skin and call it an indicant of emotion. In short, we are far more frequently engaged, as the following chapters will demonstrate, in the measurement of indicants than we are in devising scales for the direct assessment of physiological and psychological phenomena, or of "intervening variables," as they are sometimes called.

Occasionally the measurement of an indicant is sufficient for the task at hand; e.g. when we gauge a worker's ability by his productivity we may be interested in no more than the relation between his production and that of his neighbor. But more often we

would like to measure his ability, intelligence, drive, emotion, hunger, etc., on a scale of the attribute in question rather than by effects that bear a dubious relation to it.

The difference, then, between an indicant and a measure is just this: the indicant is a presumed effect or correlate bearing an unknown (but usually monotonic) relation to some underlying phenomenon, whereas a measure is a scaled value of the phenomenon itself. Indicants have the advantage of convenience. Measures have the advantage of validity. We aspire to measures, but we are often forced to settle for less.

This distinction between measures and indicants disappears, of course, as soon as we learn the quantitative relation between the indicant and the object of our interest, for then the indicant can be calibrated and used to measure the phenomenon at issue. We measure electric current by means of a calibrated indicant composed of a coil of wire suspended by a spring in a magnetic field. We measure psychological pitch with a frequency meter after we have established a scale relating pitch in mels to frequency in cycles per second. The more mature a science, the more it uses *calibrated* indicants.

Excitation and Conduction in the Neuron

FRANK BRINK, JR.
The Johns Hopkins University

The essential fact about a single nerve cell, as a component of the nervous system, is that a response to a stimulus at one part of its surface can spread to distant parts of the cell and act as a stimulus to other nerve cells (or effector organs). The evolutionary specialization of the nerve cell for this purpose is manifested in its geometrical form and in its highly developed sensitivity. For example, the cell body of a motor neuron lies in the spinal cord, and its axon may extend for a distance of many feet to reach the muscle cells (Fig. 1). Stimulation of this neuron at any point produces a response that spreads to the periphery, as a nerve impulse, and causes some muscle cells to contract.

The impulse propagated along a nerve is itself a transient change in cellular structure revealed by various physical signs. The ability to propagate an impulse is a property of the neuron that is fundamental to its functioning as an element of the nervous system. This chapter begins, therefore, with a discussion of the physical properties of the communication line of the nervous system—the axon of the single neuron.

I wish to express my sincere thanks to Dr. D. W. Bronk, Dr. H. K. Hartline, and Dr. M. G. Larrabee for their constructive criticism of Chapters 2 and 3. They were prepared while the author was on the staff of the Johnson Foundation for Medical Physics, University of Pennsylvania.

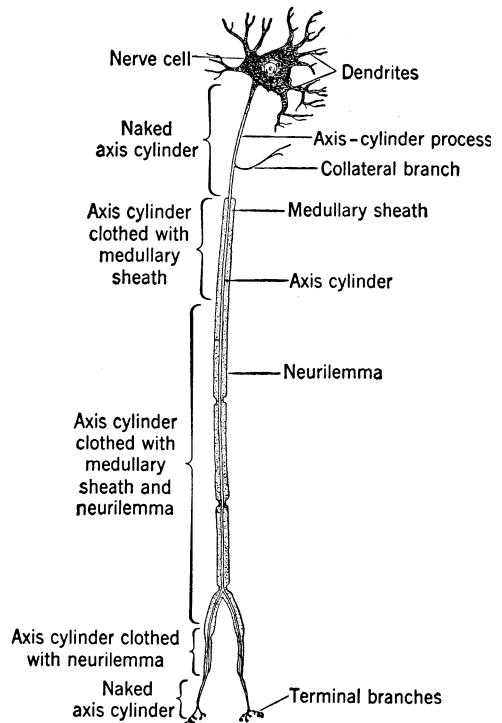

FIG. 1. Diagram of a motor neuron. The indentations in the myelin sheath, the nodes of Ranvier, may be 2 millimeters apart. The axon may be several feet long. (Stöhr.)

The Concept of Structure

In the physical sense the word "structure" implies a spatial distribution of the molecular components and larger particles of a

system, in other than the random arrangement produced by the thermal motion of noninteracting particles. Such orderly arrays require forces between adjacent molecules that are sufficiently strong to overcome thermal agitation and to insure the cohesion of the structure. There are many ways of detecting and mapping the spatial arrangements of the constituents of a structure as complex as that of a neuron. Obviously, shapes and overall dimensions are given by microscopic observation. Polarized light, by interacting with some arrangements of molecules, reveals structure in a molecular system, and, by comparison with models having similar properties, the spatial arrangements of the molecular constituents can be specified. X-rays, too, are scattered by molecular structures to produce characteristic patterns which can be analyzed into spatial maps of molecular arrangements. An electrical potential difference is evidence for a particular aspect of structure: the spatial distribution of charged particles. All these and several other physical methods for detecting structure and for following the rate and degree of change in particular structures have been employed in the study of neurons.

Optically defined structure of the axon. Historically the study of neurons became divided into several categories, defined largely by the experimental procedures employed. First there were the studies with the microscope that revealed a considerable range of detailed structure (Fig. 1) and indicated the complex organization and the range of size of the conducting units of the nervous system. This was supplemented by more detailed probing of the spatial arrangement of the constituent molecules by means of X-ray diffraction methods (Schmitt, 1941) and, in single fibers, by means of analyses, with polarized light, of the spatial arrangement of protein and lipid molecules at the surfaces of axons (Schmitt and Bear, 1939) and of cell bodies (Chinn, 1938).

Microscopic observation of living axons reveals the axis cylinder to be covered by

several sheaths that are not part of the neuron. In the fibers of crustacea these sheaths seem to cover directly the cytoplasm of the axis cylinder (Fig. 2). In the large myelinated fibers of vertebrates thick layers of myelin intervene between the axis cylinder and these outer sheaths, except at the nodes of Ranvier. The sheath around the myelin is formed from Schwann cells and is in turn surrounded by a sheath of connective tissue. In the giant fiber of the squid (*Loligo pealii*) the Schwann cells are inside the myelin sheath (Bear, Schmitt, and Young, 1937a). In addition to these observable external investments the axis cylinder presumably has a plasma membrane at its surface, as do other living cells.

The structure of the myelin sheath has been extensively studied by means of polarized light (see Fig. 3). There are layers of oriented lipid molecules alternating with layers of protein (Bear and Schmitt, 1936-37). The spatial arrangements of the constituents of this structure have been confirmed by X-ray studies. By means of polarized light the presence of similar myelin structures has been detected in the so-called unmyelinated nerves of crustacea (Schmitt and Bear, 1936-37; Chinn and Schmitt, 1936-37). The available evidence suggests that around all axons there is such a lamellar arrangement of protein and lipid molecules. This membrane may extend over the entire axon and cell body (Chinn, 1938). However, this is not true for cells in the ventral horn of the spinal cord where the surface of the cells seems to be the plasma membrane.

The axis cylinder is made up of a viscous cytoplasm that flows slowly from the cut end of a giant axon of a squid (Fig. 2) but is apparently a stiff gel in heavily myelinated mature axons of vertebrates (de Renyi, 1929). The presence of oriented protein particles in the axis cylinder of the giant axon has been detected with polarized light (Bear, Schmitt, and Young, 1937b). These

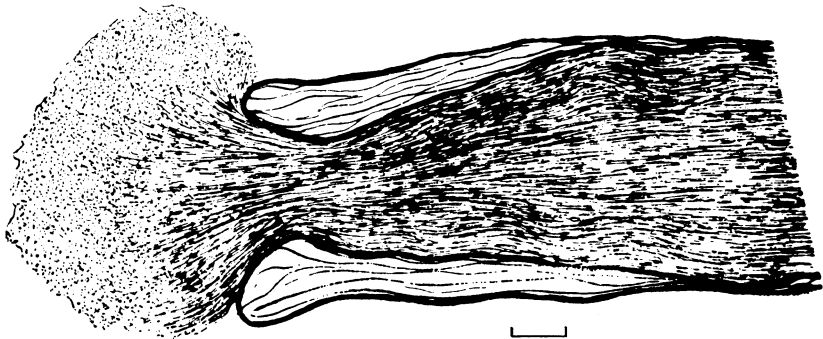

are rodlike and are oriented parallel to the long axis of the axon.

One outstanding fact about the axon is that it can persist only as long as it is con-

outside of the cell has been directly measured (Hodgkin and Huxley, 1945; Curtis and Cole, 1942). This is evidence for an orderly spatial arrangement of electrically charged

B. The viscous contents of the axis cylinder flow slowly from the cut end of a giant axon from a squid, *Loligo pealii*. The sheath structures are readily separated from the cytoplasm in this neuron. (Young, 1935.)

nected to the cell body. Another is that a cell body can regenerate this complex structure if the axon is destroyed.

Electrically defined structure of the axon. The relatively constant electrical properties of the resting cell are regarded as evidence of special arrangements of molecules within the cell structure. In one type of axon the potential difference between the inside and

molecules and for nonelectrical forces that create the electric field by maintaining a spatial separation of these oppositely charged particles. The spatial arrangement is such that the outside of the cell is positive, relative to the inside. This requires that positively charged molecules are on the average somewhat separated in a radial direction from an equal number of opposite charges.

The structure involved is the highly organized surface of the cell, which may be referred to as the nerve membrane. (The lat-

areas where electric charges accumulate, as on a condenser (Cole, 1940). Current flowing radially across the membrane then increases or decreases the potential difference between the inside and the outside of the nerve. This aspect of the nerve structure can therefore be studied by measuring the intensity and time course of the polarization potentials, or passive changes in membrane potential, created by passing current radially into or out of the cell.

The optically defined structures of the axon are not identical with the structures detected by electrical methods. For example, there is no change in structure detectable by polarized light during activity (Schmitt, 1939; Schmitt and Schmitt, 1940). Nevertheless there are profound structural changes accompanying the nerve impulse that can be detected by electrical methods (Cole and Curtis, 1938-39). The accumulated evidence suggests that the optically revealable structures are a stable molecular framework upon which are superimposed the more labile spatial arrays of molecules associated with excitation, response, and recovery. In particular, the principal electrical properties have been assigned to the regions near the surface, though it is not known how many of the observable membranes contribute significantly to these properties.

Physical Aspects of the Nerve Impulse

An impulse in a motor nerve can be conveniently detected by its physiological effect, the contraction of the attached muscle. It has been experimentally demonstrated that the conduction of such a nerve impulse along an axon is associated with an action potential. This is measured as an electrical potential difference longitudinally distributed along the fiber (Figs. 4 and 5). Since the magnitude of this electrical signal, measured by electrodes in contact with moist surface of the nerve, is a few millivolts or less, it is amplified by an electronic amplifier, which then drives a suitable recording instrument (Fig. 6).

FIG. 3. The surface of a nerve has a special molecular structure revealed by its interaction with transmitted polarized light. The upper picture is a microscopic view of a single axon dissected from a crayfish claw nerve. The lower picture shows that the surface structure transmits polarized light that is not transmitted by the axis cylinder. Diameter of axon is 60 microns. (Bear and Schmitt, 1936-37.)

ter designation does not refer to a particular histological structure.)

In addition, studies of the way in which the membrane conducts electricity suggest that it may be composed of ion-permeable, or conducting, areas, and of ion-impermeable

There is a finite time between the application of a stimulus to the nerve and the contraction of the muscle. This time interval is longer, the greater the distance from the point of stimulation to the muscle. Accordingly, one physical characteristic of the nerve impulse is that it travels at a finite measurable velocity (Helmholtz, 1852). This velocity was originally measured by stimulating a motor nerve at two points a known

FIG. 4. Potential changes during the passage of a conducted impulse, recorded between an electrode on an active part of the nerve and another on the inactive end of the nerve. This is the spike component of the action potential in a single fiber. Stimulus artifact at arrow marks time of stimulation. Time marks separated by 0.1 millisecond. (Gasser, 1939.)

distance (L) apart and measuring the two time intervals between stimulation and muscle response. The difference in these time intervals (Δt) represents the conduction time between the two points of stimulation, and the velocity of the impulse is $L/\Delta t$. Later, by stimulating an axon at two points that are at different distances from a pair of recording electrodes, the conduction velocity of the action potential was measured (Bernstein, 1866). The velocity of conduction of the physiologically effective impulse that excites a muscle is the same as that of the action potential.

The action potential is now regarded as an essential physical accompaniment of the nerve impulse. In most experiments on nerves the action potential is the primary criterion of activity in an axon, and its pres-

ence is employed to distinguish an active nerve from a resting one.

As previously mentioned, potential gradients are created in the fluid surrounding active axons. The two electrodes attached to a suitable amplifier and placed in contact with this external fluid register this differ-

FIG. 5. Diagram of instantaneous current distribution (upper diagram) around the depolarized area A during propagation of a nerve impulse. The potential change shown below becomes the recorded action potential when it is propagated past a recording electrode. In front of the depolarized area the currents flow outward from the membrane electromotive force and return by flowing inward in the depolarized region. This reversal of radial current flow occurs at the point of inflection on the rising phase of the action potential. The radial current again reverses direction at the inflection point on the descending phase of the action potential. (Modified from Howell's *Textbook of Physiology*. 15th Ed. Philadelphia: Saunders, 1946.)

ence of potential which varies in time as an impulse passes along the nerve. The moist film on the nerve is thin when the nerve is suspended in air in a moist chamber, and radial potential gradients in the external fluid are negligible. Under these conditions, as the activated area approaches the elec-

trodes, the first recording electrode becomes negative with respect to the second. Later this potential difference passes through zero, and the first electrode becomes positive with respect to the second until the nerve is re-polarized. The result is a diphasic action potential.

is followed by smaller and slower changes of potential, designated the after-potentials. These are readily observed at high amplification only. The first observable after-potential is negative, as is the spike, but subsequently the potential at the first electrode becomes positive, and thereafter the

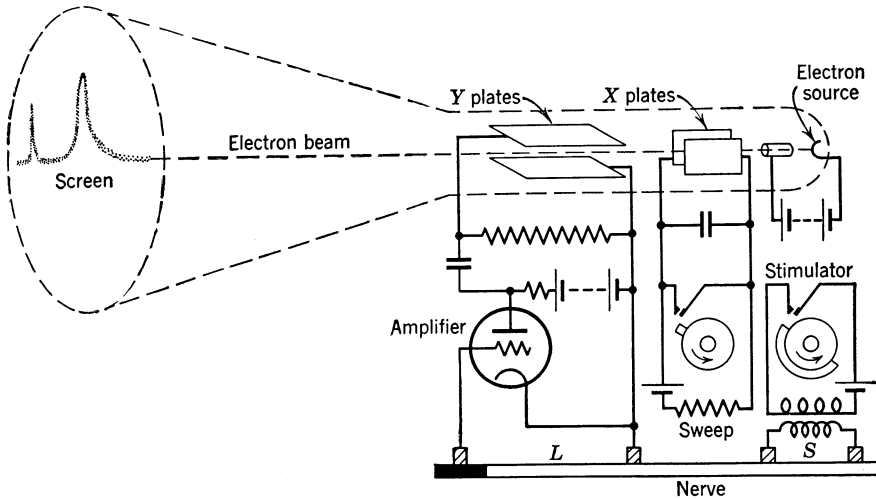

FIG. 6. Diagram of instruments for exciting a nerve and for observing the rapid electrical changes associated with a nerve impulse. One recording electrode is on a killed end of the nerve so that the recorded potential change is an undistorted representation of the sequence of changes under the other electrode. The sweep circuit causes the electron beam to move from left to right over the screen of the cathode-ray tube. The time of stimulation is marked by the first deflection on the screen. The action potential travels down the nerve and causes the second deflection when it reaches the first recording electrode. (Erlanger and Gasser, 1937.)

In order to observe the sequence of potential changes as the impulse passes one region of a nerve, it is desirable to prevent the potential changes at the second electrode. This is accomplished by placing the second electrode on a killed or otherwise inactivated part of the nerve, usually at the cut end of an excised nerve. The potential record now reflects the time course of changes at the first recording electrode, and the result is a monophasic action potential (Fig. 4).

The monophasic action potential is composed of an initial large and rapid change of potential, designated the spike. The spike

original isopotential condition is established as the nerve recovers from the activity. This total sequence of potential changes associated with a nerve impulse is called the action potential (Fig. 7).

The spike component of the action potential is not so easily modified by imposed environmental factors as are the after-potentials. This differential sensitivity to modification has been employed to establish that the spike is followed by a positive after-potential, or P_1 process. In the presence of a large negative after-potential this P_1 process is obscured. The negative after-

potential is also followed by a prolonged positive wave, designated the P_2 process. This analysis is indicated in Fig. 7.

The action potential is by no means the only physical accompaniment of the propagated nerve impulse. It is possible in some axons to detect the arrival of an impulse at a given region by the changes in the electrical resistance of the membrane, by

electrical current flowing through the nerve; i.e. a nerve is sensitive to such current flow. (2) The conduction of the physiologically effective nerve impulse along an axon is always associated with an action potential. These two facts led to the hypothesis that propagation of the impulse is mediated by the electrical current flowing out of an inactive area and into the active area of the

FIG. 7. Diagram depicting a theoretical series of potentials that, summed together, would reproduce the action potential. (Erlanger and Gasser, 1937.)

changes in the utilization of oxygen, and by the production of heat. The nerve impulse is thus a complex cycle of electrochemical changes in the nerve structure and is propagated at finite velocity from one part of a nerve cell to all other parts (the cell body may be an exception). In this sequence of events the initial part of the action potential is the earliest physical sign of the approach of the nerve impulse.

Mechanism of Conduction

There are two generalizations from experiments on isolated axons that underlie our present concepts of the physical process of conduction in nerve cells: (1) A propagated nerve impulse can be initiated by an

nerve. An obvious corollary to this proposition is that these currents are sufficiently intense to excite adjacent regions of the axon. The critical experiment was not performed until 1938 when Hodgkin presented clear evidence for the hypothesis that conduction is mediated by the electrical currents associated with the action potential.

In this experiment a few millimeters of the nerve were cooled so that a nerve impulse could not pass through the region (Fig. 8). There was then no propagated action potential in the fibers at points beyond the blocked region. When the recording electrodes were placed just beyond the blocked region, there was a change of potential correlated in time with each blocked

action potential arriving at the other side of the cooled region. The maximum amplitude of this postblock change of potential decreased with distance from the edge of the blocked region (Fig. 9). Thus the transient

FIG. 8. Current from the membrane electromotive force flows into the depolarized area of the axon at the edge of the blocked region. The outwardly directed currents beyond the block make the nerve more excitable there. Such current flow provides the mechanism for propagation of the action potential associated with a nerve impulse. (Hodgkin, 1937.)

loss of potential difference across the membrane at the site of the impulse caused current to flow from the areas of nerve on the far side of the blocked region.

Such changes of potential along the nerve merely indicate the longitudinal flow of current due to the intrinsic electromotive force of the nerve. The current flows through the external fluid and back into the axon at the

depolarized area. When this current is not intense enough to initiate a local response or a propagated impulse, as in this instance, the change in membrane potential is said to be a passive polarization in order to distinguish it from the membrane changes associated with an active response, such as a propagated wave of depolarization. These passive polarization potentials modify the excitability of a nerve and are often referred to as electrotonic potentials. Correspondingly, the associated current is described as electrotonic current and the change in excitability of the nerve is called electrotonus.

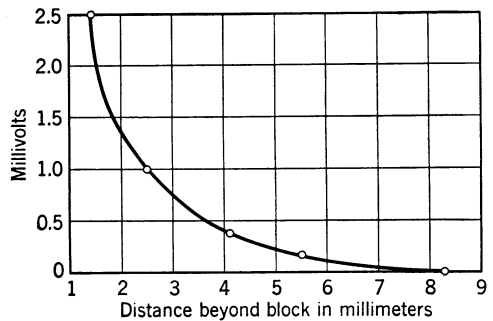

FIG. 9. The maximum potential change due to a blocked impulse decreases with distance beyond the blocked region of the nerve, as does an electrotonic potential change. (Hodgkin, 1937.)

The fact that conduction was blocked indicates that the electrotonic current on the far side of the block was insufficient to insure propagation of the impulse. However, the excitability of the nerve beyond the blocked region was increased during the transient flow of current (Fig. 8). This electrotonus was measured by the least intensity of imposed current from an external source required to initiate an action potential beyond the blocked region. In this way Hodgkin showed that the postblock changes of potential were temporally correlated with changes in excitability (Fig. 10). Quantitative studies of the changes of excitability produced in motor nerves of a frog at different distances ahead of a blocked impulse

indicated that at about 3 millimeters in front of the active area of an axon the current was sufficient to excite the region and thus insure propagation.

FIG. 10. The excitability changes (dotted curves), produced by the current flow ahead of a blocked impulse, parallel the electrotonic potential (solid curves) recorded at the same region. Thus the intensity of the excitation is related to the strength of the electrotonic currents shown in Fig. 8. Plots *a* and *b* are for cold block; *c* is for pressure block. Frog nerve. (Hodgkin, 1937.)

The strength of an action current is decreased by an increase in the electrical resistance of the external fluid through which it flows. Therefore the distance in front of an active region in an axon at which the

action current can excite is shorter, the greater the external resistance. If propagation is by means of the action currents, then the velocity should be reduced when the resistance to the flow of current in the external fluid is increased. This phenomenon has been experimentally demonstrated (Fig. 11), and it supports the hypothesis that the conduction process is electrical in nature.

FIG. 11. The conduction velocity of the action potential is reduced when the electrical resistance of the solutions bathing the nerve is increased. The time interval from the beginning of the trace to the first deflection measures the conduction time from the stimulating electrodes to the recording electrodes. *A* and *C* are for nerve bathed in seawater. *B* is for nerve bathed in oil to increase the resistance of the outside solution conducting the action currents. Time scale: milliseconds. (Hodgkin, 1938-39.)

No experiment has yet contradicted the hypothesis that propagation of the nerve impulse within a single neuron is by excitation of successive portions of the cell by the action currents.

It is possible to construct an electrochemical model having conduction properties analogous to those of a nerve (Lillie, 1936). Thus an iron wire in strong nitric acid becomes coated by a layer of oxide that prevents further dissolution of the wire into the acid. The coating on this so-called passive iron wire can be destroyed at a given place, and between the bare iron thus produced and an adjacent coated area there is a difference of potential. The current flowing between the bare areas and the coated areas is such that the coating at the boundary of the two areas is removed. Hence the electrochemical reaction is propagated along the wire, and the acid solution later restores the coating. As with the nerve fiber, this system (1) is sensitive to current flow and (2) contains an internal source of current. To this extent the structure is an electrochemical model of the axon. The analogy is even more extended in that such systems are capable of rhythmic electrical processes similar to the oscillatory local response in nerve (see below; and Bartlett, 1948). Attempts have also been made to formulate a mathematical representation of excitation and conduction in this model (Bonhoeffer, 1948). This is a promising approach to the theoretical study of the properties of metastable structures resembling those in neurons.

Velocity of conduction and types of fibers. The velocity of conduction of the action potential varies widely in different types of axons. One of the principal criteria used in classifying nerve fibers is the average velocity of conduction of the members of each class. The group of fibers of highest conduction velocity in peripheral nerves has been designated the A-group. However, there are subdivisions of the A-group defined by the average velocity of conduction of the members of the subgroup. Thus, if the A-fibers in the sciatic nerve of a frog are simultaneously excited, the time of arrival of the compound action potential at various points along the nerve can be measured and the velocity of propagation determined (Fig.

FIG. 12. Demonstration of the linearity of the velocity of propagation in α - and β -fibers. The distance from the stimulating to the recording electrodes is indicated along the vertical line, which also indicates the time of stimulation (S) for each test. "A straight line drawn through the start of the lowermost action potential and the point marking zero distance of conduction exactly intersects the starts of all of the other records. The start of *beta* is obvious only in the lowermost record where it is practically out in the clear. Another line has been drawn connecting the start of this *beta* with the zero of conduction distance. The positions of the starts of *beta* of the two intermediate records have been located by calculation and are indicated by the circles. In this way it becomes clear that the second straight line intersects reasonably closely the starts of all of the *betas*." (Erlanger and Gasser, 1937, pp. 13-14.)

12). If all the impulses traveled at the same velocity, this compound action potential would retain its size and duration as it traveled. At the longest conduction distance,

are designated the α - and β -fibers. If all the A-fibers in the sciatic nerve of a frog are excited and the conduction distance is long enough, two more subgroups of somewhat

FIG. 13. *Left-hand column:* spike potentials of A-, B-, and C-fibers. The duration of the spike component of the action potential is shorter, the faster the conduction velocity. The A-fiber spike (cat) has a duration of 0.4 millisecond, that of the B-fiber (rabbit) is about 1 millisecond, and the C-fiber spike (cat) lasts about 2 milliseconds.

Right-hand column: complete action potentials of A-, B-, and C-fibers (cat). The spike is followed by an after-potential that varies in form, size, and duration, depending on the kind of fiber. In A- and C-fibers the complete sequence is a negative after-potential (upward deflection) followed by a positive potential (downward deflection). In B-fibers the negative after-potential is not detected in single responses. (Gasser, 1941.)

however, two distinct maxima are observed in the recorded action potential. The first is compounded from action potentials, of a subgroup of fibers, that travel faster than those represented by the second peak in the compound action potential. The degree of separation of the two sets of impulses increases, the longer the distance traveled. These two subgroups of the A-group of fibers

slower average velocity of conduction are found. Thus the A-group of nerve fibers is composed of α -, β -, γ -, and δ -fibers. The average velocities of conduction decrease in that order (Erlanger and Gasser, 1937).

When conduction velocities are measured in a variety of nerves, other types of fibers are recognized (Fig. 13). One such group is the B-fibers having an average conduction

velocity much less than that for the A-fibers. However, the range of velocities of A-fibers overlaps that of the B-fibers (Table 1). Consequently other criteria are used to make a more complete distinction between these types. Both A- and B-fibers are myelinated and segmented by the nodes of Ranvier, as in Fig. 1. However, the diameter of B-fibers is less than 3 microns, whereas A-fibers can be as large as 20 microns, with an average diameter of about 10 microns. Other important distinguishing properties, such as the duration of the spike component of the action potential, are given in Table 1.

size determine conduction velocity. For example, a giant axon of a squid, which is not segmented and which is 500 microns in diameter, may have a conduction velocity equal to that of a segmented motor fiber of a frog, only 10 microns in diameter.

The differences in conduction velocity among A-, B-, and C-fibers are reflected in the speed of other processes in these cells. Thus the refractory period of an A-fiber is much less than that of a C-fiber. Indeed, the entire recovery cycle following a response is shorter in A-fibers than in C-fibers (Fig. 25). Furthermore, the after-potentials

The fibers of slowest conduction are the C-group. They are not myelinated so heavily (see p. 51) as are A- and B-fibers, and all processes seem to be more prolonged. The complete classification of mammalian fibers is given in Table 1 (Grundfest, 1940). This division of the fibers into groups is particularly useful to an understanding of the neurological function of the components of a peripheral nerve.

In fibers of the same group there is a correlation between size and conduction velocity (Fig. 14). This is particularly striking if the conduction velocity is measured at various stages in the growth of fibers of the same type. However, other factors besides

of the three kinds of axons differ as shown in Fig. 13. The slower the conduction velocity, the longer the after-potential.

The initiation of the impulse. Impulses are normally initiated in the endings of sensory nerves or in the cell body and dendrites of postsynaptic neurons. On the other hand, most of the detailed information about the sequence of physical events that lead from stimulus to conducted impulse has been derived from the electrical excitation of excised axons. In these experiments the time course of the imposed electrical current is known, and the conducted action potential provides an index of the time of response of the cell. This response always occurs an appreciable

time after the onset of the imposed stimulating current. It occurs at the cathode where the electric force causes positive ions to migrate outward across the membrane and negative ions to move inward. These spatial redistributions of ions lead to the physical events that finally develop into the propagated action potential.

stimulus is terminated, until a propagated impulse spreads over the entire axon. The significant fact that processes of excitation continue to grow after the termination of the stimulus was observed in motor nerves of the frog by Erlanger and Blair (1931a, 1936). A brief induction shock of a few microseconds duration is followed in about half a

FIG. 14. Linear relation between diameter and conduction velocity of mammalian nerve fibers. Each point represents a determination of the maximum conduction velocity in meters per second and of the diameter in microns of the largest fiber of an individual nerve. Dots: adult nerves. Circles: immature nerves. Cats and kittens. (Hursh, 1939.)

The time interval between the onset of the stimulus and the conducted action potential is called the response time. If the stimulus imposed upon a crab nerve is a prolonged direct current, the response time is shorter, the greater the intensity of the current. In addition, at each intensity of current the time of response is longer, the shorter the duration of the imposed current. However, at each intensity of current there is a minimum duration that can excite the nerve. A plot of this last relation results in the classical intensity-duration curve shown in Fig. 15, curve A.

Clearly the processes of excitation initiated by the stimulus at one region of the nerve can continue to develop after the

millisecond by a conducted impulse arising in the nerve at the cathode of the stimulator. If a stimulus of opposite polarity is imposed during this interval, the development of excitation can be stopped and no impulse occurs. This is further evidence, in another type of nerve, for the independent development of the process of excitation after the termination of the stimulatory current.

A consideration of the time relations in the development of excitation led Rushton (1937) to the idea of the localized response. He proposed that a finite length of nerve must become depolarized by current flow from adjacent parts of the membrane into the area initially depolarized by the imposed current. This process of spreading

depolarization can proceed after termination of the imposed stimulus. If the depolarized area thus created becomes large enough, the process of depolarization by circulating currents moves away from the point of imposed excitation and generates the action po-

Thus the state of excitation developed by a stimulus and the associated local electrical signs are both composite effects. One component is derived from the imposed current and is described as the direct effect of the stimulus. The other component is the self-

FIG. 15. The response time for a crab nerve depends upon the intensity and duration of a direct current stimulation. Stimuli and responses for two different intensities and durations are shown schematically at the top of the figure.

Curve A: Least duration (abscissa) at each intensity (ordinate) that will produce a response. The response at each intensity occurs at a time indicated by curve D (maximum latency of response).

Curve B: Least duration of stimulus at each intensity that will produce a response with a minimum latency (curve C). Longer durations produce no further reduction of the response time. (Arvanitaki, 1938.)

tential of the nerve impulse. Otherwise, processes of repolarization restore the nerve structure to its original polarized state, and the local action currents disappear.

If the imposed stimulatory current is sufficiently intense, the critical area of depolarization is created unaided by local circulating currents. The response time is then minimal. Only when the stimulating currents are weaker do the local action currents aid the imposed current in the creation of the area of depolarization required for conduction of the impulse.

excitation by current flow from intrinsic sources of electromotive force and is described as an active participation of the nerve in the growth of the local excited state. This dual nature of the excitatory process was recognized by Cremer in 1909 and is now incorporated in Rushton's theory of the growth of a nerve impulse.

The Local Electrical Response

The local electrical response has been detected in experiments on single motor axons excised from crabs (Hodgkin, 1938a) and

from squid (Arvanitaki, 1939; Pumphrey, Schmitt, and Young, 1940). It is most clearly revealed if the stimulus is of brief duration so that the imposed current does not continue to contribute to the recorded changes in potential. A weak pulse of current changes the difference of potential across the membrane by a passive redistribution of positive and negative ions. Under the cathode the potential difference across

(however, see Lorente de N6, 1947, Vol. 132).

This active contribution of the nerve to the process of spreading depolarization at the cathode is attributed to the local response. The local response is a change in the electromotive force and impedance of one area of the membrane that permits current to flow from adjacent areas of the membrane. As previously mentioned, it con-

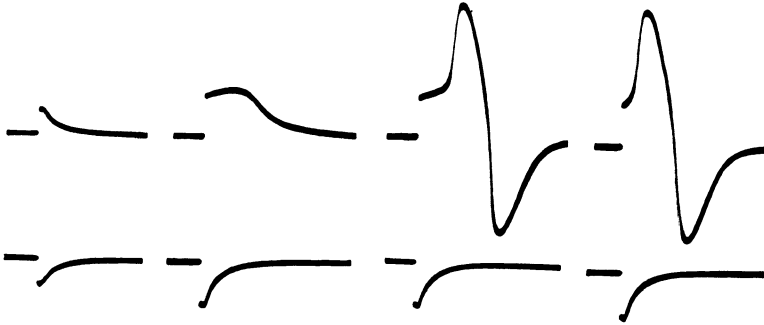

FIG. 16. Outward flow of current at the cathode (upper line) causes a local electrical response. A positive electrotonic potential change occurs at the anode (lower line). The polarizing current was weak for the first test, at the left, and the anodal and cathodal potential changes are similar. The stronger current used in the second test produced a local response as revealed by comparing the potential change at the cathode (upper) with that at the anode (lower). The last two testing currents produced local responses from which propagated action potentials developed. (Hodgkin, 1938*b*.)

the membrane is reduced, whereas at the anode it is increased. These polarization potentials decay exponentially in time at the cathode and at the anode (Fig. 16). The phenomenon resembles the passive charging and discharging of a condenser. When the brief stimulating current is of greater strength, the repolarization of the membrane under the cathode does not proceed in such a simple fashion. Some process intervenes that tends to maintain or even to increase the depolarization of the membrane (Fig. 16). This phenomenon occurs only in the area of the nerve under the cathode of the stimulator. It is the first sign of the local process of depolarization that is contributed by processes inherent in the nerve. At the anode a similar stimulus produces only the passively decaying polarization potential

tributes to the spreading of depolarization along the axon by means of minute local action currents. When the area of axon involved in the local response is great enough, this intrinsic process of depolarization spreads faster than the opposing processes of repolarization. Thus a conducted action potential grows out of the local response initiated by a threshold stimulus (Fig. 16). If the stimulus is greater than threshold value, it produces the critical size of local response earlier, and the impulse occurs sooner. The development of the action potential from the local potential change caused by the local response is shown quite clearly in Fig. 17.

The time course and the magnitude of the local electrical response are obtained by subtracting the component of potential change caused by the passive polarization of the

nerve membrane from the recorded potential change. It is assumed that the passive polarization changes at the cathode are equal to those recorded at the anode. Thus the recorded anodal polarization is subtracted from the recorded cathodal potential change to obtain the cathodal component that is the

in magnitude in each tiny area of the axon, or it could be complete in each area. In the latter case it would have the all-or-nothing character of the spike component of the action potential, and its observed variation in intensity would merely measure the total area of axon that has responded.

The local electrical response is physical evidence of the changes occurring during the interval between the application of the stimulus and the occurrence of the action potential. These changes in the structure of a nerve have been investigated in another way. This method depends upon the use of a brief electric current to bring the existing state of excitation immediately to threshold intensity (Bishop, 1928; Erlanger and Blair,

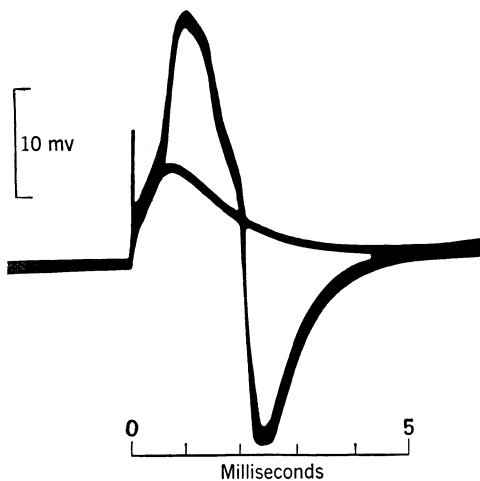

FIG. 17. Relation between a just subthreshold local electrical response and the action potential in a single crab nerve, recorded at the cathode of the stimulating current. The action potential rises out of the local response and is diphasic because it is propagated to the second recording electrode on a distant part of the axon. The two responses were produced in succession on the cathode-ray screen and were superimposed by double exposure of the same photographic plate. (Hodgkin, 1937.)

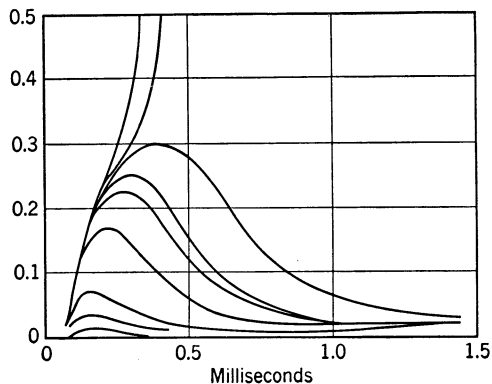

FIG. 18. Time course of local electrical responses in a single crab nerve, after subtraction of the electrotonic potential produced by the cathodal current. The size of the local response increases with the intensity of the stimulating current. The two upper traces show how, with a strong stimulus, the conducted action potential develops from the local electrical response. (Hodgkin, 1938b.)

local electrical response of the nerve (Fig. 18). The expression "local electrical response" thus refers to the changes of potential associated with the local action currents created by the occurrence of a localized response in part of the axon.

The local response may be thought of as a change in structure of the membrane similar to that occurring during the action potential. However, it is not known to what extent the local response exhibits all the characteristics of the nerve impulse. For example, the local response could be graded

1931a). The required intensity of this test shock is a measure of the difference between the existing state of excitation and that critical degree of excitation needed to initiate an impulse.

In this way the intensity of the local excitatory effect created by a subthreshold stimulus can be measured spatially and

temporally. Thus it has been shown that the local electrical response recorded in some nerves is the physical sign of the subthreshold state of excitation created by a stimulus.

A local electrical response graded in magnitude has not been unequivocally demonstrated in motor nerves of vertebrates. A local segmental response has been observed to occur at one node of a motor nerve of a frog (Tasaki and Mizuguchi, 1948), and this may be the counterpart of the graded local response of invertebrate nerves. However, the changes in excitability following a brief stimulus have been mapped in segmented axons by means of the test-shock method (Katz, 1937). When the stimulus creates a moderate increase of excitability at the cathodal region, the excitability decays exponentially. The decay of the excitation after a stronger stimulus is distorted, and the heightened state of excitation tends to be maintained. The development and decay of this additional process of excitation are similar to those of the local electrical response in crab nerve. It has been inferred, therefore, that a local response occurs in the motor nerves of frogs. The excitability that decays exponentially, in cathodal or anodal areas, is correlated with the passive polarization changes. The processes of self-excitation that appear only at the cathode have been correlated with the local electrical response. Hence they are attributed to the spread of excitation by the local action currents.

There is another point of view regarding the action of an imposed current on a nerve. This interpretation was developed recently by Lorente de N6 and is based primarily upon his studies of the electrical properties of nerve bundles, principally the sciatic nerve of the frog and the motor roots of the bull frog. This analysis suggests that the state of excitation at the cathodal region is created entirely by the action of the imposed current. The response of the nerve is to oppose this enforced change in the potential difference across the membrane. This active

process is called the nerve reaction, and it resembles in some respects the classical accommodation process (Lorente de N6, 1947, Vol. 132, p. 143).

It seems to be generally agreed that such processes of accommodation, opposing the excitatory action of a current, do occur. Accommodation is found in all nerves, but to varying degrees. Therefore the principal point at issue seems to be whether or not there is developed, in a partially depolarized area, a process of self-excitation that aids in developing a propagated action potential.

There is no doubt that action potentials can be developed in nerves without the aid of an imposed electrical current. Thus the removal of calcium by diffusion from a limited region of nerve makes that region very sensitive to electrical stimuli (Brink, Bronk, and Larrabee, 1946). Even without the aid of an external stimulating current, such a region develops successive action potentials. Consequently self-excitation by processes inherent in the nerve can initiate the electrical events leading to a propagated impulse. This has been observed in motor nerves of the frog, of crabs, and in the giant nerve fiber of the squid. In this last preparation it is possible to record the electrical events occurring after the removal of calcium ions and preceding the first conducted impulse. There is developed between the calcium-deficient area and the adjacent areas of the axon a fluctuating difference of potential (Fig. 32). This potential difference may increase in magnitude, presumably as a result of increase in the area of axon taking part in the process. The process clearly involves, between adjacent areas of axon, an interaction that is mediated by the associated current flow. In addition it is probable that local processes of repolarization in each area are active. Thus the entire excitatory process leading to the action potentials may develop from processes inherent in the axon. The action potentials arise near the negative peaks of the recorded local electrical response. Similar oscillatory local responses

to imposed electrical currents have been observed (Arvanitaki, 1939; Cole, 1941-42).

It appears then that processes of self-excitation can initiate nerve impulses in all these nerves under some conditions. The only question seems to be how much contribution to excitation initiated by imposed currents is made by the potentially self-excitatory processes? If the imposed stimulating current must continue to act until the conducted action potential occurs, then the processes of excitation inherent in the nerve must be weak and easily suppressed by the processes of repolarization. This seems to be the case in the motor nerves of the frog, where the utilization time is about equal to the response time (Lorente de Nó, 1947). However, single fibers of the frog clearly show a fluctuation in the response time to brief shocks at threshold intensity (Blair and Erlanger, 1936), and the response may occur as much as 1.5 millisecond after the end of the stimulus (Lorente de Nó, 1947, Vol. 132). If the response occurs after the termination of the imposed current, there must have been local processes of excitation that were gradually developing in the nerve. Furthermore this growth of self-excitation must have been great enough to overcome those processes in the nerve that tend to restore the initial state of the nerve.

In frog nerve then, under some conditions, there are processes of excitation within the nerve that aid an imposed current in initiating an action potential. However, the evidence is not so unequivocal as that obtained from experiments on nerves of the crab and of the squid. The reason for this seems to be that the time between the beginning of the local excitatory process and the initiation of the action potential is, in general, much shorter in frog nerve than in the nerves of the invertebrates. In addition there is some evidence that only the nodes are involved in the excitation and in the response of segmented nerves. Thus local electrical response and nodal response may be identical because of the small area of a

nodal region. Since the area involved in a nodal response is very small, prolonged growth of the incipient action potential would not occur. It may be that an area of axon the size of a node responds almost as a unit.

Accommodation to an Imposed Stimulus

The change in excitability of a nerve during the flow of a direct current can be studied by determining the least intensity of a superimposed brief shock that is required to initiate an impulse immediately. This is the test shock method previously mentioned. In the type of experiment under discussion it is desirable to stop the direct current that is conditioning the nerve just after the test shock is imposed. In this way the further development of excitation by the direct current is reduced to a minimum, and the specification of the time at which the test shock measured the excitability is more precise. This kind of study, made on motor nerves of the frog by Rushton (1932), reveals the interaction between the accommodation process, opposing excitation by the imposed current, and the development of this excitation.

The threshold of the nerve tested in a cathodally polarized area decreases at a gradually declining rate (Fig. 19). The decline in the rate of decrease of threshold is attributed to an accommodation process that opposes excitation by the direct current. If the direct current is of subthreshold intensity, the interaction of the processes of excitation and of accommodation leads to a minimum in the threshold. Thereafter the accommodation process predominates, and the threshold rises toward the initial value. If the direct current flows long enough, the nerve may become fully accommodated; i.e. the final threshold equals the initial value.

When the direct current is strong enough to excite the nerve, the initial interplay between excitation by the imposed current and the accommodation process also occurs. This is indicated, at a relative intensity of

25 units marked on a curve in Fig. 19, by the initial part of this curve having a change in slope similar to that created by a sub-threshold direct current. However, there is no minimum threshold achieved because the accommodation process is itself opposed by processes of self-excitation. These predomi-

The acceleration in the development of a response that occurs after the point of inflection on the curves in Fig. 19 is attributed to the local excitatory process. It may arise in the nerve as the local action currents aid the imposed current in creating the necessary area of depolarization.

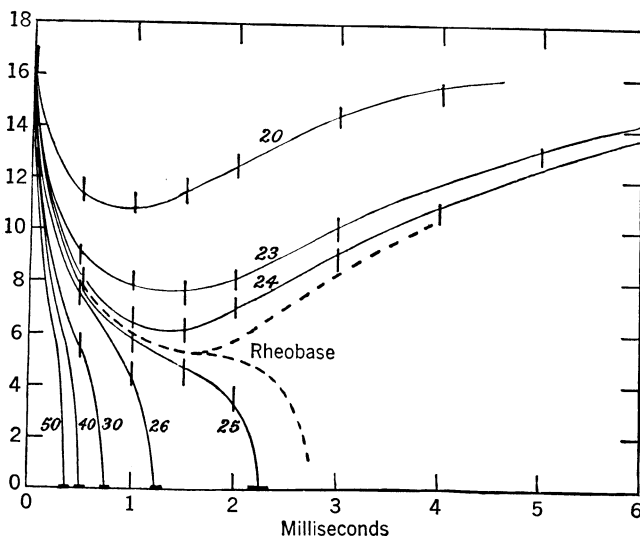

FIG. 19. During a subthreshold constant current there is a decrease in the threshold strength of a brief testing shock required to excite the nerve. After 1 or 2 milliseconds this decrease in threshold gradually disappears as the nerve adjusts to the disturbing action of the constant current (accommodation process). The relative strengths of the direct currents are given by the numbers on the curves. The strengths of the testing shocks are given on an arbitrary scale on the ordinate. When the direct current is above rheobase, the state of excitation develops at an accelerating rate. The stronger the current, the earlier the impulse is initiated, as indicated by the termination of the curves on the abscissa. (Rushton, 1932.)

nate after the point of inflection on the curve, and the threshold reaches zero on the ordinate scale. Then the impulse is initiated.

The intensity of direct current that is just sufficient to excite a nerve is called the rheobase. At the rheobase there is an unstable situation in which either accommodation or the local excitatory process may predominate. If accommodation predominates, there is no response and the usual decline of excitatory state occurs. This situation is indicated by the dotted lines in Fig. 19.

The accommodation process was postulated by Nernst to account for experimental deviations from his theory of nerve excitation. It is a prominent feature of the theories proposed later by Monnier (1934), Rashevsky (1936), and Hill (1936).

The complete time course of accommodation was first outlined by Erlanger and Blair (1931*b*). After the termination of the current flow in an accommodated nerve a test shock indicates that the threshold for excitation is very high (Blair and Erlanger,

1936b). It has, therefore, become the custom to speak of the process of accommodation as a rise of threshold for excitation, produced as the result of a change in the initial state of excitation. At the anodal region a corresponding increased excitability, or lowered threshold, occurs after the anodal current is terminated.

The relation of these complex transient changes in excitability to the associated changes in electrical polarization of the membrane has been studied for many years by many investigators (Katz, 1939). Studies by Lorente de N6 (1947) have led him to the conclusion that, within limits, a change in the potential difference across a nerve membrane will change the excitability. Though the evidence to prove the notion is not available, he proposes further that any increase in excitability is associated with a decrease in the potential difference across the membrane, and any decrease in excitability, with an increase in this potential difference. This conjecture should be considered a tentative hypothesis restricted to changes in excitability produced by an imposed electrical current.

Origin and Properties of the Action Potential

The spike is evidence for a transient change in membrane potential occupying a finite length of axon at any instant. At a particular area there is sequence of electrochemical changes which starts with the flow of current outward across the membrane. If the flow is sufficiently intense, there is rapid decrease of membrane electromotive force and a drop in membrane resistance (Fig. 20). The onset of the structural change indicated by the altered resistance is signaled by a reversal of the current flow so that adjacent areas of the axon now discharge into and through this region of the membrane where the resistance is low and the electromotive force reduced. This reversal of current flow occurs at the point of inflection on the rising phase of the action potential. The restoration of the original

potential difference and resistance of the membrane then begins. At the inflection point on the descending phase of the action potential the current is again flowing outward across the membrane. During this period of depolarization a second stimulus is ineffective. This period is therefore called the absolutely refractory period. In A-fibers

FIG. 20. During the action potential the membrane resistance to current flow suddenly decreases. Thereafter both the potential difference and the resistance are restored to their original values. The earliest deflection from the base line is the action potential, as in Fig. 4. The other trace measures the degree and duration of the associated change in resistance to current flow. Time marks are milliseconds. (Cole and Curtis, 1938-39.)

all these events occur in about a millisecond. The termination of the spike component of the action potential is obscured by afterpotentials representing further adjustments in the membrane structure as the cell processes slowly restore the original conditions at the membrane. (In so far as the phenomenon of conduction is concerned, the spike component is the essential electrical change in the membrane potential difference.)

The electrical characteristics of the nerve impulse direct attention to the nerve membrane as the fundamental structure underlying the functional properties of neurons. The membrane theory of the nerve impulse

originated by Bernstein has undergone several modifications. In one interpretation the membrane potential is attributed to the selective permeability of a membrane which allows potassium ions to pass through but holds back the negative ion of a potassium

membrane potential difference to a lower value characteristic of a free diffusion potential (Höber, 1945, Chapter 17).

This theory has been proved inadequate by direct measurements of the membrane potential between an electrode inside the

FIG. 21A. Microphotograph of the tip of a fluid-filled glass pipette that acts as an electrical connection to the inside of the axon. Upper view, at right angles to lower, was obtained by reflection from a mirror. The needle is near the center of the axon. The penetration of the needle into the fluid axoplasm does not interfere with the action potential, which depends only upon intact membrane structures. Giant fiber of the squid. Scale divisions, 25 microns. (Hodgkin and Huxley, 1945.)

salt inside the cell. This restraint on the free diffusion of the negative ion at the membrane separates it from the positive potassium ion which tends to diffuse out because of its thermal motion. The electric field created by this minute separation of charge restrains the movement of the potassium ion, and the membrane potential difference is thereby created. The action potential, according to this theory, is supposed to be a transient change in selective permeability, causing a reduction of the

squid giant axon and one on the outside surface (Fig. 21A). The resting potential was about 45 millivolts, and, when an impulse passed over the cell, the membrane potential did not just drop to a lower value, but reversed its sign and rose to 40 millivolts in the opposite direction. The action potential, about 100 millivolts, was thus almost twice the size of the resting membrane potential (Fig. 21B). The foregoing simple membrane theory is inadequate to explain this effect. According to Hodgkin, the re-

versal may be caused by the inward diffusion of sodium ions previously stopped by the membrane. Decreasing the external concentration of sodium ions reduces the magnitude of the reversed potential, which supports the hypothesis that the nerve

(1) outward flow of current across the nerve membrane acts as a stimulus; (2) the release of acetylcholine is the response; (3) the free acetylcholine depolarizes the nerve and causes the sudden drop of resistance characteristic of the active area of nerve; and (4) acetylcholine is destroyed by the choline esterase, permitting repolarization of the axon. This hypothesis was originally based upon the observation that the esterase occurs in all parts of a neuron and that it is a very rapidly acting enzyme. Conceivably it could destroy free acetylcholine quickly enough for repolarization to occur during the declining phase of the action potential. The biggest gap in the evidence for this view is the lack of a direct demonstration of the release of free acetylcholine during the development of the action potential. Furthermore acetylcholine has been shown to be a highly specific stimulator for certain types of neurons. This fact argues against its being universally utilized in the conduction process, which is common to all neurons.

FIG. 21B. Resting potential and action potential measured across the membrane between the inside and outside of an axon, as in Fig. 21A. In the resting state the inside electrode is 45 millivolts negative relative to the outside electrode. During the action potential the inner electrode becomes 40 millivolts positive with respect to the outer one, showing that the membrane potential has been reversed. Time marks are milliseconds. (Hodgkin and Huxley, 1945.)

surface becomes permeable to sodium ions during the action potential (Hodgkin and Katz, 1949). However, an adequate theory of the potential difference across the membrane must explicitly state that the membrane contains a source of electromotive force, where chemical energy of oxidative reactions is converted ultimately into electrical energy.

Another theory (Nachmansohn, 1946) states that the depolarization is caused by the release of acetylcholine from a bound form. The supposed sequence of events is:

The all-or-nothing character of the nerve impulse. The formulation of an adequate electrochemical explanation of the action potential in specific molecular and ionic terms consistent with the recognized lipoid and protein character of the cell structure is one of the principal problems in experimental neurology at the cellular level. But this phase of the problem may not be of great concern to the experimental psychologist at the present time. Nevertheless the fact that the nerve impulse is an electrochemical signal having the same physical character in all nerve cells presents the psychologist with an equally fundamental problem — that of understanding psychological phenomena in terms of a communication system in which the signals in the individual elements are transient changes of structure, or pulses, that can occur more or less frequently but have a relatively constant magnitude.

The last statement refers in part to the all-or-nothing character of the nerve impulse that was revealed by experiments on

multifiber preparations (Adrian, 1914, 1933). The law states that the intensity of the conducted response is independent of the intensity of the stimulus by which it is initiated and depends only upon the physical state of the reacting cell.

But it must not be supposed that the all-or-nothing law precludes all changes in the magnitude of response in a particular part of the nerve cell. On the contrary, a change in the local physical state of any part of the nerve cell will produce just such an effect.

FIG. 22. The conducted action potential in a single fiber is independent of the intensity of the stimulus initiating it. First trace shows deflection produced by escape of stimulating current into the amplifier; it is called the stimulus artifact. The second stimulus was stronger and produced a conducted action potential. In the last record the stimulus was much stronger, as indicated by the height of the stimulus artifact, but the action potential was unchanged. Time in milliseconds. (C. Pfaffmann, unpublished record, Johnson Foundation, University of Pennsylvania, 1940).

If the action potential is taken as a measure of the response, the foregoing proposition is clearly demonstrated by recording the action potential of a single fiber as the strength of the stimulus is varied. For weak

For example, since such changes can be produced by previous activity, the magnitude of an action potential associated with an impulse late in a train may be quite different from that of earlier ones (Fig. 23).

FIG. 23. Action potential measured between an electrode inside a giant axon and one on the outside. During repetitive response (B) the action potentials are smaller than for a single response (A) in a rested nerve. Time in milliseconds. (Hodgkin, 1938b.)

stimuli no conducted response occurs, whereas for stronger ones there is a conducted action potential of a magnitude independent of further increases in the strength of the stimulus (Fig. 22).

The functional significance of the intensity of response in a particular region of a cell must be measured (1) by its stimulating or inhibiting influence on adjacent cells or parts of the same cell or (2) by its associated after-

effects, which may modify the action of the next incoming impulse. The response of one region of a nerve cell always brings a stimulus to bear upon other regions of the same cell or upon adjacent cells, and the intensity of the response becomes, in turn, a measure of the intensity of its stimulating action. But the stimulating effectiveness of such a

decrease in the flow of electric current outward across the membrane (Fig. 24). A period of partial refractoriness is not peculiar to the conducted response, as is the absolutely refractory period, but can follow after even a subthreshold electrical stimulus. These neuronal processes, giving rise to periods of depressed excitability, are like the accommo-

FIG. 24. There is a transient change of excitability of a nerve after a subthreshold stimulus or after a conducted impulse. The excitability is inversely related to the strength of a test shock required to initiate an action potential at various times after the conditioning stimulus. Ordinates present change of initial excitability where normal level is expressed as 100 per cent. The solid dots show the excitability of a nerve following a brief shock just below threshold; the circles are for a much weaker shock. The squares show relative refractoriness following a conducted impulse. (Erlanger and Gasser, 1937.)

response depends also upon the excitability of the part of a cell to be stimulated. Consequently the all-or-nothing character of the propagated response of a nerve does not necessarily produce an all-or-nothing stimulating effect. It can produce subthreshold states of excitation that are graded in magnitude.

The irritability cycle associated with recovery from an impulse. The irritability cycle, following an impulse is far from complete at the end of the absolutely refractory period. There follows a relatively refractory period during which a second impulse can be initiated by a strong stimulus. This relatively refractory period has been identified with the postcathodal depression, the period of reduced excitability that always follows a

duction process, or nerve reaction, that occurs during the flow of current at a cathode on the nerve.

Usually the irritability cycle of an axon is even more complex because of the irritability changes associated with the after-potentials (Erlanger and Gasser, 1937). The after-potentials arise from processes in the nerve that are slow compared to the spike component of the action potential. Since they are initiated at each part of the nerve by the rapidly conducted spike, these processes begin at about the same time in rather long sections of a nerve. Therefore considerable lengths of the axon are in about the same phase of the after-potential at the same time. These slow after-potentials are significant as

electrical signs of changes in the membrane that modify its excitability.

The negative after-potential is associated with a period of increased excitability called the supernormal period (Fig. 25). The excitability is reduced during the subsequent positive after-potentials. Such correlations between changes of membrane potential and

Thus the physical aspects of the signals entering the central nervous system from visual sense cells (Hartline and Graham, 1932), from muscle-stretch receptors (Matthews, 1933), from sense organs for taste (Pumphrey, 1935; Pfaffmann, 1941), from pressure receptors in the carotid sinus (Bronk and Stella, 1932), and from pain fibers in the skin (Adrian, 1932) have been directly examined. Two fundamental facts are evident: (1) though the primary stimuli to the sense organs are physically different, the signals communicated to the nervous system are alike in that they consist of a train of action potentials; (2) an increase in the intensity of the stimulus is reflected in an increase in the frequency of transmission of impulses into the central nervous system, without significant change in the magnitude of the individual action potentials (Adrian, 1928; see chapters on receptors for illustrations).

Thus the signals conducted into the nervous system, as revealed by action potentials in a single axon coming from a sense organ, consist of brief pulselike electrochemical changes in the cell structure as each part responds.

When, by similar methods, the output from the central nervous system is examined, as in a single motor fiber, the signals are also found to be trains of impulses (Adrian and Bronk, 1928). By examining the degree of contraction of a single motor unit as a function of frequency, we observe that muscular response increases with the frequency of the nerve impulses driving the muscle cells. These observations reveal the fundamental importance of impulse frequency as the functionally significant measure (1) of the intensity of response and (2) of the stimulating effectiveness of activity in a single neuron.

The maximum frequency of impulses in a nerve cell measures the range of the functionally significant activity it can manifest. Measurements have shown, in general, that axons stimulated experimentally are capable

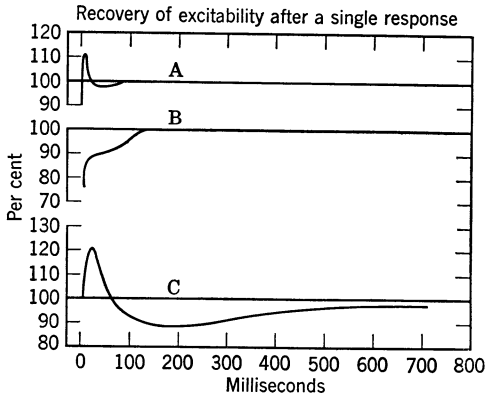

FIG. 25. Excitability curves of A-, B-, and C-fibers. During the negative after-potential the fibers have supernormal excitability, and during the subsequent positive potential there is subnormal excitability. The sequence of changes in the C-fibers resembles those for the A-fibers except in duration. In keeping with the absence of negative after-potential (Fig. 13), there is no supernormal period in the B-fibers. (Gasser, 1939.)

excitability are generally found (Fig. 26). Every change in membrane potential is associated with a change of excitability, whenever the latter can be tested. The functional significance of these phenomena is that they may occur at synapses and in receptors where they may determine the summation of excitatory effects.

Repetitive activity of neurons. The first direct information about the functional properties of the single neuron was obtained by recording action potentials in the individual axon. This method of investigation has been successfully applied to nerve fibers stimulated through sensory receptors *in situ*.

of responding much more frequently than neurons that are stimulated through sense organs or across a synapse. In the living organism the axon seems to be protected by a factor of safety in the sense that it cannot be overloaded readily by stimulation through the normal channels of the nervous system.

second. However, this rate can be achieved for only very short times, because each impulse causes changes in the nerve cell which will prolong the absolutely refractory period unless sufficient time is allowed for complete recovery after each response (Field and Brücke, 1926; Bugnard and Hill, 1935).

FIG. 26. The excitability of a nerve after passage of an impulse is correlated with the after-potential. Negative after-potential implies hyperexcitability, and positive after-potential implies subnormal excitability. These relations are preserved when changes in the time course are caused by changes in pH of the nerve. (Lehmann, 1937.)

The factors limiting the frequency of response of a given part of a neuron have been clearly revealed by studies on excised axons. As mentioned previously, following each conducted impulse there is a recovery period during which a second conducted impulse cannot be initiated. This absolutely refractory period measures the least interval between impulses and is approximately equal to the duration of the spike component of the action potential, about 1 millisecond in A-fibers. The upper frequency limit in motor nerves is, therefore, about 1000 impulses per

It has been observed that the absolutely refractory period can increase nine times in duration if a nerve responds at 85 impulses per second for some minutes. After termination of the activity there is a prolonged period of recovery to the original refractory period.

The cause of this lengthening refractoriness as a result of rapidly repeated impulses is not known. However, the oxygen uptake of a nerve after a single volley continues for a minute or more, and after a short burst of impulses at 100 per second the motor nerves

FIG. 27A. Repetitive response of a single motor fiber from a crab, caused by a constant current. The frequency of response increases with the strength of the current (proportional to numbers on curves). The onset and termination of the current is indicated by the small deflections of the baseline. The utilization time for the weakest current was almost 1 second. (Hodgkin, 1948.)

B. Some fibers accommodate to a direct current and cease responding after an interval that is longer when the current is stronger. Conditions as in A but for a different single fiber. (Hodgkin, 1948.)

of a frog have an increased oxygen uptake for as long as 45 minutes. This is evidence for long-lasting effects of previous activity and suggests that functional after-effects of activity, and limitations on rate of recovery, may be traceable to limitations on the rate of oxidation. If this is true, these functional limitations are intimately dependent upon some enzyme concentration in the cell.

Rhythmic Excitatory Processes in Axons

Because rhythmic response is a prominent characteristic of nerve-cell activity, its physi-

trasts with the former notion that rhythmic response to a constant stimulus was necessarily related to highly specialized parts of the neuron or of the sense organs (Fessard, 1936; Brink, Sjöstrand, and Bronk, 1938).

Another method, based on chemical excitation, also has revealed a rhythmic excitatory process that is latent in all parts of a neuron. These methods for studying rhythmicity involve experimental conditions to which an axon is ordinarily not exposed. They must be regarded as special procedures for uncovering latent properties inherent in axon structure.

FIG. 28. The curve indicates the per cent recovery of excitability (left ordinate) as a function of time (abscissa) after a previous response. Line A indicates strength of a weak continuously acting stimulus that initiates a second impulse (2) after the nerve has almost recovered its normal excitability. For a stronger stimulus, line B, the repetition, indicated by the numbered dots, is more frequent. Thus the interval between impulses is attributed to the rate of recovery of the neuron. (Diagram by Pitts, 1946.)

cal origins have been studied extensively in isolated single axons. In the classical studies of the response of an axon to a direct current it was emphasized that a nerve responded only once when the current began. This has been proved to be an erroneous impression, and it is now recognized that repetitive response to sufficiently intense current is a reproducible characteristic of axons (Fessard, 1936; Arvanitaki, 1939; Katz, 1936; Erlanger and Blair, 1936; Hodgkin, 1948) (Fig. 27). Processes that regulate the frequency of response in its relation to the intensity of the stimulus are inherent in all parts of the axon. This revised view con-

It is by analogy, supported by a few indirect experiments, that the mechanisms thus revealed are supposed to underly the rhythmic activity occurring normally in the nervous system. Indeed it should be emphasized that the axon, as the principal connector between one cell and another, is specialized so that it has a finite threshold. This insures that it does not respond to casual environmental changes but is always ready to conduct an impulse when excited through proper channels.

There are several prevailing explanations of the intervals between impulses in a train that is initiated by a constant stimulus. The

first, designated the recovery-cycle hypothesis, attributes the interval between impulses to the time course of the relatively refractory

Thus a weak stimulus would excite late in the relatively refractory period, and the interval between responses would be long. A

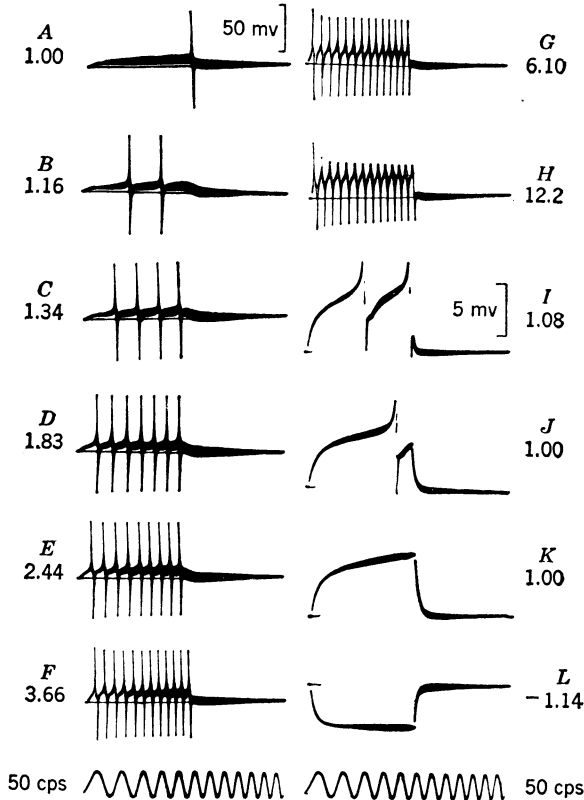

FIG. 29. Responses of a single motor nerve of a crab to direct current of different intensities, given by the numbers on each record. *A*: A single action potential occurs after a utilization time of about 0.1 second. During this time there was a slow local depolarization, indicated by the heavy trace. *B*: A stronger current initiates an impulse after a shorter utilization time, and this is followed by a second impulse. The slow depolarization develops to a critical degree as a preliminary process preceding each impulse. The frequency of impulses is determined by the rate of development of this local electrical response.

The development of the slow component of the local depolarization is shown clearly by the higher amplification in records *I* and *J*. This slow component of depolarization occurs only at the cathode (record *K*) and not at the anode (record *L*). (Hodgkin, 1948.)

period (Adrian, 1930). In this explanation it is supposed that a given intensity of stimulus creates a constant degree of excitation in the axon and that a second response occurs as soon as the nerve recovers sufficiently from the effects of the first response.

strong stimulus would excite at the beginning of the relatively refractory period, and the interval between responses would be short (Fig. 28). The upper limit of frequency would be that corresponding to an interval between impulses that is equal to the abso-

lute refractory period. In order to account for the long intervals observed in naturally occurring trains of impulses it would be necessary to attribute extremely prolonged relatively refractory periods to the regions of the cell in which the impulses originate.

A second explanation attributes the rate at which impulses recur to the periodic character of the excitatory process. One version of this explanation is based upon the observation that in some axons the depolarizing action of a direct current develops progressively after each response at a rate determined by the strength of the stimulating current. It is observed that this depolarization must proceed to a critical level in order to excite. Thus the interval between impulses is the time required for the imposed current to recreate the critical degree of depolarization (Fig. 29; Hodgkin, 1948).

For this mechanism to operate in the nervous system it would be necessary for direct currents to be created that lasted as long as the observed trains of impulses. No such prolonged steady current flow in the region of the sense organs has been correlated with the duration of the train of impulses. Thus the retinal potential in a *Limulus* eye rapidly falls off to very low values, despite the continuation of the train of impulses in the optic nerve (Hartline, 1948).

Direct-current flow in some axons can cause repetitive responses by a somewhat different mechanism. The local electrical response previously described can become oscillatory under some conditions (Arvanitaki, 1939). Then successive impulses may arise at intervals determined by the successive negative peaks of this local potential change. This kind of rhythmic response may occur as a result of a constant current flow (Fig. 30) or as an after-effect of an impulse started by a single electric shock. Therefore, if a stimulus initiates the first impulse in a train, the temporal pattern of the successive impulses may be determined by this oscillatory local response. Studies of chemical excitation of single axons have shown

that such oscillatory local electric responses can develop merely as the result of a modified chemical environment (Brink and Bronk, 1941). An imposed external current is not a necessary part of this mechanism, nor is the process a part of the recovery cycle of a previous action potential.

In the giant axon of the squid this process of self-excitation is revealed by the local electrical response recorded as a difference of potential between the chemically modified

FIG. 30. Damped rhythmic variations of membrane potential at onset and termination of a subthreshold constant current. Recorded from the cathodal region, giant fiber of squid. Relative strength of current given by numbers on records. (Arvanitaki, 1939.)

region of the axon and the adjacent normal areas. The self-excitation is developed by internal processes as a result of the removal of calcium from a part of the axon. The calcium-deficient area first becomes hyperexcitable to electric currents (Fig. 31). When the threshold is very low there is developed a rhythmic local electrical response at high frequency. The amplitude increases, with a small decrease in frequency, until conducted action potentials are developed near the negative peaks of these local electrical responses (Fig. 32). The intervals between the conducted impulses are determined by the intervals between the peaks of the local electrical response.

When the stimulating effectiveness of a local response is below a certain critical value, a conducted action potential does not occur for each wave of the local response. If an action potential occurs for every other wave

of the local response, the interval between successive impulses is twice the least interval. Other multiples of the least interval occur

pulses in a train are thus multiples of the least interval and are due to changes in the stimulating effectiveness of the rhythmic excitatory process (Fig. 33).

Since the frequency-determining process is evident before the first conducted impulse occurs, it cannot be attributed to the after-effect of a previous response. Indeed, the rhythmic local response can exist for long periods of time without initiating an impulse. These local responses can be recorded electrically or their presence detected as a random fluctuation in excitability to test shocks.

Areas of frog axons deficient in calcium also develop trains of conducted impulses. Attempts to record local electrical oscillations at the origin of the impulses have not been successful. Furthermore the activity can occur without any constant potential difference between the treated and the normal regions of the axon. There is thus no direct current acting, as in the second mechanism of rhythmicity.

The properties of the periodic processes in axons of the frog can be deduced from a statistical analysis of the intervals between the recorded action potentials (Brink, Bronk, and Larrabee, 1946). The successive intervals in a long train of impulses in a single fiber are measured (Fig. 34). Then the frequency of occurrence of each interval is plotted as a function of the duration of the

FIG. 31. The strength of current required to excite an isolated giant axon of the squid is less, the lower the concentration of calcium chloride in the fluid bathing the axon. Ordinate: threshold strength of direct current, or rheobase, as per cent of threshold of nerve in seawater. Abscissa: concentration of calcium chloride in millimoles per liter. The arrow indicates concentration at which spontaneous activity began. (Brink, Bronk, and Larrabee, 1946.)

as a result (1) of decreasing intensity of the local response and (2) of changes in the sensitivity of adjacent areas of axon to which depolarization must spread if conduction is to occur. The long intervals between im-

FIG. 32. Local electrical response, recorded from a chemically excited region of the giant axon of a squid, is oscillatory and precedes the conducted impulses. The last ten oscillations on the right of the record initiated propagated impulses which were much larger in amplitude than shown. Stimulation was by topical application of isotonic sodium chloride. The frequency of the local oscillations is about 350 per second. (Brink and Bronk, 1941.)

FIG. 33. The amplitude of the local electrical response in a giant axon (squid) deficient in calcium waxes and wanes spontaneously. During the period of increasing amplitude a series of diphasic impulses is initiated. Finally these action potentials cease, even though the local response remains large. Presumably refractoriness developed by nine action potentials makes the large local response ineffective. The frequency of the action potentials is clearly determined by that of the local response, and the long intervals between groups are multiples of the period of the local excitatory process. (Brink and Bronk, unpublished records, 1939.)

FIG. 34*A*. Impulses recorded from a branch of the sciatic nerve of a frog stimulated by topical application of isotonic sodium citrate. *B*. Impulses recorded from single fiber dissected from this nerve. (In the original record these spikes were all the same size.) Time in $\frac{1}{5}$ -second intervals. (Brink, Bronk, and Larrabee, 1946.)

interval. In this way it is observed that certain intervals occur much more frequently than others, as shown in Fig. 35. These peak values are multiples of the set of least intervals thus measured. Accordingly we may

occurrence of a conducted impulse per cycle. Furthermore this excitatory process has a variable intensity, which may decrease to subthreshold value, without significant change in the rhythm of the process.

FIG. 35. The frequency of occurrence of intervals between impulses in a train (as in Fig. 34B) having values indicated on the abscissa. The set of least intervals measures the period of the rhythmic excitatory process initiating these impulses. The other sets of intervals are approximately two and three times as long as the most probable value of the least interval. Stimulation was by topical application of sodium citrate. Intervals longer than 24 milliseconds not shown. (Brink, Bronk, and Larrabee, 1946.)

assume that the set of least intervals measures the average period of a rhythmic excitatory process. The next longer set of intervals, twice this least value, occurs when an intervening cycle of the excitatory process fails to initiate an impulse. A similar explanation applies to the higher multiples of the least interval.

From these data it is concluded that in the frog, as in the squid, the rhythmic excitatory process exists independently of the

By a similar analysis of the discharge of impulses from single receptor organs, the existence there of a similar mechanism is revealed. Such a study has been made on a Pacinian corpuscle excited by constant pressure (Scott, 1948). The measured intervals in the train of impulses are distributed about multiples of a basic value, in a manner similar to that just reported (Fig. 36). Therefore in the Pacinian corpuscle there seems to be a rhythmic excitatory process that deter-

mines the frequency of the impulses sent into the nervous system from this receptor. The

Fig. 36. The average number of impulses per second from a Pacinian corpuscle, stimulated by pressure, increases without any change in the period of the rhythmic excitatory process regulating the intervals between impulses. Records were analyzed as in Figs. 35 and 37 for chemical excitation of isolated axons. (D. Scott, Jr., unpublished records, Johnson Foundation, University of Pennsylvania, 1948.)

study has not been extended to other receptors, although published records of response of nerves in taste buds in a frog's tongue

(Pffaffmann, 1941) strongly suggest its presence there.

The existence of a periodic excitatory process makes it necessary to distinguish two characteristic frequencies of neuronal action. The rhythm of the excitatory process seems to be a relatively fixed characteristic, related, perhaps, to the specific structure of the nerve. On the other hand, the average number of conducted impulses per second varies widely in response to the strength of the imposed stimulation. It is significant to note, then, that the average number of impulses per unit time can change without a change in the average period of the excitatory process (Fig. 37). As previously mentioned, this is possible because only those cycles of the local response that are of sufficient intensity can initiate conducted impulses. The intensity of the stimulus determines the average amplitude per cycle of this rhythmic excitatory process. The average amplitude, in turn, determines the average number of conducted impulses per second. Thus there is revealed in some detail one mechanism by which the average frequency of impulses in a neuron is determined by the intensity of the stimulus.

Origin of rhythmic processes in axons. The rhythmic properties of axons are inherent in the axon structure, as revealed by reactions to current flow. When a current penetrates the nerve membrane, there is a translation and redistribution of the charged molecules that would occur at any interface between dissimilar electrolytic conductors. A distinguishing characteristic of the living nerve cell is its tendency to oppose the disturbing effects upon its structure of the electric fields imposed upon it. There are, at present, two general views regarding the interpretation of the physical phenomena associated with the flow of subthreshold currents. It is generally agreed that the membrane can conduct electricity, and this property can be represented, for purposes of analysis, as an electrical resistance. Furthermore ions can accumulate at interfaces in a way that simulates the

FIG. 37. The average number of impulses in a single fiber (frog) can be markedly increased without much change in the fundamental period. Lower: frequency of occurrence of intervals having values indicated on the abscissa. Stimulation by topical application of a solution containing sodium citrate. The average number of conducted impulses per second was about 220. Upper: similar analysis of a consecutive series of impulses recorded at height of increased response evoked by cathodal polarization of chemically treated region. The average number per second of conducted impulses was about 305. (Brink, Bronk, and Larrabee, 1946.)

charging of a condenser. Therefore the establishment of a current through the membrane will be opposed by changes of membrane potential, related to the charging of the condenser, and there will be leakage of this charge through the membrane resistance. On the other hand, when the membrane structure is disturbed by a varying electric current, there is evidence of opposition to changes in current that are not accounted for by a passive circuit containing only capacitance and resistance.

In pursuing the physical analysis of these phenomena, one group of investigators has described the results in terms of an inductive element in the membrane (Cole and Baker, 1941). In this representation certain aspects of the opposition of the membrane to changes in membrane current are attributed to a structural element (an inductance) of an equivalent electric circuit. However, in analyzing similar reactions of nerve to electric currents, other investigators have emphasized the importance of the membrane electromotive force (Lorente de N6, 1947). According to this hypothesis, flow of current of any magnitude calls forth a nerve reaction that is a modification of the membrane electromotive force. This view emphasizes the importance of the electromotive force in opposing current flow and thus links the oscillatory phenomena to metabolic processes; i.e. it directs attention to the energy sources within the nerve.

Obviously the foregoing studies reveal important aspects of axon structure. But what is their functional significance in neuron activity? Their importance is that they offer alternative physical explanations of the origin of the rhythmic character of nervous activity. As discussed, the temporal pattern of impulses in a neuron is traceable in some instances to a rhythmic process of excitation. This rhythmic process can be called forth by a current imposed on the nerve, or by a chemical modification of the nerve. In the latter case the oscillatory changes in membrane potential are entirely due to current

flow from sources of electrical energy inside the cell. But the rhythm itself could be imposed in at least two ways.

First, a cellular source of constant electromotive force could cause oscillations in membrane potential by discharging through a membrane structure that behaved like a circuit composed of capacity, resistance, and inductance. According to this view the frequency of the self-excitation process, revealed by removal of calcium from a squid axon, should be predictable from impedance measurements across the nerve membrane made with alternating current. Indeed, the undamped natural frequency of the membrane circuit as measured by Cole and Baker (1941) is about equal to the observed frequency of the oscillatory local response initiated by chemical means (Brink, Bronk, and Larrabee, 1946).

The second interpretation emphasizes the labile character of the electromotive force in the membrane. It states that rhythmic activity is a resultant of an interplay between the changes in membrane potential caused by passive polarization and the active changes in membrane electromotive force elicited thereby (Lorente de Nó, 1947). The latter view brings to the fore the chemical reactions underlying the electromotive force of the nerve cell. Future studies of the kinetics of these metabolic events in relation to changes in membrane potential may lead to a rephrasing of these hypotheses by interpreting the "inductive" element as a convenient symbol for the overall electrical aspect of the nerve reaction to current flow.

Source of Energy in Neurons

Like other living cells, the nerve cell is an assemblage of molecules maintained in an organized state by the continual transformation of energy normally derived from oxidative reactions. There are no significant properties of the nerve cell that have the permanence associated with a system of molecules in thermodynamic equilibrium. On the contrary, when the nerve cell ceases to dissipate

oxidative energy it loses its function and its electrical properties. The cell is restored to its original state when the oxidative reactions begin again. Therefore the structures underlying the electrical properties of nerve and its excitability are the resultant of opposing processes, leading on the one hand to disorganization, and on the other to an ordered arrangement of the cellular constituents. A molecular system maintained in a relatively constant state of organization by the continuous flux of matter and transformation of energy is defined as a steady-state system.

These ideas focus attention upon the organized metabolic processes of nerve which, like those of other living cells, depend upon an orderly sequence of chemical reactions controlled by enzymes. This sequence of molecular transformations of glucose and other metabolites into their final products provides the continuous production of energy used to maintain the organized state of the cell. Underlying these material transformations is a set of molecules, the enzymes, which may be regarded as a relatively stable aspect of the cell structure. For example, this enzyme structure persists during anoxia, as evidenced by the prompt restoration of the metabolic reactions when oxygen is restored. The oxidative enzymes are not static entities, however, but operate in cycles, being first oxidized and then reduced.

The enzymes are not uniformly distributed through the cell structure (Nachmansohn, 1946). In the giant axon of the squid the oxidative enzymes are located in the cytoplasm. Other enzymes, such as choline esterase, are found only in the sheath. The experimental separation of the sites of specific chemical reactions was possible in this single cell because the fluid cytoplasm, though highly viscous, can be made to flow out, leaving the sheath structures (Fig. 2). This spatial arrangement of specific enzymes suggests that molecules produced by oxidative metabolism affect the electrical properties of the membrane by diffusing there from some other cytoplasmic region. These observa-

tions are the beginnings of the experimental demonstration of a spatial distribution of sites for specific chemical reactions related to the specialized functions of neurons.

The cycle of change in structure associated with the action potential can take place many times without the immediate use of

tion of molecules in this energy reservoir, and the rate of oxygen utilization that are mutually self-regulating. For example, a series of action potentials can reduce the amount of creatine phosphate in a nerve. In the presence of oxygen this is restored by phosphorylations that are associated with in-

Fig. 38. The heat production of a nerve continues for some time after oxygen consumption is terminated. There is a greater than normal rate of heat production for some time after oxygen is again supplied. (After Beresina, 1932, modified from Feng, 1936.)

oxygen, apparently at the expense of energy stored in specific molecules by previous oxidations. The energy dissipated by the nerve impulse is thus derived from a reservoir that, in turn, is refilled by oxidation reactions. It is thought, at present, that creatine phosphate and adenosine triphosphate represent these energy stores. The supposition is that the hydrolysis of these molecules, releasing 10,000 calories of energy per mole, is somehow used to maintain the membrane potential difference (cf. Shanes and Brown, 1942).

There are connections between the structural changes during activity, the concentra-

tion of molecules in this energy reservoir, and the rate of oxygen utilization that are mutually self-regulating. (Gerard, 1932).

Oxygen requirements at rest. An isolated nerve at rest uses oxygen at a constant rate, determined in part by the chemical constitution of the solution bathing it. There is also a constant output of carbon dioxide (Tashiro, 1917; Gerard, 1932). This steady flux of chemical change is correlated with a constant rate of heat production (Feng, 1936). Most of the heat production of a resting nerve is dependent upon a continuous supply of oxygen (Fig. 38). These are the essential facts that suggest that the oxidative

metabolism of a resting nerve is in a steady state.

The rate of oxidative metabolism is different in the various types of nerves and does not seem to be directly correlated with the rates of other nerve processes. For example, the motor nerves of a crab have a high resting respiration compared with frog nerves, but the conduction velocity and the capacity for sustained repetitive activity are less in the nerves of the crab than in those of the frog. Furthermore the resting respiration of frog sciatic nerves can vary widely from one preparation to the next without corresponding variation of functional properties.

Since the rate of oxidation in nerve is regulated by enzymes, any modification of the effective enzyme concentration changes the rate of oxidation. Thus sodium azide progressively reduces the rate of respiration of a resting nerve. It is probable that the affected enzyme is cytochrome oxidase. Chloroform and some other narcotics also reduce the oxidation rate. These studies show that the resting respiration may be slowed as much as 30 per cent without rendering the nerve inexcitable. However, further slowing of the oxidative processes, as by anoxia or strong azide solution, will suppress all function.

The action of many chemical agents upon the properties of nerve cells can be traced to interference by the substance with some one of the numerous enzymes. For example, the time course of changes of excitability under the action of strong azide solutions is similar to that following the removal of oxygen. In this instance the sequence of events seems to be (1) slowed metabolism, (2) modification of essential structures, (3) loss of function. As in anoxia, a nerve poisoned with azide can continue to respond to stimuli for about an hour. This time may represent that required to use molecules previously prepared by the oxidative metabolism. However, not all chemical agents affecting the nervous system do so by imped-

ing oxidative metabolism. Some, like cocaine, make a nerve inexcitable without modifying oxygen uptake. Others, like potassium chloride, can make a nerve inexcitable at concentrations that actually increase the oxygen metabolism (Fig. 39).

FIG. 39. The rate of oxygen uptake by a nerve depends on the ionic content of the solutions bathing the nerve. The rate of respiration is always higher in the absence of calcium ions (upper curve) in the bathing fluid than it is in Ringer's solution. Small increments in potassium (K) concentration increase the respiration above that in Ringer's solution, but greater increases depress the respiration. In each test the nerve (frog) was exposed to the test solution for 60 to 90 minutes, and the respiration seemed to have reached a relatively constant rate. At concentrations above 10 millimolar the nerve is inexcitable at this time. (Bronk, Brink, and Davies, 1941.)

The rate of respiration in a resting nerve is regulated also by the concentration of ionized calcium in the fluid bathing it. As previously mentioned, this normal constituent of body fluids affects the excitability of nerves. Thus the threshold value of electrical current decreases with a decrease in concentration of ionized calcium. Over the same range of concentration there has been measured, in frog nerve, an increase in oxygen uptake (Fig. 40). However, there is no general correlation between rate of respiration and threshold.

The rate of oxygen utilization in a resting nerve thus serves to maintain structural re-

FIG. 40. The rate of respiration (as per cent of value in Ringer's fluid) of a frog sciatic nerve increases when the concentration of calcium chloride in the bathing fluid is below 1.0 millimolar. There is an appreciable increase at a concentration that is not low enough to initiate impulses. Lower figure: The excitability of a nerve to electric current depends upon the concentration of calcium ions in the bathing fluid. The changes in threshold occur over the same range of calcium concentrations as do the changes in oxygen uptake. Threshold of α -fibers of sciatic nerve of frog as per cent of rheobase of nerve in Ringer's fluid. Concentrations in millimoles per liter. (Brink, Bronk, and Larrabee, 1946.)

lations in the nerve that are essential to function. The progressive loss during anoxia of the potential difference across the membrane, and its restoration in a few minutes after restitution of oxygen, are the most

direct evidence of this fundamental relation of oxidative rate to the functional state of the nerve membrane (Fig. 41). It has been assumed that the delayed loss of function and of polarization during anoxia is, in part, due to the continuation of energy-yielding reactions in the anoxic nerve. The prolonged decay of heat production (cf. Fig. 38) supports this view. One of the most obscure aspects of neuronal physiology is the molecular mechanism through which oxidative reactions are used to maintain the functional properties of nerves.

Relation of Metabolism to Structure and Function in Neurons

The nerve cell has often been discussed as though the significant properties were located in a membrane at the surface and as though the role of metabolism was to maintain and restore these structures after a period of activity. An alternative view would be that the oxidative metabolism is directly and concomitantly concerned in the phenomena of excitation and conduction. A significant adjustment of our views on this matter has been made possible recently. Many years ago Thörner (1922) discovered that anodal polarization of a length of nerve by an imposed current could delay the loss of excitability during anoxia. This was important evidence for the ability of an inwardly directed current to maintain the excitable structures despite the absence of oxidative metabolism. This initial observation has been remarkably extended in significance through the recent studies by Lorente de Nó (1947). He has demonstrated that a nerve depolarized by the use of metabolic inhibitors, and also made anoxic, can be repolarized by a current flowing inward across the nerve membrane (Fig. 42). When the repolarization is of sufficient magnitude, the repolarized part of the nerve can conduct trains of impulses, even at high frequencies. This restoration of function in the absence of oxidative metabolism has shown that an excitable structure can be formed, provided the

potential difference across the membrane is of the correct direction and magnitude. The molecular elements of the structure must

concerned with establishing and maintaining the normal potential difference across the membrane.

FIG. 41. The membrane potential slowly decreases in the absence of oxygen and is restored when oxygen is again supplied. Compare time course of changes with that of anoxic heat production (Fig. 38). One end of the nerve, electrode *A*, was previously depolarized by KCl to produce the initial demarcation potential. The other electrode, *B*, made contact with an area of nerve bathed in Ringer's fluid (*R*). N_2 indicates that the nerve was in nitrogen, and O_2 indicates that the nerve was in oxygen. The rate of depolarization and recovery was somewhat different in the two successive tests on the same nerve. Second test 24 hours after end of first period of anoxia. (Lorente de N6, 1947.)

FIG. 42. A nerve depolarized by anoxia can be repolarized at an anode by an imposed current from an external source, and can produce an action potential as shown in record 5. As the repolarization progresses, the number of active fibers is increased, as shown by the larger compound action potentials in record 6. The height of the baseline in record 1 measures the resting membrane potential of the depolarized anoxic nerve. The arrow in record 2 indicates onset of anodal polarization. There is no action potential following the stimulus artifact at this time. Four minutes later, in record 5, the lowered baseline indicates restep repolarization. (Lorente de N6, 1947.)

exist for a time in the absence of internal sources of energy. Presumably they are organized by the electric field of force existing in the polarized membrane. On the other hand, the oxidative metabolism is directly

This experiment suggests that there are at least two distinct, but coordinated, membrane structures. One is involved in maintaining the membrane potential difference by converting chemical energy into an electrical

energy, as previously suggested. The other, only indirectly related to oxidative metabolism, is a molecular organization in the membrane that is imposed by the electric field

FIG. 43. The oxygen utilization of the leg nerve of a crab increases after a period of activity. The maximum rate is reached about 8 seconds after a single volley of impulses (lower curve). The maximum rate is higher, the greater the number of volleys produced during the indicated period of stimulation. Numbers on the curves give the number of volleys of impulses. The increase in rate above the resting level was measured by means of an oxygen electrode pressed against the nerve. (Unpublished research by C. M. Connelly, Johnson Foundation, University of Pennsylvania, 1948.)

across the membrane. The latter is the metastable structure whose cycle of change constitutes the nerve impulse. Thus the convenient distinction between the functional and metabolic aspects of nerve processes has experimental justification. The connecting link between the two aspects is the structure in

the nerve membrane that gives it the properties of a battery, i.e. an electromotive force generated from oxidative energy.

Increased oxygen requirements during activity. For a period of time after a nerve has conducted an action potential, the oxygen uptake is increased. In the leg nerve of a crab this increase is large enough to be detected after a single volley of impulses (Fig. 43). In the sciatic nerve of a frog repeated volleys are needed in order that the small amounts of extra oxygen required

FIG. 44. The steady-state rate of oxygen consumption of an active frog nerve increases with the frequency of the conducted impulses but finally reaches a maximum rate. The average quantity of oxygen per volley of impulses decreases over this same frequency range. (Brink, Carlson, and Bronk, unpublished, 1947.) More recent experiments have indicated a more gradual rise in the rate, over the lower frequency range.

be measurable. When a nerve is excited at a constant frequency, the respiration changes to a new constant rate that is greater than that of the resting nerve. The higher the frequency of response, the higher this steady-state rate of respiration. However, at some

upper frequency, usually about 100 per second for frog nerve, the increase in respiration reaches a maximum value (Fig. 44). This limitation on the maximum possible increase in respiration during activity is probably imposed by the limited concentration of enzymes within the fibers.

The increased metabolism of an active nerve is also revealed by the increased output of heat, during and after a period of

changes in the neuron last longer than any hitherto reported changes in the electrical properties. Even the prolonged positive after-potential is over in about one-half hour. However, repetitive activity lengthens the absolutely refractory period; i.e. the rate of recovery after an impulse is slowed. This slowed rate of recovery after each impulse persists as long as an hour in frog nerve. Thus the longest known after-effects of activ-

FIG. 45. The rate of heat production increases when a nerve is stimulated. At the end of stimulation there is an abrupt change in this increased rate. Thus an initial heat associated with the actual period of activity is distinguished from a delayed heat. The latter builds up during the activity (the early phase) and decays slowly after the activity stops (the late phase of the delayed heat). (After Hill, modified from Feng, 1936.)

activity (Fig. 45). Obviously the electrochemical events in the membrane of a nerve can, in turn, cause an increase in the rates of certain chemical reactions in the nerve.

This extra respiration is probably utilized to reverse the structural changes associated with the nerve impulses. However, under the action of sodium azide (10^{-4} molar) this extra respiration of activity is suppressed in frog axons for many hours with no interference with the ability to respond repetitively nor with the resting rate of oxygen utilization. Therefore, the relation of the extra respiration associated with activity to the capacity for sustained function is not clear at present.

Long-lasting metabolic effects of activity. After a short period of repetitive activity the respiration of frog nerve is increased for as long as three-quarters of an hour. These

ity in isolated nerves are increased rate of oxidation and decreased rate of recovery from a test response. Such persistent physical changes are potentially significant for long-lasting functional changes produced by activity in the intact nervous system.

Synaptic Mechanisms

FRANK BRINK, JR.

The Johns Hopkins University

The functional connections between two nerve cells occur at synapses where the terminations of one cell end upon the cell body

and dendrites of a second cell (see Fig. 1). Generally speaking, more than one cell has terminations on a particular neuron, which makes it possible for the effects of activity in two or more neuron pathways to converge and summate (see Fig. 2). Furthermore one neuron may have endings on more than one cell, providing the possibility for distributing the activity of a particular neuronal pathway (Fig. 3). Of importance to the orderly operation of such junctions in the nervous system is the one-way transmission of impulses. Thus a postsynaptic cell excited over one presynaptic pathway cannot, in general, stimulate other presynaptic cells having terminations on it. On the contrary, the stimulating action of a cell is directed solely toward those cells upon which its axon terminates.

FIG. 1A. Histological preparation of a neuron from the spinal cord of a cat, showing the cell body, or perikaryon, the dendrites, and many terminal knobs of the presynaptic axons. B. An enlarged view of a single ending on the cell surface. (Hoff, 1932.)

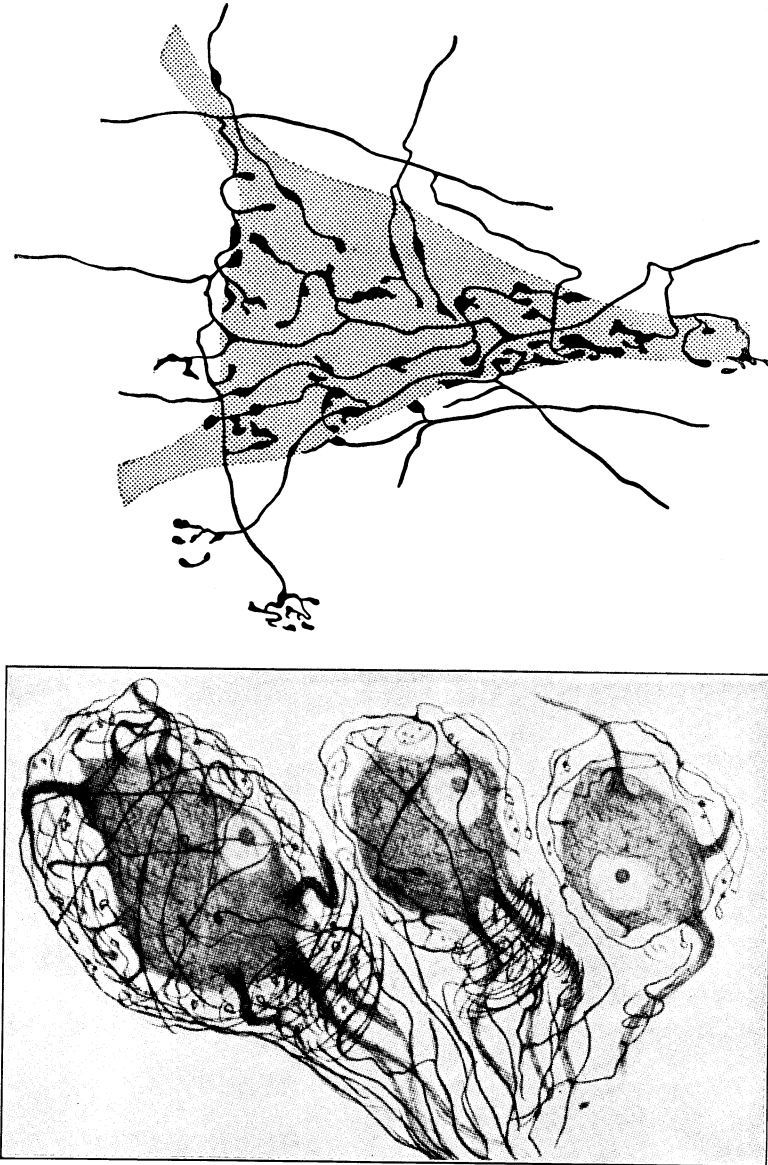

FIG. 2. Upper: Camera-lucida drawing of a motor nerve cell showing that many pre-synaptic fibers have endings on the same cell. (From Lorente de Nó, 1938*b*.) Lower: Three neurons from a stellate ganglion and the tortuous net of presynaptic fibers in their vicinity. (From de Castro, 1932.)

The transsynaptic excitatory effect of a presynaptic impulse may be sufficiently prolonged so that the stimulating actions of more than one impulse in the same presynaptic neuron can contribute to the state of excitation in the postsynaptic cell. At some synapses one presynaptic impulse is not enough to initiate an impulse in the postsynaptic cell; then summation of the effects of several presynaptic impulses is necessary.

FIG. 3. Diagram of a variety of connections between individual presynaptic axons and the postsynaptic cells. Impulses in the branched axon can enhance the stimulating effectiveness in some cells of activity in the other axons.

These fundamental synaptic properties determine, to a considerable extent, the potentialities of the nervous system for integrated activity. It is the purpose of this section to indicate the extent to which these various potentialities for functions have been utilized in the evolutionary development and specialization of such junctions between cells. In addition, the experiments on the physical and chemical mechanism of transsynaptic excitation will be examined.

Neuronal basis of behavior patterns. The experimental psychologist has resolved many complex behavior patterns of organisms into component processes that are employed repeatedly in the functional organization of the nervous system. For example, there is the reflex in which stable functional relations between receptor and effector are based upon rather simple anatomical connections (Fig. 4). The studies of reflex phenomena have

defined clearly several problems requiring analysis in the study of the physical basis of behavior: the physical mechanism* or transducer system, employed to convert environmental forces into neuronal signals; the origin of the time delays in the reflex path; the mechanism for transsynaptic excitation and one-way transmission at a synapse; and, finally, the conversion of nerve impulses into the action of effectors, such as muscle, that is graded in relation to the intensity of the specific stimulus at the receptor.

FIG. 4. The simplest reflex connection between a receptor (R) and an effector (E) involves one neural synapse at C. Other possible connections involving cross-connections and interneurons are shown. (Cowdry, 1932.)

Synaptic Origin of Reflex Properties

In classical reflex physiology there was developed a group of concepts from experiments in which receptors were stimulated and the responses of muscle observed (Creed et al., 1932). These concepts can be defined by the experimental operations by which

* The word physical is considered to include the idea of chemical (molecular) events.

they are demonstrated. A single stimulation of a small group of receptors is often not sufficient to elicit a particular reflex response, but rapidly repeated stimuli of the same strength to the same receptors may succeed in provoking the response. This phenomenon is defined as temporal summation of stimuli. Such temporal summation can be demonstrated not only by stimulating the receptors but also by direct excitation of afferent nerve trunks. Thus, if a small number of sensory (afferent) nerve fibers are directly stimulated by electrical shocks, synchronized volleys of impulses are conducted into the central nervous system. If one volley does not elicit a certain reflex response, repeated volleys may. Therefore temporal summation is not dependent upon the properties of the receptor mechanism. Instead of using the muscle response as the indicator of the reflex effect, we may employ the action potential in the motor (efferent) nerves. It is then found that repeated volleys of impulses in the same afferent nerve may be necessary to elicit a discharge of impulses in the efferent motor fibers. Thus temporal summation, as revealed in reflexes, occurs within the central nervous system. It is a property of the synaptic regions where nerve cells are functionally connected.

In the study of reflex phenomena the electrical excitation of afferent nerves and the recording of action potentials in the efferent nerve have been of great importance. In this way the receptor mechanism and the myoneural junction have been eliminated from the reflex circuit, and the unique dependence of the properties of certain stereotyped reflex patterns upon synaptic mechanisms has been revealed. In this method the intensity of the electric shock determines the number of afferent nerve fibers activated, and the number of motor nerve cells responding is measured by the amplitude of the compound action potential.

This procedure has been employed in the study of spatial summation, another basic

property of reflex mechanisms. The possibility of spatial summation depends upon the anatomical fact that, in general, more than one presynaptic cell has endings upon each postsynaptic cell. Thus a volley of impulses in a few afferent fibers may excite some motor cells. A volley in another group of afferent fibers to the same group of motor cells may also excite some of them. When these two volleys of impulses, over two different afferent pathways, arrive simultaneously at the motor cells, the number responding may be greater than the sum of the separate responses. Some motor cells that do not respond to either of the separate afferent volleys are activated by both of them (cf. Fig. 23). This is spatial summation of the stimulating effects of afferent impulses.

A third phenomenon of reflex physiology that is a property of synaptic mechanisms is facilitation. This concept of facilitation at a synapse is derived from observations in which the number of postsynaptic cells responding to a given afferent volley of impulses is increased in number over some previous control level established after a long period of inactivity. Accordingly facilitation at synapses is based upon a combination of temporal and spatial summation of excitatory processes resulting from the previous activity of presynaptic endings; also, it depends on the recovery cycle of the pre- and postsynaptic neurons.

Spatial or temporal summation of presynaptic volleys are merely mechanisms for the activation of a postsynaptic cell. Consequently the physical basis of these phenomena is but one aspect of the processes of transsynaptic excitation.

In principle, the properties of reflexes mentioned above can be deduced (1) from anatomical knowledge of cellular connections and (2) from detailed information about the time course and the intensity of all the processes underlying synaptic excitation.

FIG. 5. More postsynaptic cells respond to a volley of impulses in a fixed number of presynaptic cells when a sympathetic ganglion is perfused with a solution containing acetylcholine. The number of cells responding is measured by the height of the action potential. Horizontal black line marks period of injection of acetylcholine into perfusion fluid. Second record: 15 seconds later. Third record: 35 seconds later. Time: 0.2-second intervals. (Bronk et al., 1938.)

Factors in Transsynaptic Excitation

In synaptic excitation we are always concerned with the properties of two or more neurons. The response of the presynaptic endings produces a sequence of physicochemical events that modify the immediate environment of the postsynaptic cell. A priori it is to be expected that all these environmental changes affect the postsynaptic cell; they increase or decrease its state of excitation. One environmental factor is the action current of the presynaptic impulses; others include the chemical substances liberated in the surrounding fluid by the incident impulses. For example, in the sympathetic ganglia of the cat presynaptic activity leads to the release of potassium ions (Vogt, 1936) and of acetylcholine into the fluids bathing the postsynaptic cells (Dale, 1936a, b; Feldberg and Vartianen, 1935; MacIntosh, 1938). The excitatory effect is dependent upon the intensity of each of these environmental changes and the specific sensitivity of the postganglionic cell to each kind of change.

In the stellate ganglion small amounts of acetylcholine or potassium chloride perfused through the ganglion cause an increase in the number of postganglionic cells responding to a standard preganglionic volley of nerve impulses (Fig. 5). This increase is probably due to a change in the postganglionic neurons; indeed, larger concentrations of acetylcholine or of potassium chloride can excite these cells without the additional action of preganglionic impulses (Fig. 6). Corre-

spondingly the frequency of response of a postganglionic cell to a constant frequency of preganglionic impulses depends upon the

FIG. 6. Postganglionic cells respond repetitively to an adequate concentration of acetylcholine perfused through a sympathetic ganglion. The frequency of impulses in a single fiber increases with the concentration of acetylcholine. Concentration in micrograms per cubic centimeter are: A, 25; B, 50; and C, 100. (Bronk, 1939.)

concentration of calcium ions in the solution bathing the cells (Fig. 7). Hence it is clear that the stimulating effects of impulses and of local chemical changes can summate at synapses.

The stimulating action of acetylcholine is restricted to the postsynaptic cell, for even

large concentrations do not excite the pre-synaptic axons. But other chemical changes are not so specific. For example, a sufficient lowering of the calcium ion concentration, by

increase in calcium ion concentration reduces the frequency of response to acetylcholine (Fig. 8). The change of sensitivity to this chemical agent is parallel to the

FIG. 7. The frequency of response of a postsynaptic cell to a constant frequency of pre-synaptic volleys is reduced by increasing the calcium concentration in the perfusion fluid. Impulses discharged by a few sympathetic ganglion cells in response to stimulation of the preganglionic nerve at a frequency of 50 per second. The ganglion was perfused with a modified Ringer's solution containing various amounts of calcium chloride: Upper record, 4.4 millimolar; middle record, 2.2 millimolar; bottom record, 1.1 millimolar. The middle record represents the normal level of calcium. Time: 0.1-second intervals. (Brink, Bronk, and Larrabee, 1946.)

means of sodium citrate, leads to changes that initiate impulses in both the pre- and postsynaptic cells.

The frequency of response of a postganglionic neuron to a given concentration of acetylcholine depends upon other chemical constituents of the perfusion fluid that influence the excitability of the cell. Thus an

change in sensitivity to electrical currents exhibited by axons when the calcium ion in the bathing fluid is varied (Chapter 2, Fig. 31). Similarly a postganglionic cell exposed to high concentrations of potassium ion and acetylcholine will respond more frequently than when the potassium concentration is lowered. Thus the stimulating and inhibit-

ing actions of chemical substances are compounded to determine the response of a neuron.

The flow of action currents associated with presynaptic impulses, the release of chemical substances, the state of excitation of the postsynaptic cell determined by the prevailing environmental influences, all combine to determine whether or not transsynaptic ex-

currents of the presynaptic terminals, the effectiveness of this stimulus depending upon the excitability of the postsynaptic cell as determined in part by chemical products of previous presynaptic activity. This proposition suggests that the specific chemical events contribute mainly to facilitation and after-discharge. It seems probable, however, that at some junctions between cells the

FIG. 8. The degree of excitation of a single ganglion cell by perfused acetylcholine, measured by the frequency of the action potentials, depends upon the concentration of other ions in the perfusion fluid. Time: 0.1-second intervals. (Bronk, 1939.)

citation initiates an impulse (Bronk, 1939). Therefore the physical explanation of synaptic excitation consists of a quantitative evaluation of the intensity, time course, and stimulating effectiveness of potentially significant changes in at least these component processes which, in turn, are modified by other changes that reduce the stimulating effectiveness of presynaptic volleys.

Studies of particular synaptic mechanisms have confirmed this multiple-factor hypothesis. There are, however, differences of opinion concerning the quantitative significance of the effects of electrical fields at synapses as contrasted with the actions of specific chemicals. An important phase of this discussion is the thesis that the immediate transmitter agent is always the action

currents are the most significant aspect of the transmitter action of presynaptic impulses, whereas at others the chemical events predominate.

Analysis of Transmission at Synapses

The essential fact for which a physical explanation is sought is that a sufficient amount of activity in presynaptic endings can initiate a nerve impulse in the postsynaptic cell. The excitatory effectiveness of presynaptic activity depends upon the number of active endings on a particular cell, the intensity of the transsynaptic stimulus developed at each ending, the excitability of the postsynaptic cell near each ending, and the area of the cell that must respond to insure the initiation of a postsynaptic impulse.

The detailed analysis of these components of the synaptic mechanism is far from complete.

As in the study of axons, some preparations are more favorable than others for revealing particular aspects of synaptic transmission. For example, a desirable simplification is obtained if the amount of activity in the presynaptic fibers is directly controlled and the activity of the postsynaptic cells directly measured. This is accomplished in studies of synaptic transmission in the sympathetic ganglia where the presynaptic fibers end on cell bodies of the postsynaptic axons in which the response is measured. This is also true of monosynaptic reflex pathways through the spinal cord. In these preparations the properties of synapses are revealed without undue interference from more complicated phenomena caused by interneurons that form additional pathways leading to the postsynaptic cells in which the response is measured.

The most favorable experimental arrangement for some studies is a preparation in which a single presynaptic fiber excites a single postsynaptic neuron. A simple synapse of this sort has been discovered in the nervous system of the squid.

In the giant fiber system of the squid it is possible to record the electrical changes near the junction between two fibers. The initiation of a conducted action potential in the postsynaptic axon by an impulse in the presynaptic axon is preceded by a local electrical change in the postsynaptic cell (Fig. 9). Thus initiation of the postsynaptic activity seems to occur by way of the same physical mechanism that is responsible for direct excitation of an axon by an electric current (see Chapter 2, Fig. 17). The time relations between the postsynaptic local response and the presynaptic impulse are such that the action current of the latter could be the primary stimulus to the postsynaptic axon.

This conclusion is further supported by the fact that artificial synapses between two

fibers have similar properties. These artificial synapses can be made by appropriate contact between two axons; specialized parts

FIG. 9. Potential changes near the synapse between a pair of giant fibers in the stellate ganglion of a squid. The presynaptic fiber was excited by electrodes shown as vertical lines at the left of the inset diagram. The lower trace is the action potential of the presynaptic fiber recorded at the middle pair of electrodes in inset diagram. The upper trace is the simultaneous record from the postsynaptic axon near its exit from the ganglion at the right-hand pair of electrodes in inset. The upward trace (going off the record) is due to the first electrode becoming negative, and the subsequent downward trace signals the arrival of the impulse at the last recording electrode. Responses to repeated volleys are superimposed. The conducted diphasic action potential occurs later and later and seems to arise from the top of a monophasic potential, which persists even when the conducted response finally fails. This monophasic potential is the local electrical response to the stimulatory action of the presynaptic impulse. (Bullock, 1948.)

are not essential (Jasper and Monnier, 1938; Arvanitaki, 1942). At this artificial junction the electric current from the electromotive force in the presynaptic axon seems to be the principal transmitter agent responsible for the functional connection between the two

neurons. We are left, however, without a satisfactory explanation of the one-way transmission across natural synapses between giant fibers.

A local depolarization and a reduction of impedance (Katz, 1942) also occurs at the

13). Temporal summation of the stimulating effects of the nerve impulses thus takes place in the muscle cell. When the electrotonic potential at the endplate is great enough, an action potential is initiated in the muscle cell.

FIG. 10. Termination of a motor nerve on a single muscle fiber of a frog. The enlarged ending is the endplate. One recording electrode makes contact with the muscle near this endplate region, while the other is placed at a distance on the muscle. (Kuffler, 1942a.)

endplate in muscle cells following an impulse in the motor nerve endings (Figs. 10, 11, and 12). The associated flow of current from adjacent areas of the muscle membrane creates electrotonic changes of potential along the muscle membrane near the endplate. The duration of this change of potential is revealed by partially curarizing the preparation so that one nerve impulse is not sufficient to cause an action potential in the muscle (Fig. 12). In a curarized preparation repeated nerve impulses will increase the electrotonic potential in the muscle (Fig.

The action current of the presynaptic ending precedes by a short time this endplate potential in the muscle cell (Kuffler, 1948). And the local electrical change is the earliest known transsynaptic response to the presynaptic activity. The short time interval between them may represent the time required for the development of the changes in the muscle that lead to a local response—like the utilization time following a short shock to a motor nerve of a crab. On the other hand, this time interval may be in part the time required for the production and ac-

tion of a transmitter agent that is physically distinct from the action currents of the motor nerve ending.

The existence of such a transmitter agent has been demonstrated. This agent is pro-

the local endplate potential can reappear after the muscle action current has passed the endplate. Therefore an agent that initiates the local electrotonic potential in the muscle was still present after the action cur-

FIG. 11. Magnified view of histological preparation of endplate region. *A*: The terminations of a single fiber (bat) are spread diffusely on the muscle. *B*: The endplate (cat) is a complex structure containing the end of the motor nerve. (Cowdry, 1932.)

duced by motor nerve impulses but acts longer than the associated action currents (Kuffler, 1948). It initiates the local electrotonic potential by depolarizing the muscle cell at the endplate. Proof of its duration depends upon two facts: (1) when the muscle cell is stimulated directly, the action potential sweeping over the endplate region wipes out the local electrical change in the muscle; (2) if this occurs shortly after the action current in the motor nerve, part of

rents in the motor nerve had ceased. On the other hand, if the muscle response to direct excitation wipes out the endplate potential at a later stage of its development, then this potential does not reappear. The duration of the action of the active transmitter agent is thereby measured and is found to be about 5 milliseconds (Kuffler, 1942*b*).

The measured period of active depolarization by the transmitter agent is brief compared to the duration of the recorded elec-

FIG. 12. A single impulse in a motor nerve (frog) produces an electrotonic potential in the muscle that is confined to the neighborhood of the endplate. The muscle action potential is in turn produced by this endplate potential. Under curare only the local electrical change occurs in the muscle (top record). As the curare action is reduced, the successive traces show the development of the conducted muscle action potential. This action potential occurs earlier, the lower the concentration of curare. In a normal muscle all but the beginning of the endplate potential is obscured by the action potential (bottom record). There is a delay of about 0.5 to 1.0 millisecond between the arrival of the nerve action potential and the beginning of the electrical change in the muscle. Temperature, 22 degrees C. (Kuffler, 1942a.)

trotonic endplate potential in the muscle. This is indicated also by an analysis of the time course of the recorded electrotonic endplate potential. The time course of the stimulus causing the redistribution of charge on the membrane of the muscle can be calculated by means of equations worked out for electrotonic effects in peripheral nerve (Hill, 1936). In this way the transmitter ac-

FIG. 13. In a curarized myoneural junction the local electrical changes produced in the muscle by two successive nerve impulses are added. This temporal summation of the excitatory effects of nerve impulses can increase the endplate potential so that a muscle action potential is finally produced, if the concentration of curare is not too great. (Eccles, Katz, and Kuffler, 1941.)

tion is found to have a rapid rise, reaching its maximum in about 2 milliseconds and decaying by the end of 5 milliseconds (Fig. 14). Hence the calculated duration of the transmitter action agrees with the measured value.

The duration of the transmitter action is increased by eserine (Eccles, Katz, and Kuffler, 1942) and decreased by curarine (Kuffler, 1942b; Eccles, Katz, and Kuffler, 1941). These chemical facts suggest that the agent depolarizing the muscle cell at the endplate is acetylcholine.

According to a recent interpretation of the available facts (Kuffler, 1948; Acheson, 1948), the significant transmitter agent in the normal myoneural junction of frogs and

of cats is acetylcholine. However, at synapses in the central nervous system the chemical component of the transmitter action is thought to be of negligible importance compared to the direct effect of the action currents from the presynaptic nerve endings (Eccles, 1947). Indeed, the properties of all myoneural junctions are not readily explained either by the acetylcholine

impedance (the local response) in the muscle, and (4) the initiation of a conducted action potential by the electrotonic current developed from the local response.

Anatomically, the usual connections between nerve cells do not resemble the two kinds of intercellular junction just discussed. There are many terminations on each postsynaptic cell, and the terminal enlargements, or knobs, are contributed by several presynaptic neurons. There is considerable evidence that the combined action of single impulses in each of several presynaptic fibers is required to excite a postsynaptic cell. Nevertheless it is probable that electrochemical events similar to those described for the simpler junctions occur at each region of contact between the terminal knobs and the dendrites or cell body of the postsynaptic neuron. According to this hypothesis, the principal additional factor to be considered in this complex synaptic mechanism is how the local responses at each junction add to produce excitation in the postsynaptic axon.

If local responses occur in the postsynaptic cell, electrotonic potential changes would spread along the postsynaptic axons. In the cardiac nerve of the stellate ganglion, or in a ventral root of the spinal cord, such axons are compactly arranged in bundles a short distance from the cell bodies. This part of the nerve should be negative to more distal parts whenever the cell bodies are partly depolarized. As a matter of fact, such electrotonic signs of local electrical responses have been measured in motor neurons (Bonnet and Bremer, 1938; Barron and Matthews, 1936, 1938; Eccles, 1946; Brooks and Eccles, 1947*a*) and in ganglion cells (Eccles, 1943, 1944).

Since the conducted response of a postganglionic cell, like that in muscle tissue, will obliterate the local response, it is necessary to prevent the postsynaptic action potential. Mild curarization is employed for this purpose in the stellate ganglion. In the absence of the postsynaptic action potential there is only the prolonged local electrotonic

FIG. 14. The local electrical change in a muscle lasts for about 25 milliseconds (dotted line) and is produced by a transmitter (solid line), or depolarizing agent at the endplate, that achieves its maximum action in 2 milliseconds and is finished in about 5 to 8 milliseconds. These events begin 0.5 to 1.0 millisecond after the arrival of the nerve action potential. (Eccles, Katz, and Kuffler, 1941.)

mechanism of transmission or by the direct effects of the action currents. The possibility of a dual mechanism, involving both kinds of transmitter agents, has been discussed (Monnier, 1936). The proper emphasis is probably attained if the previous evidence is considered to indicate merely the predominant role of acetylcholine in transmission at neuromuscular junctions of skeletal muscle in cats and frogs. This leaves open the possibility that other substances, or the action currents themselves, may play the significant role at other neuromuscular junctions (Pantin, 1937).

To summarize, neuromuscular transmission involves four steps: (1) the response of the nerve terminals, (2) the production of a chemical transmitter agent, (3) the development of a local depolarization and change of

potential in the postsynaptic neuron (Fig. 15, curve *B*). This occurs with an estimated latency of about 4 milliseconds after the arrival of the presynaptic volley at the synapses. The maximum amplitude is reached

preganglionic volley produces only a sub-threshold postsynaptic local response. Repeated volleys will, however, add to the local potential change, and finally the summated electrical changes cause a postsynaptic ac-

FIG. 15. The upper trace, *A*, is the potential recorded from a stellate ganglion of a cat at the point of emergence of the postsynaptic nerves when they are excited by a single presynaptic volley of impulses. The conducted action potential spike is followed by a prolonged positive after-potential. When the preparation is curarized only an electrotonic potential, *B*, originating in or near the cell bodies of the ganglionic neurons, occurs in response to a preganglionic volley. This local electrotonic potential is called the synaptic potential. Time marks: 10-millisecond intervals. (Eccles, 1943.)

FIG. 16. The calculated transmitter action in the stellate ganglion, reaching its maximum in about 2 milliseconds, decays rapidly at first and then slowly over a period of 50 milliseconds. The recorded synaptic potential in the muscle lasts much longer. Ordinate for the transmitter action is arbitrary. (Eccles, 1943.)

in 10 to 20 milliseconds, and it drops to half-value in 90 more milliseconds (Fig. 16). Thus the time course of this electrotonic potential in a cat's stellate ganglion is longer than the similar physical changes at the end-plate in a muscle of a cat.

The postsynaptic action potential occurs whenever this synaptic potential is of sufficient magnitude (Eccles, 1943). In the curarized stellate ganglion a single maximal

potential. Thus the temporal summation of preganglionic volleys shows up as the addition of electrical changes in the postsynaptic cell. Since the local synaptic potential lasts about 0.2 second, this is the longest permissible interval between volleys if they are to add their effects by this mechanism.

There are no direct experiments to indicate how long the transmitter agent pro-

ducing the local electrical response acts. By indirect procedures, based upon Hill's excitation theory, it has been calculated that the local electrotonic changes are produced by an agent that acts upon the postsynaptic cell for 50 milliseconds (Fig. 16). The physical nature of this transmitter action is unknown, but it is composed of a rapid intense part that decays in about 20 milliseconds and a small slow component lasting as long as 50 milliseconds (Fig. 16). Eccles (1944) has suggested that the initial phase, reaching a maximum in 2.5 milliseconds, is the stimulus due to action currents in the presynaptic terminals. (The action currents arising in different fibers are assumed to be asynchronous and hence more prolonged than that of a single impulse.) He further suggests that the slow component of the transmitter action is due to the chemical products of presynaptic activity that depolarize the postsynaptic neuron.

The synaptic potentials and the associated transmitter action that have just been described occur after one or two impulses. However, if a train of presynaptic impulses at high frequency (50 per second) impinges upon the ganglion cells, the electrotonic potential is more prolonged and may persist for several seconds. Analysis of this prolonged synaptic potential indicates that an additional transmitter agent is accumulated under these conditions. This component of the transmitter agent is greatly prolonged when the cells are bathed in solutions containing eserine to inhibit the cholinesterase. It seems, therefore, that the accumulation of acetylcholine, as a result of frequent presynaptic impulses, causes this prolonged depolarization of the ganglion cells. In contrast, the transmitter action occurring after a single volley of presynaptic impulses is not changed by eserine. Thus there seem to be several transmitters of transynaptic excitation in sympathetic ganglia.

In résumé, synaptic transmission after a single presynaptic volley of impulses in the stellate ganglion seems to occur in four prin-

cipal steps, each having a characteristic time course. (1) The presynaptic action potentials arrive asynchronously at the terminals, and action currents flow for 20 milliseconds or less, leading to excitatory effects in the postsynaptic cells. (2) The chemical component of the synaptic transmitter action persists for at least 50 milliseconds, having a prolonged excitatory effect. (3) Under the action of these combined excitatory processes there occurs a local response at each active synapse on a postsynaptic cell, causing an electrotonic potential change that rises slowly to a maximum at 20 milliseconds. (4) However, if the total excitation is adequate, the conducted action potential develops early, in response to the rapid phase of the transmitter action, and the synaptic potential is barely measurable.

Further considerations concerning acetylcholine. Another set of facts seems to place a rather different emphasis upon the significance of acetylcholine as a component of the transmitter action in sympathetic ganglia. As Dale (1939) has emphasized, the facts to be enumerated must be either controverted by further experiments or encompassed by the electrical hypothesis of transmission.

1. Acetylcholine is released in significant amounts by nerve activity in sympathetic ganglia as well as at myoneural junctions.

2. The stimulating action of a presynaptic volley of impulses is blocked by curarine at the same concentration at which the postsynaptic cells become insensitive to applied acetylcholine. At this time the cells can be excited by applied potassium chloride.

3. In the prolonged absence of metabolic substrates the synthesis of acetylcholine stops and transmission is also blocked. Both transmission and acetylcholine synthesis are restored when glucose, or other substrate, is added to the perfusion fluid.

4. In the absence of calcium ions in the perfusion fluid the release of acetylcholine by presynaptic activity is stopped and so is transmission.

The second of these observations can be adversely criticized. In order to offer such an experiment as controverting the electrical hypothesis, it would be necessary to show that curarine does not decrease the sensitivity of postsynaptic cells to electrical currents. The response to potassium chloride is an unsatisfactory control in this connection, for this agent can excite axons, and the curarine may act only at the synaptic regions. A rather similar experiment was reported by Bronk, Larrabee, and Gaylor (1948). In this instance anoxia caused a failure of transmission through the stellate ganglion at the same time that the direct excitation of ganglion cells by acetylcholine failed. However, this result could be caused by the cells becoming insensitive to all stimuli.

The third and fourth observations are also open to analogous criticism, for it is possible that the imposed environmental changes eliminate all response of the presynaptic nerve endings, including the action potential as well as acetylcholine liberation.

Hence the difficult and provocative question of the importance of acetylcholine in synaptic transmission in sympathetic ganglia remains unanswered. Nevertheless the ingenious experimentation that has been devoted to this problem has uncovered many important facts about nerve cells and synapses.

Nachmansohn (1946) has recently proposed an hypothesis, regarding nerve conduction and transmission, that attempts to unify the chemical and electrical theories. This hypothesis proposes acetylcholine as a depolarizing agent that is released from the postsynaptic cell by the action currents of the presynaptic terminals. The free acetylcholine then causes the local electrical response by its depolarizing action on the cell membrane. Subsequently it is resynthesized into a bound form, but some of it inevitably diffuses away from the reaction site. It is this

latter portion that is detected in a perfusate, provided its destruction by cholinesterase is prevented.

Summation of Stimuli in Sympathetic Ganglia

Only under the action of a substance like curare has the full time course of the local electrotonic potential been directly demonstrated in ganglionic cells and the dual transmitter action deduced therefrom. However, the operation of several excitatory processes in normal ganglia can be indirectly revealed by studies of subliminally excited ganglion cells (Eccles, 1944). The time course of such excitation processes is revealed by facilitation developed through temporal and spatial summation of the effects of presynaptic impulses.

Of the several electrical processes occurring after the arrival of a preganglionic volley that does not initiate an impulse in a postganglionic cell, the synaptic potential is the most prolonged. The total duration of this physical effect in the postganglionic cell is less than 200 milliseconds in cells of the stellate ganglion of a cat. Therefore these local electrical changes show no significant overlapping when the preganglionic volleys occur at five per second or less. But temporal summation of individually ineffective afferent volleys occurs at much lower frequencies (Larrabee and Bronk, 1947).

The quantitative aspects of this summation can be studied particularly well if a response of a single postsynaptic cell is recorded. Thus in a sympathetic ganglion an occasional volley of impulses in a restricted group of presynaptic fibers may be unable to excite a particular postsynaptic cell. However, if the frequency of the impulses over the same presynaptic pathways is increased, their stimulating effects are summated until one of them finally causes a response in the postsynaptic neuron. At higher frequencies the first response of the postsynaptic cell occurs sooner and after fewer presynaptic volleys (Fig. 17). In such an experiment each re-

sponse of the single cell is related in time to a particular volley of presynaptic impulses. It seems that each volley contributed a transient change at some part of the synaptic mechanism. If a second volley occurs before this change has subsided, it adds its effect. Finally, a particular volley causes the discharge of an impulse.

located in the endings of presynaptic fibers.

In support of this view, the detailed study of prolonged facilitation in stellate ganglia has suggested that the stimulating effectiveness of a preganglionic volley can be enhanced as an after-effect of a previous volley (Larrabee and Bronk, 1947). Such prolonged facilitation can be revealed only by

Fig. 17. Impulses discharged by a ganglion cell in response to volleys of presynaptic impulses repeated at various frequencies. The presynaptic impulses were initiated by supramaximal stimulation of the thoracic sympathetic trunk, between the fourth and fifth roots, at instants indicated by the short vertical lines above the time marks (0.1 second). The first stimulus in each record was applied after a long period of rest. In *A* the postsynaptic cell did not respond to any of the presynaptic volleys. Temporal summation of four volleys at 0.5-second intervals was required to produce the first response, shown in *B*. At higher frequencies of preganglionic volleys, fewer were needed to initiate the first impulse in the postsynaptic cell. (Larrabee and Bronk, 1947.)

Consequently either the after-effects of a single volley must produce subthreshold excitatory changes in the postsynaptic cell that persist more than 0.5 second, or else the stimulating effectiveness of successive preganglionic volleys at these low frequencies must increase. The first explanation is excluded because a prolonged after-effect due to a volley cannot be demonstrated by the spatial summation of impulses in preganglionic fibers. In order to demonstrate this prolonged subthreshold effect it is necessary that the successive volleys enter the ganglion over the same presynaptic fibers. It is very probable, therefore, that the persisting change is

the changes in the response to a standard testing volley that enters the ganglion over the same preganglionic fibers used to condition the synaptic mechanism (Fig. 18).

These latent modifications of the synaptic mechanism occur even after a single supramaximal stimulus to a given group of preganglionic axons. Such a stimulus insures that a constant number of preganglionic fibers are stimulated in conditioning and in testing. The changes in the excitatory effectiveness of these fixed volleys of presynaptic impulses are measured by the number of ganglion cells responding, i.e. by the height of the postganglionic compound action poten-

FIG. 18. Impulses from a ganglion cell in response to single and to rapidly repeated volleys in a constant number of preganglionic fibers. Arrows indicate application of single supramaximal stimuli to the preganglionic nerve, once every 5 seconds. No impulses were discharged when these stimuli were applied for more than a minute. The lack of response to the last two stimuli is shown at the beginning of the figure. The preganglionic stimuli were then repeated at the rate of 50 per second for about a second (indicated by bracket), causing one of the cells to discharge six impulses. The facilitating effects of this high-frequency stimulation did not disappear at once, for the cell was able to respond to a single volley after as long as 10 seconds. After 15 seconds it was no longer possible to excite the cell by single volleys at 5-second intervals. Time: 0.1-second intervals. (Larrabee and Bronk, 1947.)

tial. At short intervals after the conditioning volley there is an increased number of ganglion cells activated by the testing volley. After 0.2 second there is a period of depression, and fewer cells respond. Then from 0.4 second onward the period of prolonged facilitation occurs (Fig. 19).

The conditioning volley obviously excited some cells to activity and others to a sub-threshold degree. A testing volley imposed in less than 0.2 second is thus able to excite more ganglion cells when those responding to the conditioning volley have recovered their excitability. This summation of sub-threshold effects at these short intervals has been correlated with the previously described local electrical changes in the ganglion cells (Eccles, 1944). At longer summation intervals the reduced excitability associated with the positive after-potential develops in the cells responding to the conditioning volley (Eccles, 1935). Then there are fewer cells responding to a test volley, because the number depressed by this after-effect of post-synaptic activity is greater than the number recruited by temporal summation of subliminal excitatory processes. Thereafter, the period of prolonged facilitation can be traced for as much as 10 seconds after a single conditioning volley.

This facilitation process, which can last for minutes after a prolonged period of stimula-

FIG. 19. Variations in the number of ganglion cells responding to a preganglionic volley following a single conditioning volley of preganglionic impulses. Both conditioning and test volleys were initiated by a single supramaximal shock to the third preganglionic ramus. Ordinate: ratio of postganglionic spike height in test response to the spike height in conditioning response. Abscissa: intervals between conditioning and test responses. Open circles show that there is little difference in height of spike in response to test and conditioning volleys when both are applied directly to the postganglionic nerve. (Larrabee and Bronk, 1947.)

tion (Figs. 20 and 21), does not seem to be associated with any electrical change. Nor is there direct evidence for its exact location

within the synaptic mechanism. However, Larrabee and Bronk (1947) have eliminated as explanations (1) persisting chemical activators and (2) persisting changes in the state of excitation of the postganglionic cell. The

When facilitation is caused by changes in the postsynaptic neuron, then both spatial and temporal summation can be effective in increasing the number of cells responding to successive presynaptic volleys. This circum-

FIG. 20. Action potentials recorded from the postganglionic nerve trunk before, during, and at the indicated times following a 10-second period of repetitive activity. In *A*, supramaximal stimuli were applied to a preganglionic root; in *B*, to the postganglionic nerve. The larger spike potentials following the train of repetitive activity in *A* are due to the response of a larger number of ganglion cells. Time marks on lower edge of record indicate 0.2-second intervals. (Larrabee and Bronk, 1947.)

FIG. 21. Time course of prolonged facilitation after various durations of repetitive stimulation of a preganglionic nerve at a frequency of 24 per second. Ratio of spike height of postganglionic action potential to height of response to a similar preganglionic volley after a long period of rest (control response) is plotted against time after the final conditioning volley. All testing and conditioning volleys were initiated by supramaximal stimuli to a preganglionic root. (Larrabee and Bronk, 1947.)

authors suggest that prolonged facilitation is caused by a change in the preganglionic terminals whereby the stimulating effectiveness of an impulse is enhanced as a result of previous responses.*

This view emphasizes the importance of temporal summation in synaptic facilitation.

* Since the completion of this chapter this same type of facilitation has been discovered in the monosynaptic pathways through the spinal cord (Lloyd, 1949).

stance provides a unique experimental differentiation between pre- and postsynaptic mechanisms of facilitation. If the facilitation can be obtained by the spatial summation of two volleys in each of two separate presynaptic pathways, then it can not be caused by changes in the presynaptic cell terminations.

All the known components of the synaptic mechanism have thus been introduced to

explain one or another aspect of synaptic function. The early period of facilitation is mainly attributed to summation of sub-threshold excitatory processes in postsynaptic units and to the addition of transmitter actions. The period of depression is attributed to the reduced excitability of the post-

nisms, inhibition occurred only as an after-effect of a response of the postsynaptic neurons. It was part of a recovery cycle. To explain central inhibition, based on only this kind of inhibitory mechanism, elaborate schemes have been devised involving complex neuron networks. Now it is known that

FIG. 22. Facilitation of the biceps reflex by an afferent (conditioning) volley from a small branch of the biceps nerve. *A* and *O*: Biceps reflex in response to test shock, applied to large branch only. *B* to *N*: Biceps reflex when the volley in the large branch occurs coincident with and at various intervals after the arrival of the conditioning volley in the small branch. The conditioning volley by itself evokes no reflex response. (Lloyd, 1946*a*.)

synaptic cells during the recovery cycle. The prolonged facilitation is attributed to residual changes in the presynaptic terminals and is an after-effect of previous activity therein.

Facilitation and Inhibition in the Spinal Cord

A prominent feature of coordinated neuronal events in the central nervous system is the inhibition of activity in one group of neurons during excitatory action in another group. Thus the motor neurons to a flexor muscle are inhibited during excitation of neuron pathways to an extensor muscle. In the previous discussion of synaptic mecha-

presynaptic activity can have a direct trans-synaptic inhibitory action on a postsynaptic cell that is not an after-effect of an impulse in this cell (Lloyd, 1941).

The motor cells of a monosynaptic reflex pathway are innervated by excitatory afferent nerve endings. The synapses involved have some properties similar to those described in the general discussion of synaptic mechanisms except that, in the central nervous system, processes occur faster than in sympathetic ganglia. Thus the early facilitation (Lloyd, 1946*a*) related to electrical events in the postsynaptic cell (Brooks and

Eccles, 1947b) is over in about 13 milliseconds (Figs. 22 and 23). In addition there

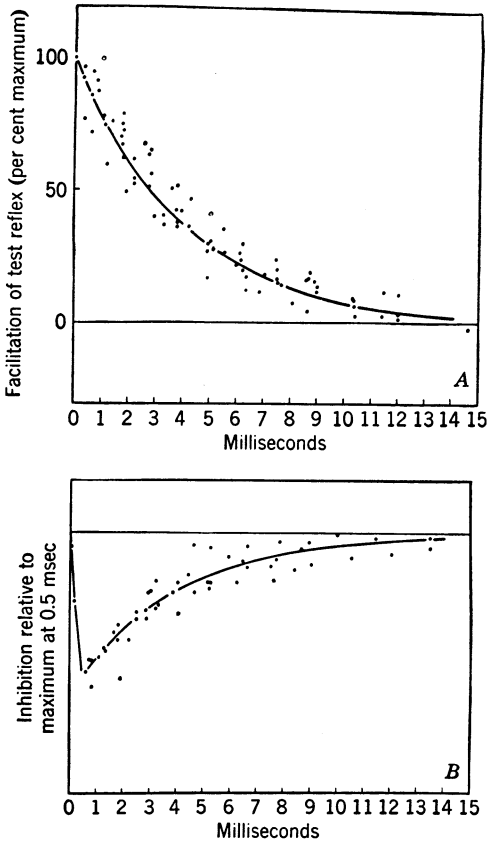

FIG. 23A. Facilitation of motor neurons by impulses in primary afferent fibers. Data from seven experiments (four for flexor and three for extensor nuclei) are scaled on the ordinate to coincide at the time of maximum facilitation. An individual experiment on facilitation is shown in Fig. 22.

B. Inhibition of motor neuron by impulses in primary afferent fibers. Points from four experiments are scaled to coincide at an interval of 0.5 millisecond between the conditioning volley and the test volley. Three experiments were concerned with flexor nuclei, the remaining with an extensor nucleus. (Lloyd, 1946a.)

are types of inhibitory nerves that end on motor neurons where they supply impulses that make the postsynaptic cell less sensitive

to presynaptic activity of the excitatory endings. The time course of this inhibitory action has a finite rising phase and then declines along a time course similar to that for the decline of facilitation (Fig. 23).

The combination of the excitatory and inhibitory effects probably occurs on the postsynaptic neuron. Although the physical nature of the inhibition is not so well known as is that of excitation, an electrical mechanism has been proposed (Brooks and Eccles, 1947). Many experiments are suggested by analogy with studies of the excitatory mechanism. For example, it is not known whether the inhibitory afferents will suppress activity of a motor neuron excited directly by chemicals or whether the inhibition affects primarily the transsynaptic excitatory processes. Here we are definitely on the frontier of the science of neuronal action.

Transmitter Actions at Different Synapses

The transmitter agent is the immediate stimulus causing the response in the postsynaptic neuron. The duration and intensity of the action of the transmitter is deduced from the time course of the electrotonic potentials recorded from the postsynaptic cell. As previously discussed, when this method is employed, the effects of the response of the postsynaptic cell must be eliminated, for the action potential of this neuron obscures the recorded synaptic potential.

In the stellate ganglion of a cat the transmitter action is composed of a brief intense part associated with the asynchronous action currents of the many presynaptic endings. Thereafter there is a slower component that outlasts these action currents. This second phase of the transmitter action is attributed to chemicals, released by the presynaptic activity, that can depolarize the postsynaptic cell. The dual nature of the transmitter action is deduced from the time course of the electrotonic potential in postsynaptic axons. Another interpretation of the form of this synaptic potential is that the local electrical response of the postsynaptic cell has a slow

component caused by the stimulating effect of the presynaptic action currents. Such slow changes of membrane potential difference following brief pulses of current have been observed in peripheral nerve (Lorente de N6, 1939). If this is the explanation, the transmitter agent is solely the brief flow of electric current from the electromotive force in the presynaptic terminals. Then the prolonged component of early facilitation is entirely attributed to the addition of long-lasting local changes in the postsynaptic cell.

At some synapses of the central nervous system spatial summation of afferent volleys is not possible unless these volleys arrive at the neuron within 0.5 millisecond of each other. Both the transmitter action and the postsynaptic local response must be of very brief duration. This seems to be a response that lasts for less time than the spike component of the presynaptic action potential. At such synapses temporal summation of effects is impossible, for the absolute refractory period of the presynaptic fibers is longer than the stimulating effect of the previous impulse. Such synapses have been demonstrated in the oculomotor nucleus (Lorente de N6, 1939).

Other synapses of the central nervous system, as described previously, exhibit spatial summation for as long as 13 milliseconds. This is correlated with the duration of the prolonged local electrotonic potentials in the postsynaptic neurons.

Early facilitation at all synapses is composed of a very brief component attributed to the summation of the effects of the action currents in the many presynaptic terminals. In some central synapses and in sympathetic ganglia there is a second component to the early phase of facilitation. This is attributed to the time course of the postsynaptic local electrical response or perhaps to a second slow component of the transmitter action. Finally, at synapses in sympathetic ganglia there is a third very prolonged component to facilitation that is attributed to persisting changes in the presynaptic endings. These

changes are such that the transmitter action of the next volley of impulses is enhanced. How the transmitter action is thereby increased has not been determined (cf., however, Lloyd, 1949).

These observations support the previous statement that experimental studies are required to discover how many of the potentially significant synaptic processes are utilized in the functioning of each synaptic region.

The relation of irritability cycle to facilitation and inhibition. Thus far in the study of facilitation and inhibition the proposed mechanisms have emphasized events preliminary to the occurrence of a postsynaptic response. However, the irritability changes associated with the recovery of the postsynaptic cells from activity are potentially important to facilitation and inhibition. Suppose, for example, that a subthreshold stimulus is acting upon a cell when this cell is excited through other channels. We might expect that during the negative after-potential following the response the previously subthreshold stimulus would become effective. In this way the weak stimulus would keep the cell active until accumulated subnormal excitability again drops it out of action (Erlanger and Gasser, 1936). The period of subnormal excitability following a response can also prevent excitation by a stimulus of threshold intensity, as previously discussed.

In the experimental search for the operation in the spinal cord of these mechanisms, the cord potentials have been examined in relation to facilitation and inhibition of reflex action (Gasser, 1939; Hughes and Gasser, 1934; Hughes, McCouch, and Stewart, 1937). Following a response the motor cells undergo a period of reduced excitability correlated with a positive after-potential. This is sufficient in degree to inhibit reflex responses mediated by these motor cells. The attempts to demonstrate reflex facilitation related to a supernormal period and the negative after-potential in the motor neuron have not been successful (cf. Bernhard, 1947).

Temporal Pattern of Impulses at Synapses

Activity in the single neuron has been resolved into trains of conducted nerve impulses. The functional significance of the temporal pattern of the impulses in an afferent nerve can be evaluated, in part, by observing how these impulses, in combination with those from other cells, are transformed at a synapse into a train of impulses in the postsynaptic neuron. In general, the temporal pattern of the presynaptic impulses is not preserved in the responses of the postsynaptic cell (Bronk, 1939; Bronk and Larrabee, 1940). On the contrary, each impulse arriving at the termination of a presynaptic neuron contributes a transient increment to the state of excitation of a postsynaptic cell. The state of excitation in the postsynaptic cell thus builds up to a degree determined by the frequency of impinging impulses and by the rate of decay of this state of excitation in the postsynaptic cell (cf. Fig. 17). The degree of excitation required to initiate impulses is determined by the specific physical state of the postsynaptic cell.

This summation of excitatory effects is illustrated by studies of synaptic transmission in a sympathetic ganglion. The frequency of response of a postsynaptic cell depends upon the number of active presynaptic fibers. A few presynaptic fibers, stimulated ten times per second, cause a repetitive response of a postsynaptic neuron at about one per second. When more presynaptic fibers are stimulated at the same frequency, this ganglion cells responds at a higher frequency (Fig. 24). The state of excitation developed by presynaptic impulses of a certain frequency in a given number of presynaptic fibers, in conjunction with the contemporary local physical state of the cell (cf. Fig. 7), determines the frequency of conducted impulses in the postsynaptic unit. Since each impulse in one cell does not, in general, produce one impulse in each of the cells on which it terminates, the detail of

the temporal pattern of impulses in one nerve may not be preserved in a multineuronal pathway through the nervous system. However, when the number of active presynaptic cells is great enough, each volley may produce one response in a postsynaptic neuron (Fig. 25).

FIG. 24. The frequency of response of a postsynaptic neuron depends upon the number of active presynaptic fibers. *A*: Stimulation of a few presynaptic fibers at 10 per second. *B*: Stimulation of more presynaptic fibers at 10 per second. *C*: Stimulation of all the presynaptic fibers at 10 per second. Time: 0.1-second intervals. (Larrabee and Bronk, unpublished.)

Other properties depend upon the anatomical fact that many presynaptic cells are functionally connected to each postsynaptic cell. If a few preganglionic fibers are excited at low frequency, conducted impulses may appear in a certain number of postsynaptic axons (Fig. 26). However, if additional preganglionic fibers are simultaneously excited at a higher frequency, then more cells respond to the volleys at the low frequency (Fig. 26). Hence the state of excitation of

some cells was raised by spatial summation of the stimulatory effects in many presynaptic terminals. Since the frequency of impulses in the several presynaptic neurons will, in general, be different, it is obvious that the

nerve cell. There is no possibility of spatial summation of the excitatory effect in the muscle of impulses in several neurons. It is observed, furthermore, that each nerve impulse produces one action potential in each

FIG. 25. Each preganglionic volley of impulses initiated at a time marked by the higher vertical line excited one ganglion cell. (Bronk, 1939.)

FIG. 26. Above: Schematic representation of the innervation of ganglion cells by fibers from different roots. Below: First record, postganglionic responses to preganglionic volleys in root A; second record, arrows indicate responses to similar volleys during concurrent repetitive stimulation of root B; last record, stimulation of root A alone. Time: 0.2-second intervals. (Bronk, 1939.)

frequency of response in a postsynaptic axon excited by spatial summation cannot be like that of more than one presynaptic cell.

There are systems, however, in which a change in the temporal pattern of impulses does not always occur. At the neuromuscular junction in mammals one axon branches and terminates on many muscle cells, and each striated muscle cell is innervated by one

muscle cell, and the temporal pattern of action potentials in skeletal muscle is usually a faithful reproduction of the temporal pattern of impulses in the motor nerve. This kind of transsynaptic relation of neuronal impulses may also occur in some parts of the central nervous system. In that case the temporal pattern of impulses is transmitted unchanged.

After-Discharge and Rhythmic Activity of Neurons

When volleys of impulses in many pre-synaptic fibers impinge at high frequency upon a ganglion cell, the discharge of impulses in this cell may continue after termination of the presynaptic volleys. This continued discharge of postsynaptic impulses is called an after-discharge. The quantitative aspects of this phenomenon are revealed by recording from a single postsynaptic axon. The impulses may be developed for such a

but they traverse different pathways of interneurons before reaching the motor nerve cell (Forbes, 1922; Lorente de N6, 1938c). Thus the first response of a motor cell is caused by impulses traversing a monosynaptic pathway through the spinal cord, and the subsequent responses are initiated by impulses arriving later over longer pathways.

The pathways of interneurons thus convert a synchronized volley of afferent impulses into a temporally dispersed series of impulses that impinge at different times upon

FIG. 27. Repetitive after-discharge from a ganglion cell following 20 seconds of preganglionic stimulation at 60 per second. Continuous record. The last impulse occurred 27 seconds after the stimulation ceased. Time: 0.5-second intervals. (Bronk, 1939.)

long time after the last preganglionic volley (about 30 seconds) that none of the known electrical signs of synaptic activity can be evoked as evidence of the underlying physical process (Fig. 27). It is highly probable that some excitatory substance accumulated by the repetitive activity is the causal agent (Bronk, 1939; Eccles, 1944). The prolonged repetitive response of ganglion cells to continued perfusion by acetylcholine shows that accommodation to such a chemical activator is slow or absent.

The prolonged discharge of impulses in an efferent nerve, after termination of the primary stimulus to the afferent nerve, is a common property of reflex mechanisms. Here the after-discharge occurs because impulses in many different neurons continue to bombard the motor nerve cell. These impulses are all initiated by the primary afferent volley of impulses in the sensory fibers,

a motor neuron. These delayed impulses may serve not to initiate an impulse in the motor cell but merely to increase its state of excitation. Since these impulses arrive during a considerable period of time, a prolonged state of enhanced excitability can be created in this way. This is the prevailing view of the origin of the central excitatory state first observed by Sherrington.

At the time this hypothesis was proposed it was thought that excitatory states created in a neuron by a synchronized volley of presynaptic impulses could not last more than a millisecond. Since then Lloyd (1946a) has shown that, in the cord, such a state of excitation can last at least 13 milliseconds. In addition, Larrabee and Bronk (1947) have shown prolonged facilitation at synapses in a sympathetic ganglion that endures for minutes. It seems, therefore, that the central excitatory state may in some cases

be like that of the synaptic mechanism of a sympathetic ganglion during the period of prolonged facilitation (see footnote, p. 111).

The prolonged states of enhanced excitability and of after-discharge following a primary stimulus are prominent characteristics of chains of neurons in the central nervous system. In addition, some aggregates of neurons in the brain exhibit rhythmic changes of electrical potential (Berger, 1929; cf. Davis, 1936). These changes of potential, arising within the brain, can be recorded from the skull (electroencephalogram) or from the exposed cortex (electrocorticogram). The cortex is electrically active even in the absence of sensory impulses (Bremer, 1935). Hence some brain cells must be spontaneously active (Adrian, 1931).

In the occipital cortex the waves occur at about ten per second, the α -rhythm (Adrian and Yamagiwa, 1935). Impulses in the optic nerve, initiated by a flash of light on the retina, penetrate to the cortex and modify this rhythm (Jasper, 1936; Bishop, 1936). Furthermore, periodic flashes of light on the retina can produce periodic changes in the α -rhythm of the occipital cortex (Adrian and Matthews, 1934). The α -rhythm is, therefore, a state of activity of the visual cortex that is affected by sensory stimulation.

The exact function of these rhythmic electrical processes in aggregates of neurons is not known, but it has been suggested that they determine, in some manner, the neurons in the sensory cortex that will be excited by an incoming volley of impulses (Bishop, 1933 and 1936; Bremer, 1947a; Adrian, 1947). According to this hypothesis, these rhythmic processes would determine the pattern of cortical activity created by sensory stimuli.

There are slow potential waves in the motor cortex, too. Here the function is somewhat clearer because the discharge of groups of impulses down the pyramidal tracts is related to the period of the cortical waves (Adrian and Moruzzi, 1939).

It is probable that variations of the electromotive force in the membranes of indi-

vidual neurons are the source of this rhythmic current flow through the brain (Adrian and Buytendijk, 1931). Furthermore it seems likely that the rhythm depends, in part, upon organized interaction between groups of neurons in the brain (cf. Gerard, 1936; Bishop, 1936). Moreover, as mentioned in Chapter 2, chemical agents can develop rhythmic fluctuations of potential across the membrane of a single axon. It is not impossible, therefore, that the cortical rhythm may arise from electrochemical processes inherent within a neuron (Jasper, 1936, 1948).

Sensory Mechanisms

T. C. RUCH

University of Washington

The physiology of the sensory systems was, until shortly before World War II, mainly concerned with the problem of localization. The localization or "where" problem is the province of anatomy, and much that has passed for physiology has been functional anatomy. The ultimate concern of physiology is "how," not where. Yet little, except behavioristic studies (e.g. correlation of stimulus and response), can be accomplished until the where is known. This is axiomatic. Moreover, only when physiological analysis penetrates deeper than the morphological level to the cellular level (e.g. single-unit analysis) and to the cytological level (e.g. histochemistry, membrane phenomena, synaptic transmission, etc.) do the where and how problems merge. In relatively simple structures in which cells and their processes are geometrically organized, as in peripheral nerve, this order of progression has brought innumerable successes. One may venture the prediction that structures that are not so arranged, such as the cerebral cortex, will not readily yield to single-unit analysis. And, if analysis is accomplished, synthesis will probably not be realized by mere multiplication. Methods of physiological analysis must be devised to deal with manifold structures and with circular rather than parallel-linear organizations. Electronics is a double-edged sword; it provides the instruments for stimulation and recording, and it provides the analogies and, with its mathematics, the analysis. The outlines of things to come are

now discernible. With the analysis of perception and judgment being undertaken on a physiological basis (Marshall and Talbot, 1942; Pitts and McCulloch, 1947), there is new hope for the convergence of physiology and psychology.

SURVEY OF NEUROLOGICAL TECHNIQUES

Early neurophysiological investigation depended heavily upon the techniques of ablation and transection (Galen, 131-201 A.D.; Robert Whytt, 1714-1766; Charles Bell, 1774-1842; Magendie, 1783-1855; Flourens, 1794-1867; and Marshall Hall, 1790-1857). Electrical stimulation was made possible when an anatomist, Luigi Galvani (1737-1798), performed his fundamental experiments on the excitability of nerve and muscle, including stimulation by contact with "dissimilar metals," and when Volta developed the voltaic pile in 1800. Electrical stimulation played a small part in differentiating the functions of the posterior and anterior roots of the spinal cord. But the effective use of electrical stimulation in research on the central nervous system dates from the last decades of the nineteenth century (Fritsch and Hitzig, 1871; Ferrier, 1876; Bubnoff and Heidenhain, 1881) and the early decades of this century (Sherrington, Cushing, and many others).

To these methods of ablation and stimulation has been added the recording of evoked

and spontaneous potentials from the central nervous system. Galvani's experiment (1794) on "contraction without metals," in which the injury potential of a muscle stimulates a second nerve-muscle preparation, is counted the first demonstration of animal electricity. The action potential, because of its fleeting nature, was not demonstrated until nearly half a century later (Matteucci's experiment with the "rheoscopic frog," and DuBois-Reymond's demonstration with physical instruments).

The early application of this technique to the central nervous system by Gotch and Horsley in 1891 was beset with technical difficulties; effective electrical recording from the central nervous system, and from nerve and muscle, awaited the introduction of vacuum-tube amplification which permitted the use of low-sensitivity, rapid, linear recording devices such as the iron-spring oscillograph (Adrian, Matthews) and the cathode-ray oscillograph (Gasser and Erlanger in 1923). Apart from Hans Berger's pioneer work in establishing the technique of electroencephalography, the study of the electrical manifestations of central nervous system activity has been prosecuted for barely two decades. In fact it has been recognized only recently that action potentials recorded from nerve tracts are not of the same configuration as those in nerve trunks suspended in a dielectric (air) because a mass of nervous tissue constitutes a volume conductor (Lorenz de N6, 1939; O'Leary, 1941).

Ancillary to these physiological techniques for the study of the brain are the operative procedures by which the brain is made available for stimulation, ablation, or recording *in a normal physiological condition*. The modern technique for surgical exposure and manipulation of the brain owes much to Halsted and Cushing, and to the adaptation of that technique to the animal brain by Fulton and Keller (1932), the Johns Hopkins group, and others. Postoperative infection and epilepsy are no longer seen in experimental laboratories. Barbiturate anesthesia has

simplified the surgical procedures. Accurately controlled stimulation and electrolytic destruction of focal regions deep within the substance of the brain became possible with the development of the stereotaxic instrument (Fig. 1). This instrument is essentially

FIG. 1. Horsley-Clarke stereotaxic instrument applied to the head of a monkey. The horizontal bar seen against the shoulder is the ear bar, inserted into the external auditory meatus; the other fixed points, the inferior margins of the orbits, are concealed by the instrument.

a frame that can be fixed to the skull at the external auditory meatus and the inferior margin of the orbits. The frame carries racks and pinions with suitable millimeter scales by which a stimulating or an electrolytic electrode can be maneuvered to any point in the horizontal plane and introduced to any desired depth. Developed by Clarke and Horsley in 1905, this technique was lost sight of during World War I only to be revived and brought to a high perfection by Ranson and his school since 1928. Its use is described by Ranson (1934).

The experimental animal is an inescapable variable that must be reckoned with in interpreting results. The neurophysiology, neuroanatomy, and behavior of living organisms at all stages of ontogeny and phylogeny are traditionally and properly the legitimate objects of investigation by the comparative psychologist. However, the human physiolo-

gic physiology, which has been formally expressed by Fulton (1937-39), was manifested by 1925-1930 and has steadily increased (Ruch and Fulton, 1942). Guides to the literature on nonhuman primate anatomy, physiology, and behavior, and to primate colony management, taxonomy, etc., are available (Kennard, Ruch, and Fulton,

FIG. 2. A graph showing the growth of primate literature since 1800. Note the shift in emphasis from morphological to functional studies, and the acceleration of the tempo in the use of the primates for functional studies. The analysis was based on Ruch (1941) and described by Ruch and Fulton (1942).

gist and psychologist are properly interested in man and are sometimes actually misled by experimentation on the lower animals. The higher primates, the monkeys and apes, alone of the phylogenetic series have a cerebral cortex morphologically comparable to that of man. Encephalization and corticalization of function have progressed steadily throughout the mammalian series. The use of primates in experiments has, therefore, been considerably stressed. The value of the primate in neurophysiological research was early recognized by the English neurologists, Ferrier, Sherrington, and Horsley, but, like the stereotaxic technique, it was lost sight of during and for a time following World War I (Fig. 2). However, renewed interest in pri-

1946; Ruch, 1941; Yerkes, 1943; and Zuckerman and Fulton, 1934).

A further trend in experimental neurology is the development of methods for objective and quantitative observation of sensory, motor, and other types of behavior, and the use of these methods in studying the localization of function in the brain. The clinical neurological examination used by the pioneers of cerebral physiology, when supported by detailed protocols, continues to be fruitful, especially when the investigator is trained in the neurological clinic. Pavlov, the physiologist, early applied the conditioned-reflex method to problems of cortical localization; and Franz and Lashley worked with the objective techniques developed by

the early comparative psychologists (Yerkes, Thorndike, and Watson *).

The growth of physiological knowledge is bound up with the growth of anatomical knowledge of the nervous system. Histology provides not only the control which determines the extent and locus of an experimental lesion, but also the guide for experimentation. The histology of the cortex (cytoarchitecture, the study of the cellular pattern; and myeloarchitecture, the study of the fiber stratification) guides the physiologist in placing lesions and provides a topographical frame and a language for the description of experimental lesions. Most commonly used for this purpose are Brodmann's demarcation and numeration of cytoarchitectural areas (Brodmann, 1909; and Fig. 3) and the modification of them by Vogt and Vogt (1919) and others (e.g. McCulloch, 1944b). Many find Brodmann unsatisfactory, and von Bonin and Bailey (1947) have published a monographic revision of the cortical cytoarchitecture of the macaque and have presented a new terminology based upon that of von Economo. Functional cyto- and myeloarchitecture in which the connections of neuron to neuron are studied by silver impregnation (Lorente de N6, 1943) may

* Sherrington (1906) closes his chapter on the excitability of the motor cortex with the following prescient remark:

... The results before you must appear a meagre contribution toward the greater problems of the working of the brain; their very poverty may help to emphasize the necessity for resorting to new methods of experimental inquiry in order to advance in this field. New methods of promise seem to me those lately followed by Franz, Thorndyke, Yerkes, and others; for instance, the influence of experimental lesions of the cortex on skilled actions recently and individually, *i.e.* experientially, acquired. Despite a protest ably voiced by v. Uexküll, comparative psychology seems not only a possible experimental science but an existent one. By combining methods of comparative psychology (*e.g.* the labyrinth test) with the methods of experimental physiology, investigation may be expected ere long to furnish new data of importance toward the knowledge of movement as an outcome of the working of the brain. [P. 307.]

be contrasted with the cartography of Brodmann. Correlation of such information with electrical events is attempted (O'Leary, 1940, 1941). Silver impregnation, which shows the ramifications and interconnections of neurons, was first used by Golgi and Cajal. For some unknown but fortunate reasons, only an occasional cell precipitates the silver salts, which simplifies enormously our ability to follow the complex neuronal pattern of the cerebral cortex. Contemporary studies by Polyak on the retina (1941), and by Lorente de N6 (1934, 1943) and by O'Leary (1940, 1944) on the spinal cord, thalamus, and cerebral cortex determine the course of experimentation on synaptic and cortical physiology.

The tracts of the spinal cord and brain present a bewildering complexity under the microscope. To simplify this picture, Flechsig (1883) took advantage of the fact that various systems of tracts myelinate at different periods during pre- and postnatal development. A more critical means of accomplishing the same end is the method of experimental degeneration. Ablation and transection cause a degenerative fragmentation process in the myelin sheaths in those portions of axons separated from the cell body, so-called "secondary" or Wallerian degeneration. Such changes in the myelin sheaths are accompanied by chemical changes, altering the affinity to various dyes. Weigert's stain (hematoxylin, 1882) reveals the degeneration by failure to stain, *i.e.* affords a picture in negative. In Marchi's method (1886) mordanting with a chromic salt, followed by osmic acid, selectively stains degenerating myelin sheaths and gives a positive picture of black granules or dots against a yellowish-brown field. This method suffers from artifacts, stains only myelinated fibers, and must be carefully applied and critically interpreted.

Degenerative changes occur in the cell bodies of certain neurons if their axons are sectioned — "retrograde degeneration." These are revealed by toluidine blue and other ani-

line dyes, as Nissl originally showed in 1892. This method has been successfully employed by Le Gros Clark and Boggon (1935) and

retrograde degeneration establishes which thalamic nucleus projects to the particular area ablated.

FIG. 3. Areas of the cerebral cortex of *Macaca mulatta*, based on cytoarchitectonics and physiological neuronography. The cerebral hemisphere is shown in side view, and the names of some of the principal fissures are given in the legend of Fig. 7. Apart from the use of Brodmann numbers and the inclusion of areas 8, 4s, and 2, the parcelation of the sensory motor cortex and the posterior parietal region is similar to that of von Bonin and Bailey (1947). Areas 8, 4s, and 2 are functionally distinct but not cytoarchitecturally recognizable.

The following list will aid in identifying some of the cortical regions referred to in the text by name. Identification is necessarily only approximate.

- 4 motor area, precentral gyrus
- 4s strip area of Marion Hines
- 6 premotor area
- 8 "eye fields"
- 4, 6, 8 motor areas
- 9, 10, 45, 46 prefrontal area, lobe or lobule, frontal association area, orbito-frontal area
- 3, 1, ?2 primary sensory area, postcentral gyrus
- 5, 7, 40, 39 posterior parietal lobule. Note that areas 40 and 39 are included in Brodmann areas 5 and 7
- 17 striate area
- 18 parastriate area located on the simian or lunate sulcus
- 19 paristriate area
- 18, 19, 5, 7, 39, 40, 37 parieto-occipitotemporal region

The upper end of the superior temporal sulcus is just below the number 39, the intra-parietal sulcus just above, and the simian sulcus is centered in area 18.

by Walker (1938) in studying the connections of the thalamus and cortex. The ablation of a cortical area truncates the axons running to it, and the locus of the resulting

These two types of degeneration (secondary and retrograde) stop, in accordance with Waldeyer's neuronal doctrine, at the boundaries of the neuron injured. In the third

type of degenerative reaction — “transneuronal degeneration,” first observed by von Gudden — the cell body on which the injured neuron terminates is affected. The pathological changes are atrophic in character and are sufficiently pronounced for study in only a few neuron systems, notably the lateral geniculate body.

With the exception of the work of Cajal and of those he has taught or influenced, neuroanatomy has, until recently, been largely the study of myelinated fibers organized into tracts and the organized nuclei giving rise to them, i.e. the cities and arterial highways of the nervous system. The reticular substance of the brain which often fills the spaces between the tracts and nuclei is little known. It consists of small clumps of cell bodies embedded in a dense pile of fibers with no easily detectable pattern. However, important motor functions of the reticular substance have been demonstrated (Magoun and Rhines; A. A. Ward). Another gap in our knowledge has come about through excessive dependence on the myelin sheath stains, which are incapable of demonstrating bare axons. The axon cylinder, being an extension of the cell body, is, like the dendrites, stained only by silver stains. Greater use is now being made of silver stains. Unmyelinated axons in peripheral nerves have been extensively studied by Ranson, and systematic study of the unmyelinated fibers of the central nervous system has been undertaken, notably by Lassek and by Glees. The central and peripheral nervous systems are exceedingly rich in such fibers, and their physiological significance remains to be worked out.

Because the terminations of myelinated fibers are bare axon buttons or loops, the exact termination of tracts cannot be studied by myelin sheath stains; again silver impregnation is required. Unfortunately, differentiation of normal from degenerating terminal buttons cannot as yet be made with certainty.

Finally, the phase and the electron microscopes, and the youthful science of histochemistry, including the use of tracer elements, are contributing to an understanding of the basic structure and metabolism of nervous tissue.

THALAMUS AND CORTEX

The study of these structures since 1935 has reached a stage of synthesis in which a variety of functional and structural information can be correlated. The purely morphological definition and ticketing of the thalamic nuclei has given way to a parcellation based not only upon cellular and fiber characteristics but upon the origin and termination of the thalamofugal fiber systems. This knowledge of thalamocortical projections has profoundly affected the division of the cerebral cortex into functional regions. The topographical arrangement within systems of fibers passing to and from the thalamus has been intensively investigated. This work has provided a structural framework that has led to physiological deductions and experiments.

A second point of view considers the thalamus and somatosensory cortex as a unit, and further developments in this direction are clearly to be expected. Only a small part of the primate thalamus has purely subcortical connections. The activities of the remainder are expressed via thalamocortical projections. Therefore the thalamic contribution to sensation and perception obviously cannot be deduced from decortication experiments; the thalamus and cortex are a functional unit. A second reason for this belief is that the thalamus receives an extensive projection from the cerebral cortex. Whereas these fibers were once thought to be inhibitory, later developments in neurophysiology have directed attention to reverberating circuits, i.e. an interplay between thalamus and cortex, and cortex and thalamus. This interaction can be studied only by elec-

trical methods. The participation of the thalamus in such reverberating circuits has also been demonstrated in connection with cortically initiated movements (see Chapter 5).

Another trend receives impetus from the fact that the thalamus projects not merely to the postcentral gyrus but to a wide expanse of the cerebral cortex, including the

morphological language is necessary for description, and it can be gained by a study of Fig. 4. The thalamus, a part of the diencephalon or "tween-brain," consists of two egg-shaped gray masses separated by the third ventricle. Each half is divided by a vertical plate of fibers, the internal medullary lamina, which bifurcates anteriorly to form a Y. In this fashion the nuclei are

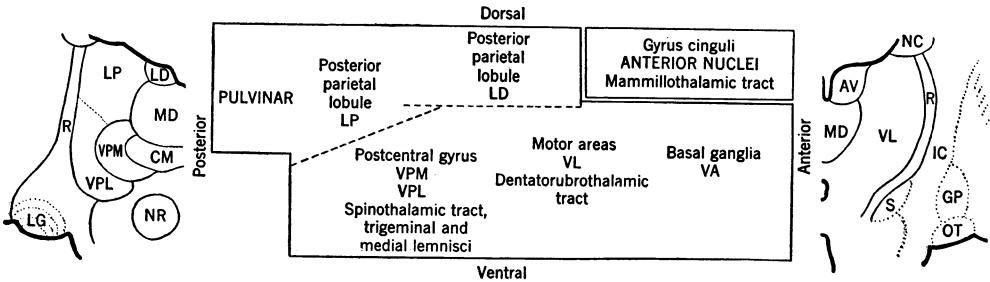

FIG. 4. Center diagram shows a schematic longitudinal view through the lateral nuclear mass of the thalamus. The abbreviations represent the principal thalamic nuclei. Projections to the thalamus are shown below the abbreviation; projections from the thalamus are shown above. Diagrams to the left and right are cross sections through the posterior (left) and anterior (right) thalamus.

Abbreviations: AV, n. anteroventralis; CM, n. centrum medianum; GP, globus pallidus; IC, internal capsule; LD, n. lateralis dorsalis; LG, lateral geniculate body; LP, n. lateralis posterior; MD, n. medialis dorsalis; MG, medial geniculate body; NC, n. caudatus; NR, n. ruber; OT, optic tract; VA, n. ventralis anterior; VL, n. ventralis lateralis; VPM, n. ventralis posteromedialis; VPL, n. ventralis posterolateralis.

motor areas and the parietal and frontal association areas. Conversely, the postcentral gyrus of the cerebral cortex gives origin to some fibers in the pyramidal tract. As a consequence, the distinction between the motor and sensory cortical areas is lessened, and the concept of association areas is broadened. A further example of the broadening concept of the sensory mechanisms is that the cerebellum, once considered "motor" in function, is perhaps implicated in sensory processes.

Anatomico-physiological classification of the thalamic nuclei. The connections of the thalamus far outweigh in importance the details of its cytoarchitecture and nuclear constitution to the understanding of thalamocortical function. However, a minimum

divided into anterior, lateral, and medial nuclear groups. The medial portion of the medial group is separately distinguished as the midline nuclei. The posterior extension of the lateral mass constitutes the posterior nuclei. The lateral mass itself is divided, in turn, into a ventral and lateral group. Thus the nucleus ventralis posteromedialis (arcuate nucleus) is the most caudal and medial part of the ventral portion of the lateral mass.

A classification of the thalamic nuclei, which is proving meaningful from a functional point of view, is given below. It is based on the connections of the nuclei determined by appropriate degeneration studies carried out principally by Walker (1938) and by Le Gros Clark (1935).

Nuclei with subcortical connections. This group does not undergo retrograde degeneration after complete decortication, and hence we conclude that it sends no fibers to the cerebral cortex. This group is made up of nuclei scattered along the midline and along the internal medullary lamina. One of the intralaminar nuclei, the centromedian, is large and well organized and has undergone considerable phylogenetic development. These scattered nuclei must serve whatever sensory function is left to the decorticated animal. They form a surprisingly small portion of the thalamus in the primates. The main role of the thalamus, therefore, lies not in its functioning independently of the cortex, but in its thalamocortical relations.

Cortical relay nuclei. These are defined as those nuclei that receive fibers directly from the ascending afferent systems and project to the cerebral cortex. All sensory pathways, with the exception of the olfactory, are synaptically interrupted (relayed) in the diencephalon. The relay nucleus for vision is the lateral geniculate body; for audition it is the medial geniculate body; and for somatic sensation it is the nuclei ventralis posteromedialis and ventralis posterolateralis. As shown in Fig. 5, the latter nucleus receives impulses from the spinal nerves via the spinothalamic tract and via the posterior columns-mesial fillet system. It receives impulses from the face via the trigeminal lemniscus. In turn, it projects to the post-central gyrus of the cerebral cortex (areas 3-1-2 in Fig. 3), the classic "primary somato-sensory area." This leaves a fourth principal relay nucleus (nucleus ventralis lateralis, or the lateroventral nucleus) quite different from the other three in its connections. Numerous fibers pass from it to the precentral gyrus of the cerebral cortex (areas 4 and 6 in Fig. 3) — the classic "motor area" — and it receives fibers from the dentate nucleus of the cerebellum. By this tract the cortical motor area is in potential connection via the cerebellum with the spinocerebellar systems, mainly proprioceptive in function.

Only functional studies can decide whether or not this system of fibers is a part of the sensory mechanism.

Association nuclei. These thalamic nuclei project to the cerebral cortex but, unlike the

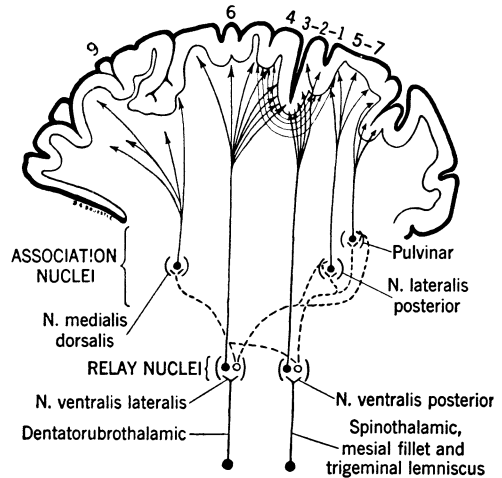

FIG. 5. A schematic representation of the thalamic nuclei and their connections, as determined by the method of retrograde degeneration. The frontal lobe is to the left, the occipital to the right. The numbers along the surface of the cerebral cortex are Brodmann cytoarchitectural areas; the deep indentation near the number 3 is the fissure of Rolando; area 3, the area of densest projection, is buried on the posterior wall of the fissure; the order is 3-1-2. The connections shown by dotted lines are not established as definitely as those indicated by solid lines or arrows. Filled and unfilled circles represent cell bodies. Only the fiber systems to the "potential sensory area" are shown; therefore, nuclei with purely subcortical connections, as well as the medial and lateral geniculate bodies, are omitted. (After Ruch, 1946.)

relay nuclei, do not receive impulses direct from the ascending sensory systems. Their afferent input appears to be from the thalamic relay nuclei. Their projection is to the so-called "association areas" of the cerebral cortex, hence the choice of name, association nuclei. The principal association nuclei and

the cortical termination of their projections are as follows:

Nucleus	Cortical Projection
Dorsomedial	Frontal lobe anterior to motor areas
Dorsolateral } Posterolateral }	Parietal lobe posterior to primary sensory area
Pulvinar	Junction of parietal, occipital, and temporal lobes

These association nuclei form perhaps one-third of the thalamic nuclear mass. The fact of a projection to the association areas has long been known, but the extent and details of this projection have only recently been appreciated.

The newer knowledge of the thalamocortical projection systems provides several guiding principles in the design and interpretation of experiments. The existence of association nuclei suggests that the thalamus must carry out some integration of impulses, which must be expressed through the cerebral cortex. Since decortication simply blocks their "way in" to the cortex, the work of these nuclei can never be learned by that procedure. Therefore, as has been pointed out above, the thalamus and the cortex are best considered as a unit. A second prediction from the anatomical data is that the association areas of the cerebral cortex are potentially sensory areas, an assumption that has received experimental demonstration. Third, the existence of an extensive projection to association areas must alter our ideas of the function of such areas. The association areas, especially those in the frontal lobe, cannot simply elaborate information reaching the primary sensory areas and translate that information into action via the motor areas. The frontal association areas have their own "way in" and their own "way out," and it is not surprising that recent studies show that they subserve functions not implied by the term "association area."

A Functional Terminology for the Cerebral Cortex

The design and description of cortical localization experiments was first in terms of lobes, gyri, and sulci. Later cytoarchitectural studies by Brodmann provided a language of the cortex. This has proved a difficult language and has become a babel of tongues. The difficulty of establishing recognizably different types of cellular architecture and of knowing which areas are homologous in different primate brains—even the possibility of any but the simplest parcelation into cytoarchitectural areas—renders the subject highly technical. Von Bonin (1944) and McCulloch (1944*b*) have embodied the work of Le Gros Clark and Walker in a terminology based on *sectors*, a suggestion that promises to be of value (Fig. 6). A sector is defined by the thalamic nuclei from which it receives impulses. For example, the central sector is the cortical region receiving impulses from the lateral nuclear mass (both its lateral and ventral portions). A subsector may receive impulses from a single nucleus. Other suggestions for systematizing terminology are that "area" designate a region having similar cytoarchitecture, that "field" designate a somatotopic division, as the arm field or the leg field, and that "region" designate a group of functionally related areas.

The potential somatosensory cortex. This term was coined (Ruch, 1943, p. 359) to include all that portion of the cerebral cortex that receives projection fibers from the thalamic nuclei that are directly or indirectly connected with the trigeminal and medial lemnisci, and the spinothalamic tract. "Sensory" is used here in the broadest sense, i.e. without regard to mentalistic implications of "conscious sensation." The question, therefore, is to determine not so much *whether* the subareas of the potential sensory area are sensory, but in *what way* they are sensory. Whether these areas subserve conscious sensation may be deduced from anatomical data

but must be finally decided by functional studies.

The potential somatosensory cortex has two parameters. Along the anterior-posterior axis one finds a succession of vertically running bands or zones with different cyto-architecture and projections. By analogy with cortical motor function, zonal difference in kind of function along this parameter is

face or from strychninization of the cerebral cortex (intracortical neuronography), and (4) ablation in animals, combined with objective behavior techniques.

In the strychnine method of studying cortical localization, introduced by Dusser de Barenne (1924), a small piece of filter paper soaked in strychnine is applied to the cortical surface. The animal bites, licks, scratches,

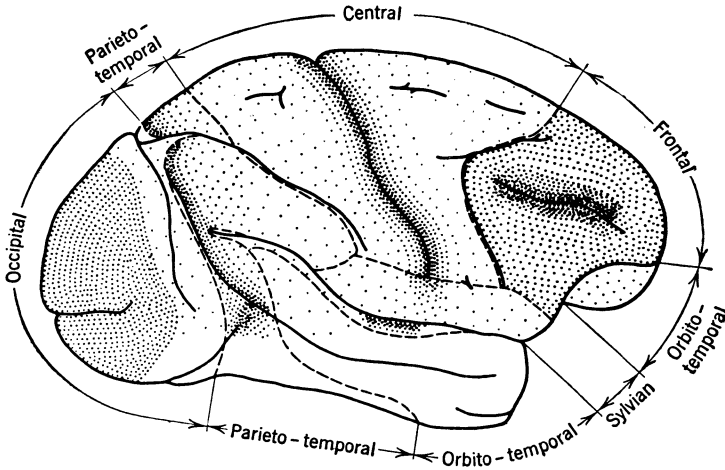

FIG. 6. Regions of the cerebral cortex of *Macaca mulatta* based on thalamocortical projections and physiological neuronography. The stippling represents the density of thalamocortical projections. (After McCulloch, 1944b.)

to be expected. On the inferior-superior axis, extending from the midline nearly to the sylvian fissure, is a well-documented topographical localization which is most marked in the postcentral gyrus and also quite marked in the precentral gyrus. The problem of functional localization of sensory process in the cerebral cortex thus is twofold: (1) the localization of the areas devoted to various segments of the body surface and (2) the localization of the kinds and levels of sensory and quasi-sensory functions. By and large, a given experimental approach yields some data on both points. These approaches are: (1) histological studies, (2) electrical stimulation in man and strychnine stimulation in animals, (3) evoked potentials from stimulation of the body sur-

or examines some point on its body surface. In short, it experiences a projected paresthesia. It also exhibits hyperalgesia and hyperesthesia over some specific area of the body surface. The method of evoked potentials consists in recording the pattern of electrical activity on the cortex in response to stimulation of a single point on the body surface. The technique of physiological neuronography is discussed in detail in a later section.

*The prefrontal sector.** The prefrontal sector, or lobule, despite a rich projection

* The expression "prefrontal," although established in usage, is avoided by some authors on the grounds that it implies a structure "in front of the frontal lobe." However, White gives as a specific meaning of "prae" in its proper usage "at the tip or extremity of," e.g. in *praecido*. (A

from the thalamus, has no known somatosensory function. However, the underneath or orbital surface of this sector receives viscerosensory impulses from the lungs by way of the vagus nerve. Also, the cingular gyrus, lying in the longitudinal fissure that separates the two hemispheres, may receive some visceral impulses via the mammillothalamic tract and the anterior nuclei of the thalamus. Stimulation of these two regions in monkeys produces visceral or combined visceral and somatic patterns of responses, some of which are interpretable as emotional behavior. Ablation of the latter area in monkeys induces changes in the sphere of emotion, apathy, loss of fear of man, and changes in the reaction of the monkeys to one another.

The significance of the projection from the medial nucleus to the prefrontal sector is largely a matter of inference from anatomical considerations. Walker (1938) suggests that "The intricate arrangement of this nucleus would appear to be a mechanism for the integration of synthesized somatosensory and visceral impulses from the adjoining lateral nuclear mass and midline nuclei, respectively, and their relay to the cortex of the prefrontal region."

The precentral subsector. That this sector of the cerebral cortex is the focus for cortically initiated movements has been proved by a variety of techniques since Fritsch and Hitzig's original demonstration of the electrical excitability of the motor cortex. There is a growing body of evidence that this sector is, in some manner, concerned with sensory processes, in the broadest sense of the word. Application of strychnine to the precentral gyrus of the monkey, containing the cortical motor areas, produces

Latin-English Dictionary. (9th Ed.) Boston: 1893.) Prefrontal has not proved confusing, whereas "frontal," by American usage, means the whole lobe lying in front of the central fissure and includes the motor areas. "Orbito-frontal" has recently been suggested as a substitute for "prefrontal," but this terms does not entirely avoid the ambiguity of "frontal."

signs of sensory activity similar to those following application of strychnine to the postcentral gyrus (Dusser de Barenne, 1924, 1934; Fig. 7). Stimulation in conscious human subjects at the time of surgical operation yields sensory responses from the precentral and postcentral gyrus alike, although the responses from the postcentral gyrus are

FIG. 7. A schematic view of the macaque cortex, as seen from the side, showing the potential somatosensory area as demarcated by strychninization. Note that this area, shown by stippling, extends anteriorly throughout the motor area and posteriorly to include the posterior parietal area. The prefrontal lobule, though in receipt of thalamic projection, does not produce sensory symptoms when strychninized. FS, sylvian fissure; C, central or rolandic fissure; SA, arcuate sulcus; SS, simian sulcus, i.e. the lateral parieto-occipital sulcus.

more numerous (Rasmussen and Penfield, 1947). Sensory responses from the precentral gyrus persist after ablation of the adjacent portion of the postcentral gyrus, and the phenomena cannot be ascribed to any form of current spread or to spread of impulses to the postcentral gyrus. Stimulation of posterior spinal roots causes electrical activity in the precentral cortex (Woolsey, Chang, and Bard, 1947). Since evoked potentials in the precentral sector are not observed from stimulation of the skin, this perhaps indicates that only proprioceptive impulses reach the precentral sector. Ablation experiments offer suggestive evidence that hopping reactions and weight discrimination are to some degree carried out by the motor

areas, since these functions persist after parietal lobectomy. Bard and Woolsey (Bard, 1938) believe that the hopping reaction is little affected by parietal lobectomy, although there is not complete agreement on this point. Considerable ability at weight discrimination survives parietal lobectomy, even in chimpanzees (Ruch, 1935; Ruch, Fulton, and German, 1938). That hopping reactions and weight discrimination are functions of the precentral sector is difficult to prove because the cortical motor apparatus is needed for the manipulations involved in the tests. However, supporting evidence has been found by approaching the problem at the subcortical level and thus avoiding motor disturbances. (Sjöqvist and Weinstein, 1942). When the sensory components destined to reach the precentral sector (dentatohalamic fibers) are included in a destruction of the main ascending somatosensory systems, the disturbances of proprioceptive functions, including weight discrimination, are rendered more severe.

Although the evidence of a sensory function on the part of the precentral sector comes from several directions, the evidence is not conclusive. However, there is a growing tendency to think, not of distinct sensory and motor areas, but of a paracentral sensorimotor area. This practice is further justified by recent evidence implicating the postcentral area in motor functions.

Sensory Representation in the Cerebellum

The thalamic projection to the precentral gyrus is derived from the cerebellum via the dentatorubrothalamic tract with a synaptic interruption in the lateroventral nucleus of the thalamus (Fig. 5). Until recently this system was considered purely proprioceptive in function because, in turn, the afferent input to the cerebellum was thought to be entirely proprioceptive. However, studies from three laboratories have clearly demonstrated that exteroceptive sensory fibers—cutaneous, auditory, and visual—pass to the cerebellum (Adrian, 1940; Dow and An-

derson, 1942; Snider and Stowell, 1944). Moreover there is evidence from studies of evoked potentials that the spinocerebellar projection is topographically organized. Stimulation of fore- and hindfoot activates different cerebellar cortical areas. Tactile impulses of the feet are doubly represented, once in the anterior lobe and again in the posteriorly situated paramedian lobe. Each half of the body surface is represented in both lateral halves of the cerebellum.

That the cerebellum receives exteroceptive impulses illustrates the necessity for scrutinizing with care the supposed facts of neurophysiology. Few "facts" were more universally accepted prior to these experiments than the proprioceptive character of the spinocerebellar projections. As a comfortless *arrière pensée* comes the thought, "How could anatomical studies, in which spinal tract fibers are on the whole nameless, ever have led to such a conclusion?"

Open to re-evaluation is the well-established clinical finding that neither disturbance of proprioceptive nor disturbance of cutaneous sensory function is detectable in human cases of cerebellar damage. That this fact excludes the cerebellum from a role in sensation is a conclusion that would be justified only if cerebellar damage were added to interference with the parietal lobe of the cerebral cortex or the main afferent pathway to it, as in the experiments of Sjöqvist and Weinstein (1942). Provisionally, the cerebellum must be included in the potential sensory mechanism. It is not improbable that the dentatohalamocortical pathway is concerned with sensory processes involved in the control of movement, which do not enter consciousness, but it is by no means proved.

The discovery of a projection of exteroceptive impulses to the cortex, via the cerebellum, may aid in explaining several facts of somatic sensation otherwise puzzling. As pointed out above, the conscious sensory responses to stimulation of the precentral gyrus are cutaneous as well as proprio-

ceptive, as are the monkey's responses to strychninization of that area.

Posterior Parietal Sector

Ablation experiments on monkeys and chimpanzees trained to discriminate lifted weights establish the ability of the posterior parietal sector to serve sensory functions (Ruch, 1935; Ruch, Fulton, and German, 1938). The evidence is as follows: (1) Ablation of the postcentral sector, especially in monkeys, does not produce grave, enduring disturbances of weight discrimination. With retraining, the preoperative level of performance can be re-established after such lesions. This proves that the primary sensory areas of the postcentral sector are not the sole "way-in" to the cerebral cortex (assuming corticalization of somatic sensation). (2) The initial impairment of the ability to discriminate weight (following ablation of the posterior parietal sector) approximately equals that following postcentral lesions. Evans (1935) found grave disturbances of discriminative functions in man after small posterior parietal lesions. The higher level sensory functions—localization, two-point threshold, etc.—were especially affected. This suggests that the whole parietal lobe is involved in discriminatory sensory processes. At one time it was thought that impulses reached the postcentral sector and then were relayed to the posterior parietal sector for "elaboration." This is certainly not the sole pathway of sensory impulses through the cortex (Fig. 5). Because recovery virtually to preoperative level occurs after the postcentral lesions, the parietal region must be able to function independently of the postcentral region. Moreover, ablation of the two subsectors in one stage or serially (parietal lobectomy) produces a deeper and more persistent discriminatory defect than does ablation of either of the constituent areas separately. If the posterior region merely elaborates impulses from the postcentral subsector, ablation of it would be the equivalent of parietal lobectomy, which is

not the case. One reservation must be made, however. If, as suggested above, the precentral sector is also a "way in" to the cortex, there is the possibility that impulses are relayed from the precentral region to the posterior parietal lobe. Testing of this hypothesis was attempted but was unsuccessful because of the interference with the manipulatory abilities needed for the sensory examination.

The question naturally arises whether different modalities or groups of modalities are separately localized in the cerebral cortex. In chimpanzees the ability to discriminate roughness has been tested in observations parallel to those on weight discriminatory ability. The results were broadly similar for both tests. For the monkey, data are available on two types of sensory testing, namely, weight discrimination, and the hopping and placing reactions of Bard and Rademaker (Bard, 1938). If the foot of a blindfolded animal is brought into contact with the edge of a table, the foot is brought up and set down on the table. If the contact is light, the response is the *tactual placing reaction*; if heavy enough to bend joints, it is the *proprioceptive placing reaction*. The *hopping reaction* is elicited by blindfolding an animal and allowing only one leg to support the body. Translocating the animal in space calls forth a series of quick, neat hops which keep the leg under the body. There appears to be a real difference between the cortical management of weight discrimination, and the hopping and placing reactions. In the monkey, ablation of either the postcentral gyrus or the posterior parietal lobule, separately, is virtually without demonstrable effect upon ability at weight discrimination, given time for recovery and retraining. A complete parietal lobectomy is required to produce demonstrable discriminatory defects that persist after the initial postoperative disturbances are over. On the other hand, the *tactual placing reaction* is very severely disturbed by ablation of the postcentral gyrus alone (Bard, 1938), though perhaps

not completely abolished unless a parietal lobectomy is performed (Kennard and Kessler, 1940). Hopping reactions appear to be less severely affected by equivalent lesions than are the placing reactions. Two explanations have been advanced. The first is based on the modality difference: hopping is a proprioceptive function like weight lifting, whereas placing is a tactual phenomenon like roughness discrimination. Bard and Woolsey (Bard, 1938) believed that hopping is less affected by parietal lesions because it is served by the sensory projections to the precentral gyrus. The interpretation is supported by the evidence from evoked potentials described above (Woolsey, Chang, and Bard, 1947).

In comparing two functions such as weight discrimination and the tactual placing reaction, we find two other ways, besides the modality difference, in which the two responses differ. In the discrimination type of experiments, recovery of function is favored by two factors: (1) the high degree of motivation elicited by a food reward and (2) the opportunity to practice the same maneuver under stable circumstances, which may lead to maximum utilization of whatever sensory cues remain to the animal. Another difference which may prove to be critical is that weight discrimination or roughness discrimination is an intensity function, whereas in placing and hopping reactions there is a definite spatial element. When the side of the foot is touched to the table top, the foot is moved laterally; when the front of the foot is touched, the foot is moved forward in order to place. In the hopping reaction the direction of the hops is determined by the direction of the translocation of the animal through space. It is possible that these reactions demand a stable, topographically organized projection system, so that there is relatively little chance for another system of somatosensory fibers to compensate for those destroyed. In contrast, weight or roughness discrimination, being intensity functions, may not de-

pend upon any given set of thalamocortical projection fibers. Although numbers of receptors, sensory tract fibers, and cortical cells may be a factor in intensity discrimination, frequency of impulse discharge, be-

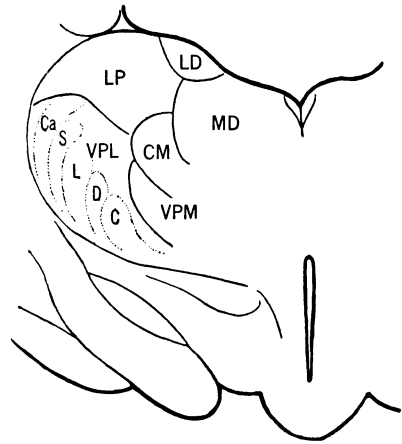

FIG. 8. A cross-sectional diagram through the left half of the thalamus, showing the areas of nucleus ventralis posterolateralis (VPL), in which the spinothalamic tract fibers from different levels of the spinal cord terminate. From Marchi degeneration studies on a monkey with a prehensile tail. The comma-shaped areas enclosed in fine dots show the termination of spinothalamic tract fibers. Order of termination from lateral to medial is: Ca, caudal; S, sacral; L, lumbar; D, thoracic; C, cervical. For abbreviation of the thalamic nuclei see legend of Fig. 4. Note that degeneration was not found in the nucleus ventralis posteromedialis (VPM), the "face" and "taste" nucleus. (After Chang and Ruch, 1947.)

cause of its enormous range, is probably a more important factor. If so, even a small part of the sensory system remaining after surgical interference may be able to serve intensity functions and, with practice and re-education, may enable the animal to approach or regain the preoperative facility.

Postcentral Subsector

This subsector contains the classic "primary somatosensory area." The anatomical

justification for this is three-fold: (1) it is a highly granular koniocortex typical of primary sensory areas elsewhere in the cerebral cortex; (2) it is the area of densest thalamo-

graphical organization, which feature, however, is shared by the projection to the precentral sectors. The evidence for this will be briefly outlined.

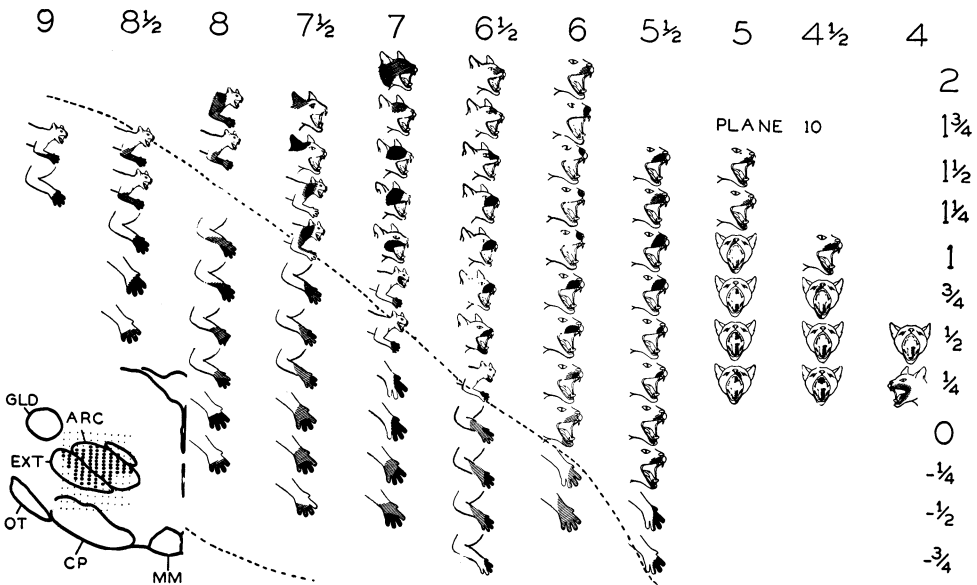

FIG. 9. An evoked-potential mapping of the representation of the body surface on the thalamus of the cat. The insert in the lower left corner is a cross section through the posterior part of the thalamus. The grid of small dots shows the points from which electrical records were made; the enlarged dots are the points from which potentials were recorded on tactual stimulation. For each of the larger points a figurine is located in the main diagram (millimeter scale), showing which area of the skin or mucosa yields a strong (black) or weak (cross-hatched) response at the given thalamic point. The line of dashes running diagonally represents the boundary between the pars externa (EXT) and pars arcuata (ARC) of the ventrolateral nucleus, which in monkey is known as the posteroventral nucleus. Other abbreviations are: OT, optic tract; CP, cerebral peduncle; MM, mammillary nucleus; GLD, lateral geniculate body. Note that the medial portion of the pars arcuata (to the right) did not yield evoked potentials to touch stimulation and may be the area that relays taste and/or visceral impulses from the vagus nerve. The trunk and leg appear in similar drawings made from more anterior planes. (Henneman and Mountcastle, 1948.)

cortical projection, although the number of fibers coming to it is not greatly different from the number passing to the anterior wall of the central fissure; (3) it is the area of cortex most directly connected with the ascending sensory systems via the relay thalamic nuclei (Fig. 5). It differs from other sectors of the potential somatosensory area by virtue of a high degree of topo-

Walker (1938) made lesions of the trigeminal lemniscus, the cuneate, and gracile nuclei in different animals. He traced the resulting degeneration to the posteroventral nucleus. Fibers from the face (trigeminal lemniscus) ended in the medial portion (arcuate nucleus) of that nucleus. Fibers from the nucleus cuneatus (arm) ended more laterally, and those of the nucleus gracilis

(leg) still more laterally (Fig. 10). Chang and Ruch (1947) have described the termination of spinothalamic fibers arising from various levels of the spinal cord, confirming in more detail the topographical projection of the body surface onto the posteroventral nucleus (Fig. 8).

The projection of the body surface upon the posteroventral nucleus of the thalamus was worked out in greater detail by Henne-man and Mountcastle (1948), employing the method of evoked potentials (Fig. 9). Monopolar electrodes inserted into the thalamus by the stereotaxic instrument recorded the action potentials to punctate stimulation of the body surface. The termination of ascending sensory fibers in the posteroventral nucleus was confirmed; impulses were detected in no other nucleus of the thalamus. Cutaneous areas having a rich innervation, e.g. the lips or fingers, were represented over a wider area than relatively insentient surfaces such as the trunk. The contralateral body surface is represented in great detail, with the face posteromedial and the tail anterolateral. The axial portion of the body is represented superiorly and the extremities inferiorly in the nucleus. Thus the study of the topographical organization of the spinal and trigeminal systems is fully demonstrated both anatomically and functionally.

In other experiments Walker (1938), and Le Gros Clark and Boggon (1935) removed parts of the cortex of the postcentral gyrus and located the areas of retrograde degenerative reaction in the thalamus. In this projection the spatial arrangements are also preserved (Fig. 10). The medial "face" nucleus of the thalamus projects to the sylvian end of the postcentral gyrus. The lateral leg area of the thalamus projects to the postcentral gyrus lying near the midline. Fibers for the arm are intermediate at the thalamus and at the cortex. The evidence is clear, then, that the ascending sensory systems and thalamocortical connections project the body surface onto the postcentral gyrus of the cortex, keeping spatial rela-

tions to some degree intact. Whether this is actually a point-to-point projection cannot be learned by the relatively crude methods of experimental degeneration but can be decided only by physiological experiments.

Strychnine stimulation yielded the map of the cortex shown in Fig. 7. Here we have

FIG. 10. A cross section through the cerebral hemispheres showing the reversal of the medial-lateral relation of the somatosensory projection between thalamus and cortex. SS is the sylvian fissure; for other abbreviations, see Fig. 4. (After Walker, 1938.)

a functional localization of the three major body regions: face, arm, and leg. No finer localization was demonstrable, yet the boundaries between arm and leg, for example, were sharp within 2 or 3 millimeters. Stimulation in conscious human subjects (Fig. 11) gives evidences of a finer topographical localization. The method of evoked potentials (Woolsey, Marshall, and Bard, 1942) shows clearly that the dermatomal segments, not simply regions or limb segments, are reflected in the topographical organization of the post-central gyrus (Fig. 12). Woolsey, Chang, and Bard (1947) have verified this more

recently by stimulating the posterior roots successively and by mapping on the cortex the points of maximal electrical activity. The method of evoked potentials does not demonstrate a strict point-to-point representation. A single point on the skin surface

substrate for spatial discrimination. Examination of Figs. 11 and 12 shows that the vertical extent of the postcentral gyrus devoted to a given area of the body is out of proportion to the area of skin represented. The area for the lips or fingers is far greater

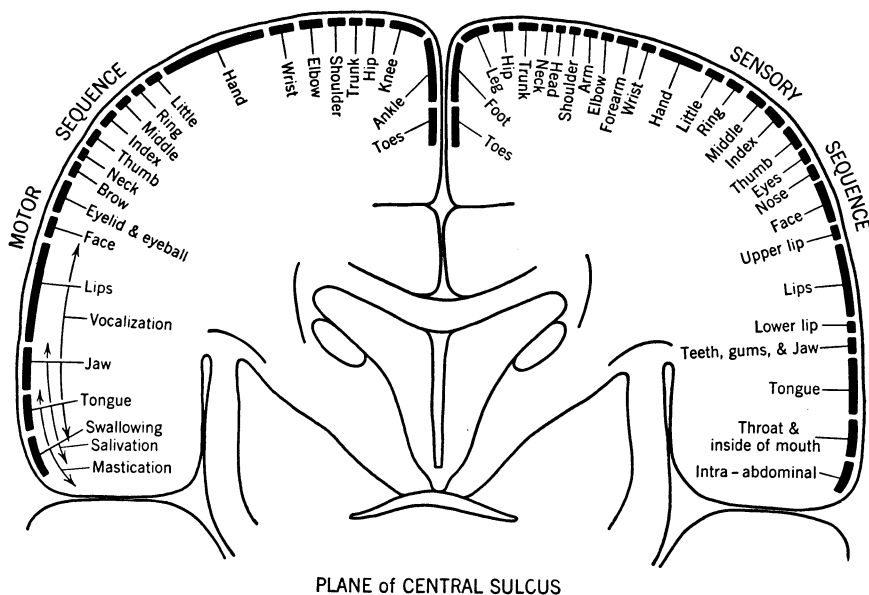

FIG. 11. A schematic diagram combining a cross section through the postcentral gyrus (right) and the precentral gyrus (left) in the plane of the central fissure. The diagram shows the motor and sensory sequence of representation in the cerebral cortex of man, determined by electrical stimulation of conscious patients at operation. With stronger stimulation wider zones for a given part might be found, and there is considerable variation from individual to individual. Note that the sensory area devoted to the fingers and hand is greater than that devoted to the much larger skin area lying between forearm and shoulder. (From Rasmussen and Penfield, 1947.)

may activate several millimeters of the superior-inferior extent of the postcentral gyrus. What such studies do show is that for each point on the skin surface there is a point on the cortex of greatest electrical activity. Later on, in the discussion of the neural mechanism for the two-point threshold, we shall see that the requirement for spatial discrimination is the existence of "modal excitation fields," not a strict point-to-point representation.

It is believed that a topographically organized projection system constitutes the

than that for the arm or for the trunk. Whether these differences simply reflect the greater density of receptors in the lips and fingers is not yet known. The situation is possibly analogous to that presented by the visual system. The fovea of the retina differs from the periphery, not so much in the concentration of receptors, but in the greater number of private paths coming from the fovea (Polyak, 1941). This is continued by a greater representation of the fovea in the lateral geniculate body and in the occipital cortex. In both systems one can regard the

large cortical representation as meaning a greater number of cortical cells or "fineness of the cortical grain," by which greater ac-

curacy of spatial discriminations is made possible. As the name suggests, it forms the common ground between the three great sensory lobes of the brain. It is an asso-

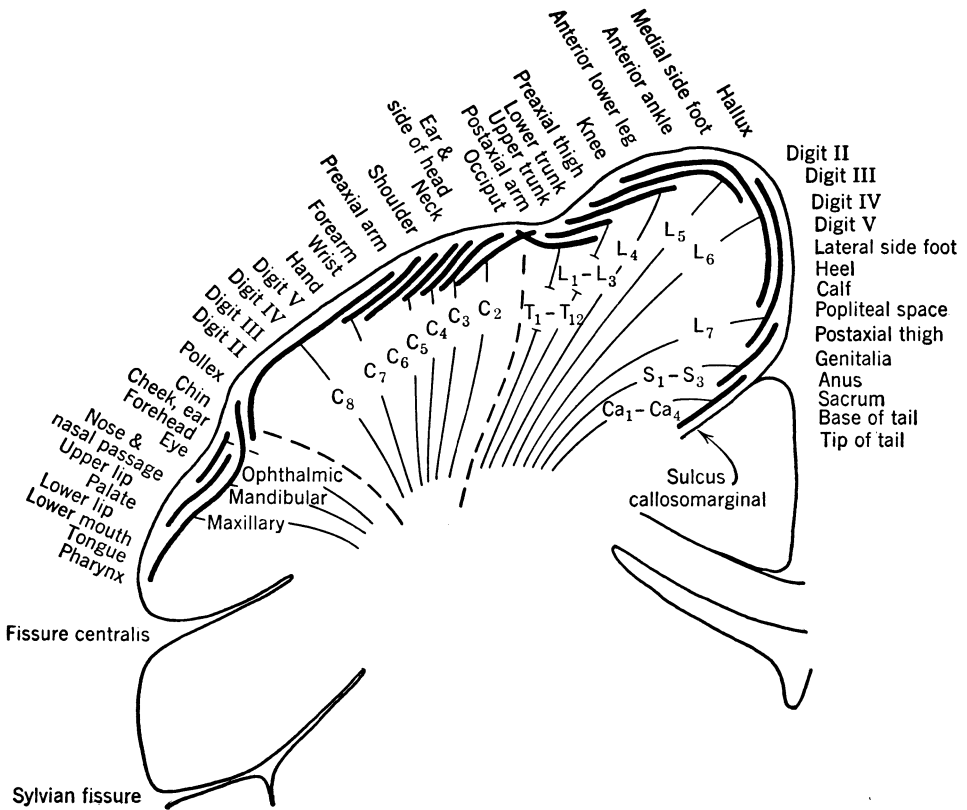

FIG. 12. A reconstruction showing the representation of the body surface upon the post-central gyrus of the cortex, as determined by cortical potentials evoked by stimulating the body surface. The left cerebral hemisphere is shown in cross section, medial to the right and lateral to the left. The body regions are based on experimental data; the letters and subscripts are dermatomal designations deduced from known innervation: Ca, caudal; S, sacral; L, lumbar; T, thoracic; and C, cervical segments of the spinal cord, and the ophthalmic, mandibular, and maxillary divisions of the trigeminal nerve. The subscript is the number of the posterior root within the spinal cord region. Compare with Fig. 11, and note that most of the foot area is buried in the longitudinal fissure and that the cervical dermatomal representation is reversed *en bloc*. (After Woolsey, Marshall, and Bard, 1942.)

curacy of spatial discriminations is made possible.

Parieto-occipitotemporal Region

The parietal portion of this region of the cortex has been discussed in part in a previ-

ous section. As the name suggests, it forms the common ground between the three great sensory lobes of the brain. It is an asso-

with the expansion of the parieto-occipito-temporal region in the higher primates. In man the posterior ends of the sylvian and supramarginal sulci are capped by the supramarginal and angular gyri, respectively, which are concerned with the receptive aspects of speech.

The projection to the parieto-occipito-temporal region is derived from the nuclei lateralis dorsalis and lateralis posterior and from the pulvinar (Fig. 5), which is a large posterior outgrowth of the nucleus lateralis posterior. The pulvinar projects to the posterior parietal lobule just posterior to the projection of the parent nucleus, nucleus lateralis posterior, and also to the anterior border of the occipital lobe and the posterior portion of the temporal lobe.* Like the parent nucleus, the pulvinar does not receive fibers directly from the great sensory systems (Fig. 5). The pulvinar, like the cortical region of its projection, has undergone conspicuous phylogenetic development. Once incorrectly supposed to receive fibers directly from the optic tract, it is now believed to receive somatic, visual, and auditory impulses from their respective relay nuclei (Walker, 1938). These connections cannot be traced by Marchi degeneration; they are probably unmyelinated. The pulvinar is in close proximity to other posterior nuclei, the geniculate bodies, and contiguous retrograde degeneration in these nuclei results from the same cortical lesion.

An analysis of this contiguous degeneration leads to the thesis that the posterior and medial parts of the pulvinar are related to the medial geniculate body; the lateral portion to the lateral geniculate body, and the anterior and medial part of the pulvinar to the nucleus ventralis posterior. This arrangement brings the somatic sensory, auditory

* It is a matter of definition whether areas 5 and 7 (Fig. 3) be considered a part of the parieto-occipitotemporal region. Von Bonin (1944) is ambiguous on this point. Areas 5 and 7 receive a projection from association nuclei, and the pulvinar is derived from these nuclei. For this reason areas 5 and 7 are here included in the parieto-occipitotemporal region.

and visual systems into close relationship, and allows integrations between these systems. Those fibers passing to the superior parietal lobule, the angular gyrus, and the lateral temporo-occipital region presumably are mainly associated with visual integrations, those to the anterior part of the supramarginal gyrus with somatic sensory, and those to the posterior part of the supramarginal gyrus with auditory. [Walker, 1938, p. 248.]

The pulvinar and the nuclei lateralis posterior and lateralis dorsalis, superimposed as they are upon the direct pathway of sensory impulses to the cortex, have no *raison d'être* unless they in some manner elaborate sensory impulses before passing them on to the cortex. Walker (1938), speaking of this group of nuclei, says:

They appear to be related to the highest and most recently developed sensory modalities.

Through these three groups of nuclei the thalamus receives incoming stimuli, integrates them to varying degrees, and then relays them to other subcortical ganglia or to the cerebral cortex. In this way the crude stimuli received by the peripheral end organs become elaborated to be presented to the highest hierarchy of the central nervous system, the cerebral cortex, as complex and at least partially synthesized impulses.

It has already been pointed out that the anterior portion of this region is able to carry out proprioceptive discriminations after ablation of the postcentral gyrus. However, the function of the parieto-occipitotemporal region is largely known from clinical cases, where the lesions are likely to be massive and unverified. Evans (1935), in a study of surgical excisions where the destruction is macroscopically known, locates an integrative center for the higher levels of somatic sensation in the region of the supramarginal and angular gyri (Fig. 13). The degree of disturbance from lesions in this region is greater in man than in chim-

panzee, and greater in chimpanzee than in monkey, a clear illustration of encephalization of function and perhaps of a posterior migration of such function.

Experimental analysis of this area in animals should yield information about the kind

lesion, though visual discrimination of them was perfectly retained. The cone versus pyramid discrimination by touch was quickly and completely re-established, but protracted retraining failed to restore the pyramid versus wedge discrimination. It is not

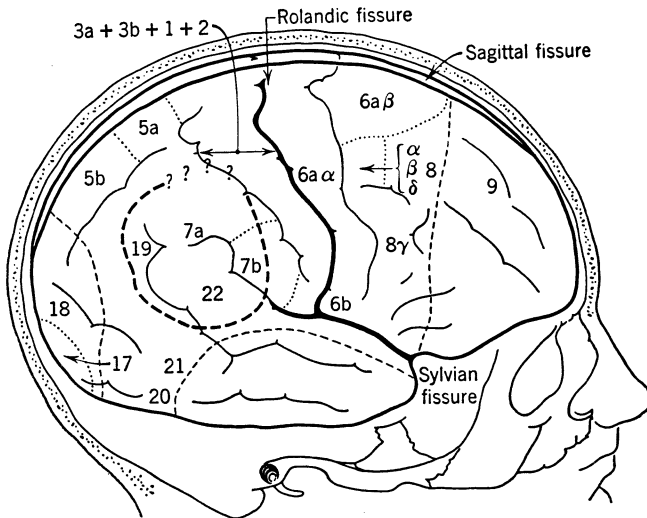

FIG. 13. Diagram showing the "common denominator" of a series of surgical excisions posterior to the postcentral gyrus that gave disturbances of somatosensory perceptions and judgments (sense of position, weight discrimination, topognosis, two-point threshold, stereognosis, etc.). The question marks completing the heavy dashed line denote uncertainty about the superior extent of the effective area. Note that the area includes the supramarginal gyrus which bends around the superior end of the sylvian fissure, and the angular gyrus at the superior end of the superior temporal fissure which is parallel and inferior to the sylvian fissure. This chart is used in the Montreal Neurological Institute for charting the location of brain operations. The numbers and letters and fine dots and dashes denote cytoarchitectural areas. (Evans, 1935.)

of function impaired and should supply the details of localization not readily obtainable in human studies. In a single experiment on a chimpanzee, Ruch, Fulton, and German (1938) demonstrated that discrimination of three-dimensional form may be disturbed by lesions in the area. Prior to operation a chimpanzee was taught to discriminate by palpation between a pyramid and a cone, and between a pyramid and a wedge. The latter was a more difficult discrimination to establish. Both discriminations were temporarily lost consequent to a posterior parietal

unlikely that the cone and pyramid problem was solved on a "sensory basis" (sharp edges versus no edges), whereas the pyramid versus the wedge presented a problem in the relation of geometrical planes and demonstrated a higher order of sensory activity. Thus what little evidence exists suggests that the posterior parietal area is concerned with the higher levels of sensory process.

In man lesions within the parieto-occipito-temporal region are accompanied by disturbances of functions characterized by

intermodality elements. Pure astereognosis (inability to recognize common objects by palpation not accompanied by any marked disturbance of basic sensory modalities) is clinically associated with this region. The appreciation of three-dimensional form appears to require a synthesis of data from more than one somatic sense modality. The recognition of common objects probably involves, in addition, synthesis with visual data. Receptive aphasia, e.g. "word blindness," is traditionally associated with lesions of the angular gyrus which is located in this region. It may be concluded that the region lying between the parietal, occipital, and temporal lobes serves the higher levels of somatosensory response, especially those involving more than one modality. To what degree this is accomplished by the region correlating the sensory data from the primary sensory areas for vision and audition, and to what degree this is accomplished by the pulvinar and the association area acting as a unit, await experimental and clinical investigation.

Visual perceptual defects are also found in lesions lying between the visual and parietal lobes. Holmes (1918) and others have described, under the syndrome of *visual disorientation*, symptomatology believed characteristic of the parieto-occipitotemporal region. Although movement is not ataxic, eye-hand coordination is at fault. Visual estimation of distance is faulty; the patient will attempt to reach an object 5 or 6 feet away. The patient judges with difficulty the length of a line, or whether an object is moving away or towards him. Common objects may be clearly seen but not recognized. Disturbances of eye-hand coordination have been observed in chimpanzees with posterior parietal lesions (Ruch, unpublished). A detailed search for disturbances of high-level visual function from lesions of areas 18 and 19 in the monkey failed to confirm the clinical findings of Holmes (Ades, 1946; Lashley, 1948).

Double Sensory Representation

A duplication of sensory areas has been demonstrated for vision, audition, and somatic sensation. The evidence comes largely from the method of evoked potentials (Adrian, 1940; Woolsey and Fairman, 1946). As shown in Fig. 14, the second somatic area* is located in the upper wall of the sylvian fissure, inferior to the sensory area I. The second somatosensory area is topographically arranged, the parts of the body coming in reverse sequence to that in the postcentral gyrus, so that the face areas I and II are contiguous, and the order is face, arm, and leg in going deeper into the sylvian fissure. Sensory area II responds electrically to ipsilateral stimulation of the body surface, though not so strongly as to stimulation of the contralateral half of the body. Like the postcentral gyrus, this area is sensory-motor because stimulation of it elicits movements of the limbs and face. Rasmussen and Penfield (1947) recorded, in a few patients, sensations referred to the arm, leg, and face, when the region immediately adjacent to the sylvian fissure was stimulated. Since these responses are aberrant with respect to the ladder of sensory representation, they suggest the existence of a second sensory area in man. In many of the experiments on hopping and placing reactions and on weight discrimination, carried out prior to the discovery of the second sensory areas, the second sensory area was not included in the ablations. However, Bard and Woolsey have shown that somatic area II cannot compensate for the loss of area I in the management of tactile-placing reaction, though there was some initial slowing of the reaction from ablation of it.

* Following Woolsey and Fairman, these areas are referred to as the sensory areas I and II, or first and second sensory areas, to avoid implications of "primary" and "secondary" as applied to sensory areas. Somatic area I is the primary sensory area, but somatic area II implies nothing more than second in time of discovery. Neither in function nor in position is it a secondary sensory area, a phrase that is sometimes used to describe the posterior parietal lobule.

McCulloch (1947) integrates the second sensory areas into the general plan of the cerebral cortex as follows:

Sectors of cortex, defined by their connections with thalamic nuclei, severally exhibit a receptive area or a pair juxtaposed but

sylvian fissure, extending on to the Island of Reil, direct the carriers of their appropriate receptors, and the superior surface of the second temporal convolution pricks up the ipsilateral ear.

This close cortical coupling of each sensory input to output affecting that sensory input

FIG. 14. Diagram showing the positions and relative sizes of somatic areas I and II, and other sensory areas in the monkey. The sylvian fissure is shown opened, revealing the insula and the normally concealed parietal and temporal walls of that fissure. The dotted portion of the auditory area is Auditory II; Auditory I is not dotted. B, M, and A refer, respectively, to base, middle, and apex of the cochlea. From the cross-hatched portion of somatic area I for the face, ipsilateral responses were obtained. (From Woolsey and Fairman, 1946.)

oriented reversely, each surrounded by a zone to which it gives many extrinsic axons. From each of these composite fields arises a projection whose activity affects that part of the body in which its organs of sense are situated. Thus the *area striata* and its surrounding zones move the eyes toward the place in the visual field corresponding to the position of excitation. The first and second somesthetic areas and the zone anterior to the former and deep to the latter in the

by moving the organ of sense is a mode of functional organization whose circuit leaves and returns to the body. [P. 450.]

Ipsilateral Representation

Up to this point, the potential sensory area for a given side of the body has been considered to be that portion of the *contralateral* hemisphere that receives cortico-thalamic projections from nuclei connected

with the ascending sensory systems. It must be remembered that the potential sensory area for a given half of the body may include the ipsilateral cerebral cortex as well. A variety of evidence can be accounted for only on the supposition that in some degree each half of the body is bilaterally represented in the cerebral cortex, or, in other words, that there is some ipsilateral representation. This is apparently not equally true of all modalities of sensation, but is most conspicuous for pain; nor is it equally true of all areas of the body surface, but is most marked for the face. The evidence is as follows. Strychnine applied to one sensory cortex will produce paresthesia and hyperesthesia on both sides of the body (Dusser de Barenne, 1924, 1934). Proprioceptive sensations do not exhibit this ipsilateral representation. Woolsey et al. (1942, 1947) confirmed both conclusions in their studies of evoked potentials. In man bilateral or ipsilateral projection of sensory responses induced by cortical stimulation occurred only in the face and in only 13 per cent of the stimulations (Rasmussen and Penfield, 1947). Bilateral representation is not accomplished by fibers crossing from the thalamus of one side to the cerebral cortex of the opposite side through the corpus callosum. Retrograde degeneration following cortical ablation is found only in the thalamus on the side of the lesion (Walker, 1938). Any crossing that occurred at or above the level of the thalamus would have to be actually within the diencephalon, as, for example, in the massa intermedia. Nor is ipsilateral representation gained by failure of, for example, pain fibers to decussate in the spinal cord. Were they conducted on the ipsilateral sides of the cord, a unilateral section of the spinothalamic tract (anterolateral cordotomy) could not produce analgesia to cutaneous pain, as it appears to do. On the other hand, there is evidence of a *recrossing* of spinothalamic tract fibers in the brain stem, in fact, at many points in the brain stem. Chang and Ruch (1947) have re-

cently described the crossing of such fibers in the posterior commissure. The present status of the perplexing problem of ipsilateral representation may be summarized by saying that the phenomenon is most pronounced for pain, is most pronounced in the representation of the face, and is probably due to a recrossing of pain fibers within the brain stem or to cross connections between the two thalami.

THE TOPOGRAPHICAL PRINCIPLE AND THE TASTE PATHWAY

Of the eleven or more modalities of sensation, the pathways and cortical localization are known in considerable anatomical and physiological detail for vision, audition, and some of the somatosensory group. Until the last decade little was known of the cerebral pathways for gustatory, olfactory, labyrinthine, and visceral sensations. In varying degrees these modalities of sensation are now yielding to experimental analysis. Neither the older functional anatomy nor the random exploratory approach yielded accurate information. On the other hand, some of the newer knowledge of the thalamocortical projections, especially the details of their topographical organization, has proved of definite predictive value in the design of experiments on the lesser-known sensory pathways.

Two principles, sometimes conflicting, seem to govern the organization of neural systems. The functional principle is that two systems of fibers closely related functionally pursue similar courses. A good example of this is the collection of fibers, serving pain from cutaneous, muscular, and visceral nerves, that pass grouped together in a common tract (the spinothalamic) in the spinal cord. The topographical principle is that peripheral origins, including spatial relations, are reflected or continued in the organization of ascending sensory tracts, in the point of thalamic relay, and in the cortical termination, as has been described above.

That these principles may conflict is illustrated in our growing knowledge of the gustatory system.

The fact that taste is so closely linked psychologically and functionally with olfaction is probably the main reason for the general acceptance of the view that gustation and olfaction have an adjacent cortical localization. Actually this inference is virtually without experimental or clinical basis. In fact, there is evidence, going back to 1890, for different cortical localizations of taste and smell—evidence that has largely escaped notice because of the plausibility of the localization dictated by the functional principle. Börnstein (1940*a, b*) has pointed out the many dissimilarities between the gustatory and olfactory systems at all levels between the sense organs and the cerebral cortex. He proposed the alternative hypothesis that taste is an evolved somatosensory modality, and that a similarity between gustatory and *somatosensory* pathways, including their cortical termination, is to be expected. He found evidence in man that the cortical localization of taste does, in fact, lie in close proximity to the face and tongue sensory area of the postcentral gyrus, not in the hippocampal region adjacent to the olfactory area.

The locus of the thalamic relay for taste fibers, even the existence of such a relay, was for many years largely a matter of conjecture. The studies of thalamocortical projections established that the somatosensory fibers for the tongue and face relay in the most medial portion of the posteroventral nucleus (so-called arcuate nucleus). It was predicted that the taste fibers also relay in this nucleus. In monkeys tested preoperatively by the preference method (Patton and Ruch, 1944), lesions of this nucleus were made by means of the Horsley-Clarke apparatus. The expected lowering of taste sensibility resulted, and the arcuate nucleus was thereby established as the thalamic taste nucleus (Blum, Ruch, and Walker, 1943; Patton, Ruch, and Walker, 1944). The lo-

calization has not yet been confirmed by the method of evoked potentials. However, in the study by Henneman and Mountcastle (1948), in which the projection of the body surface on the thalamus was mapped, an area in the medial part of the arcuate nucleus was found that was not activated by somatic stimuli. This may well be the portion of the arcuate nucleus in which taste impulses are relayed.

According to the topographical principle, the thalamic relay for visceral sensation (exclusive of pain) from the chest and upper abdomen should be sought at the medial extremity of the posteroventral nuclei; and its cortical representation should be sought at the lateral extremity of the sensory cortex. Sensory impulses from the pelvic viscera should pass through the lateral portions of the posteroventral nucleus of the thalamus and should be projected to a region near the midline in the postcentral cortex. In Fig. 11 it will be noted that intra-abdominal sensations are elicited in man by stimulation just inferior to the throat area, i.e. on the lip of the sylvian fissure. Visceral pain from the chest and abdomen should be projected to the trunk areas, since it is largely conducted to the spinal cord over the thoracic and upper lumbar posterior roots. In turn, labyrinthine sensations should be located in close relation to the auditory cortical area, an expectation for which there is some evidence. Confirmation of these predictions can be found in the studies of Amassian (1950) and of Walzl and Mountcastle (1949).

NEURONOGRAPHY OF THE SOMATOSENSORY CORTEX

The cerebral cortex is centripetally and centrifugally linked with subcortical nuclei. The cortices of the two hemispheres are linked with one another by the corpus callosum, and the various cortical areas are interconnected by abundant short (U-fibers) and long association fibers, and the corti-

cal gray matter itself contains laterally coursing fiber systems. The latter are termed by Sperry "intracortical" as opposed to the "intercortical" association fibers coursing through the white matter of the cerebral hemispheres. Anatomically these intracortical and intercortical fibers, being so numerous, give the impression of complete interconnectedness of cortical areas. Such is not the case. There are at least main highways, often one-way highways, between cortical areas.

Physiological analysis of the interconnection between cortical areas, and between cortex and subcortex, was given the name "physiological neuronography" by Dusser de Barenne (McCulloch, 1944a). In strychnine stimulation he hit upon a tool for charting the neuronographical relations of cortical areas. Strychnine acts only at synapses, probably on the cell body of neurons, since the impulses are propagated only in the direction of conduction from cell body to axon. Strychnine appears to discharge a group of neurons synchronously, and, with the aid of an oscillograph, the synchronously propagated action potential — the strychnine spike — can be detected and distinguished from spontaneous activity wherever the axons of the stimulated cell bodies are distributed. The requisite synchronicity for the strychnine spike is apparently lost whenever the volley crosses synapses. The method, therefore, plots the first-order connections between one region and another.

Intracortical association through the gray matter was demonstrated by Rosenblueth and Cannon (1942) in the highly reactive cortex of animals under chloralose anesthesia. This propagation of activity is slower than that produced by strychnine, and it does not respect cytoarchitectural boundaries. The strychnine spike persists even when the cortex is more heavily depressed under Dial anesthesia and is not blocked by circumcoagulation of the strychninized area. Physiological neuronography, carried out by means of strychnine, apparently plots unisynaptic

connections by way of association fibers of the white matter, whereas the Rosenblueth-Cannon phenomenon is a multisynaptic spread through horizontal fibers of the cortex itself.

Intra-areal and interareal effects are to be distinguished. Strychninization of, for example, the arm area of the postcentral gyrus will "fire," i.e. cause strychnine spikes to appear, throughout the whole arm area but will not spread to adjacent somatotopic areas. Interareal effects in the macaque cortex further document the close interrelation of the pre- and postcentral subsectors. Area 4, exclusive of its anterior border (4s), fires all areas of the parietal lobe, as does area 6. Conversely, with the exception of area 2, the zones of the parietal lobe available to stimulation (areas 1, 5, and 7) activate all other areas in the parietal lobe and area 4 of the frontal lobe. (Area 3 is buried in the central fissure.) Whether these interconnections pertain to sensory function or to the motor function of the sensory-motor areas is not yet known. They will be discussed in more detail, along with the "suppressor areas," in Chapter 5.

CORTICOTHALAMIC CONNECTIONS

The significance of corticothalamic projection has been a puzzle since its first description by von Monakow more than half a century ago. The details of the projection show that thalamus and cortex are reciprocally related. Thus a given sensory area of the cerebral cortex projects back to that thalamic nucleus from which the given cortical area receives an ascending projection. Head and Holmes believed that this system of fibers is inhibitory to the thalamus and, when damaged, causes the hyperpathia of the thalamic syndrome that was ascribed to overactivity of a hypothetical thalamic mechanism for affect. Dusser de Barenne (1934) demonstrated by the strychnine method that cortical stimulation induces

strychnine spikes in the thalamic nuclei. The effect of these impulses reaching the thalamus appears to be excitatory and not inhibitory. Ablation or novocainization of all except an island of cortex of sensory-motor area for the arm, which is strychninized, is followed by projected paresthesias over the entire arm (Dusser de Barenne, 1924, 1934). Since it is unlikely that the whole arm is re-

Experiments of this type outline the neural substrate for long reverberating circuits between the thalamus and the cortex, as a part of the sensory mechanism. The clearest demonstration that such reverberation occurs when the cerebral sensory mechanism is activated through sense organs was made by Chang (1950). The electrical activity from the cortical auditory area in response to

FIG. 15. Left: Cortical potentials from the somatosensory area evoked by posterior root stimulation. *A*: Under light Nembutal (barbiturate) anesthesia. *B*: Under very deep Nembutal anesthesia. The cortical potential is a downward (surface positive) spike-like excursion. Note the regularity of the rhythm and the decreasing amplitude.

Right: Highly schematic diagram to illustrate two possible mechanisms of thalamo-cortical interaction. *A*: The reverberation employs the main projection. *B*: The different projections are involved for the reverberation and for the initial volley. (Chang, 1950.)

represented many times in the cortex, this experiment constitutes evidence that the sensory cortex activates rather than inhibits the thalamus by way of corticothalamic fibers. Ablation or undercutting the sensory cortex causes a diminution in the spontaneous electrical activity of the appropriate thalamic nucleus (1941). Conversely, integrity of the posteroventral nucleus of the thalamus is essential for a normal electroencephalograph pattern in the somatosensory cortex, a fact indicative of a thalamo-cortical linkage.*

* Interaction of cortex and thalamus is not solely responsible for the maintenance of spontaneous electrical rhythms of the cortex. Fibers

click stimuli was recorded with a very slow sweep of the oscillograph. Following the initial burst of activity on the cortex were three or four smaller, broader waves of activity, coming at regular intervals but with gradually decreasing amplitude (Fig. 15). The first wave of the repetitive discharge occurs in about 220 milliseconds, a time lag

and nuclei along the internal medullary lamina, and especially the "medial intralaminar region" — the massa intermedia and related structures — are clearly pacemakers for widespread and synchronous bilateral rhythmic activities of the cortex (Dempsey and Morison, 1943; Jasper and Droogleever-Fortuyn, 1946; Morison and Dempsey, 1942). Also, the thalamus can engender spontaneous rhythmical discharge after decortication (Morison and Bassett, 1945).

indicative of conduction over multineuron pathways. Various features of the repetitive electrical response suggest that it is due to a circuit from the cortex to the medial geniculate body and back to the cortex. Similar phenomena were demonstrated for the visual and somatosensory systems with minor differences, such as a greater frequency of the repetitive discharge.

The delayed repetitive potentials following the initial burst elicited by a click stimulus were also detected in the record from the medial geniculate body. The clinching observation was that removal of the auditory cortical area abolished all but the initial response to the click stimulus in the medial geniculate body. Presumably a thalamocortical reverberatory circuit was broken by the cortical intervention.

As pointed out above, experiments of this type suggest a close interplay between the thalamus and the cerebral cortex. In the simple reception of a sensory stimulus, the cortex and the thalamus appear to function as a unit. Beyond this generalization little more can be said of the physiological significance of thalamocortical reverberation.

NEUROPHYSIOLOGY OF PERCEPTION

The method of evoked potentials, as applied to the cerebral cortex, has so far been used mainly in functional anatomical studies. Several pioneering studies encourage the belief that the study of cortical potentials can throw light on the problems of perception, judgment, conception, and other cognitive processes. The minimum separable and the two-point threshold seem to present the most convenient points of attack experimentally (Marshall and Talbot, 1942), though analysis of concept formation has been attempted biomathematically (Pitts and McCulloch, 1947). The neural basis of two-point discrimination will be discussed here as an example of a basic discriminatory process — one that may be considered the

prototype of sensory discrimination in all sense modalities.

The two-point threshold of the skin was popularized as a clinical test of sensation by Sir Henry Head. He considered it a valuable indication of cortical defect. To a limited degree clinical neurology employs this test, though rarely in the quantitative fashion familiar in psychological laboratories. Although Head is to be credited with strengthening neurology by borrowing psychological methods, he and the others who followed him have not always been sensitive to the concepts developed by psychologists. They leave the impression that there exist sensory systems or sensory impulses that specifically serve the function of two-point discrimination, whereas each of the cutaneous senses has its own two-point threshold. Touch happens to be served by a system capable of making finer discriminations than those made by other forms of somatic sensation. As yet, no systematic comparison of the various sensory modalities with respect to the two-point threshold has been made, though such a study would seem feasible.

The two-point threshold is widely different in different regions of the body surface (see Fig. 16). Weber sought to explain these differences on the basis of the size of the skin area to which the terminals of a single sensory neuron are distributed. This area was called a "sensory circle." The thought was that compass points resting on adjacent areas would be appreciated as one stimulus, but, if an unexcited fiber was interposed, two points would be appreciated. Similar explanations of the mechanisms underlying visual acuity have been advanced. In audition, the resonance theory of pitch, based on sharp tuning of the basilar membrane, is somewhat comparable. In these cases the concept of an excited receptor and an adjacent unexcited receptor, each with a private path to the cortex, has been proved a gross oversimplification. The same appears to be true of somatic sensation. A variety of facts dic-

tate a more dynamic concept, involving a statistical process on the part of the cerebral cortex in which a spatial discrimination involves an intensity of discrimination.

The static concept of two-point discrimination would predict an anatomical organi-

S' represent the points of a compass esthesiometer applied to the finger tip. The line above this represents skin deformation, so that physically the stimulus spreads beyond the points of the compass. Neurohistological studies (Weddell, 1941*a, b*; Woollard, Wed-

FIG. 16. A mnemonic diagram showing the magnitude of the two-point threshold in various regions of the body. The length of the vertical line closely approximates the actual separation of compass points just perceptible as "two" when applied to the point from which the line is erected. (From Ruch, 1946.)

zation consisting of parallel, insulated chains of fibers ("private lines") from skin surface to cerebral cortex. A variety of evidence fails to support this prediction and in fact has disclosed a degree of intermingling of axon terminations within the skin and opportunities for cross-talk at synaptic junctions which suggests, paradoxically, that such an arrangement is more efficient than parallel fiber chains.

As shown in Fig. 17, opportunities for overlapping or spreading excitation in topographically adjacent systems occur at several levels of the sensory pathway. S and

dell, and Harpman, 1940) have given us the picture of a single sensory fiber ramifying within the skin, overlapping and interlocking, but not fusing protoplasmically, with the terminations of other fibers. Meissner's corpuscles occur in groups and are innervated by fibers approaching the group from different directions. Tower (1940) discovered that a single parent pain fiber is distributed to roughly one quadrant of the cornea and the adjacent conjunctiva, an area varying in size between 50 and 200 square millimeters. Within this region are silent areas, presumably innervated by interlock-

ing axons. In short, there is a wide topographical distribution of the "sensory unit," a term by which she designates a parent

In Fig. 17 the gradient of excitation (in terms of frequency of discharge b , b') between what may be termed the core fiber

FIG. 17. A theoretical diagram of the neural factors involved in the discrimination of two points applied to the skin. S and S' are the points of the esthesiometer or compass used in determining the two-point threshold. Note that the deformation of the skin extends beyond the compass points. a is a plexus of interlocking terminals, so that more than one afferent fiber is stimulated, but the rate of discharge (b and b') is higher in the "core" neuron stimulated where the terminals converge on the parent axon. The dotted arrows, c , show how a divergence at the synapses of the spinal cord results in convergence and summation at the thalamus, contributing to the peaking of curve d or d' (modal excitation fields). The summed effect of the activity pattern is represented by e . So long as the distance between the volley intensity difference and the peak is discriminable, the points are perceived as two. For further explanation see text. (Ruch, 1946.)

sensory axon and all its terminal branches. Interlocking to the degree disclosed by these studies precludes the possibility of an excited neuron and an adjacent unexcited neuron limiting the two-point threshold.

(n) and an adjacent fiber interlocking with it is not due merely to the degree of deformation of the two fibers. Tower stimulated with equal intensity the periphery and the center of an area served by a single neuron,

while recording from the parent axon. This is quite possible in the cornea where the sensory unit area is large. A higher rate of discharge was obtained from the center than from the periphery of the area served by a single axon. The frequency of discharge (b') in the core neuron is therefore shown to be high, relative to that in an adjacent neuron (b). From this discussion two reasons emerge for plotting the frequency of excitation at the cortical level as a bell-shaped curve: (1) the physical conformation of the skin deformation and (2) the more rapid rate of discharge from the core neurons stimulated in the center of their fields than from the adjacent neurons stimulated in the periphery of their fields.

At each of the synaptic relays — medulla, thalamus, and cerebral cortex — there are cross-connections between neuron chains. Such cross-connections have been demonstrated histologically, and they are much more abundant than the diagram in Fig. 17 suggests. This arrangement is variously termed "partially shifted overlap" (Lorente de Nó, 1934) and "reciprocal overlap" (Marshall and Talbot, 1942). Such connections obviously would spread the excitation horizontally to a degree determined by the number of such connections multiplied by the number of synaptic levels. However, as Lorente de Nó has pointed out, such collaterals, which are, at the first synaptic layer, divergent in effect, would concentrate rather than spread the excitation at the second synaptic relay. This is indicated by the dotted arrows, c , showing that the collateral system would tend to facilitate the core neuron, causing it to maintain a differential rate of discharge, with a consequent peaking of the pattern of cortical stimulation.

The *raison d'être* for this type of arrangement, rather than parallel chains of fibers, is probably as follows: The frequency of discharge is unquestionably one correlate of intensity of stimulation, in so far as the sense organ is concerned. The problem is how frequency of discharge becomes an in-

tensity signal at the cortex. Parallel "insulated" chains of fibers could, at best, merely translate that frequency to the cerebral cortex.* Such chains are relatively inefficient in summing their effects for the following reasons. According to one well-founded theory of synaptic excitation, temporal summation at the synapse is hindered by the briefness of the excitatory effects on the neuron soma from a discharge of impinging axonal terminations which, at some synapses (Lorente de Nó, 1938, 1939), does not last at peak value beyond the refractory period of the axon.† Spatial summation at the synapse, the additive effect of two adjacent axon terminals firing, occurs at peak intensity and is more effective in discharging the postsynaptic neuron. Dichotomizing and multiple terminations of single axons, typical of synaptic terminations, favor excitation by increasing the statistical probability of spatial summation between terminations of the same axon. The collateral systems in Fig. 17, through the pathway indicated by the dotted arrows, may be regarded as a further provision for multiple termination. For example, instead of one stream of impulses, at the thalamic level, there are three streams converging from different fibers upon the third-order neuron. Because the fibers are different, refractory periods do not prevent the close timing of impulses favorable for summation. The net effect may, therefore, be to sharpen rather than spread the excitatory field.

The dotted lines at the top of Fig. 17 represent the cortical excitation from each

* This ability to follow frequency varies in different sensory systems. In the visual system flicker is paralleled by a cortical activity up to 53 per second. Synchronous volleys tend to become asynchronous in crossing synapses. The low following rate points away from simple chain transmission.

† Even if excitatory effects outlast the refractory period, the latter offers a considerable barrier to temporal summation. If the soma change effected by an arriving impulse decreases exponentially, a very considerable portion of its peak level will be lost during the refractory period.

compass point separately, as it distributes over the layers of cortical neurons. The curves are purely hypothetical, and, since no shape is critical, they have been termed "modal excitation fields" (implying only that they are "peaked") (Ruch, 1943). The cortical excitation is plotted in terms of impulses per second. The number of cortical cells active would be another possible correlate of intensity, which would derive directly from frequency of impulses. At the periphery, intensity of stimulation is translated into number of receptors firing and frequency of discharge of each. Number of receptors firing can be translated at each synapse into frequency of discharge of the postsynaptic neuron, because number of receptors firing governs the probability that spatial summation will be sufficient to discharge the next neuron. However, at the final cortical level, frequency may possibly be translated into number of cells responding within a system of divergents-convergents, as diagrammed. A population of cortical cells having different thresholds, probably normally distributed, is a reasonable assumption. A high frequency of impinging impulses from converging terminals would have a greater probability of discharging two adjacent boutons within the critical time interval for summation. Since a low-threshold neuron is probably simply a neuron receiving a sparse bouton innervation from the fibers in question, the importance of frequency is apparent. The type of record of electrical activity of the cortex obtained by stimulation of a single point on the skin surface provides evidence for a curve approximately of the character shown in Fig. 17 (Wooley, Marshall, and Bard, 1942). The electrical activity has a maximum point and quite a large lateral distribution. The point of maximal activity shifts with shifts in the position of the stimulation over the body surface. Such experiments do not tell us whether it is frequency or number of neurons active that correlates with intensity at the cortical level. About

all that can be said is that the number of units active strongly affects the recording instrument, especially when these units are synchronously involved. Frequency in the presence of asynchronicity tends not to be effectively recorded electrically.

What is the limitation on the two-point threshold? Theoretically, two points are perceived as such, provided the valley between the two peaks is sufficient to permit an intensity discrimination between them. Closer together, the bimodal pattern becomes unimodal, and the intensity discrimination is no longer possible. According to this view, then, spatial discrimination has an element of intensity discrimination.

This interpretation is supported by analogy with Hecht and Mintz' (1939) quantitative analysis of visual minimum separable. A shadow of a fine wire thrown on the retina is visualized as producing a valley in the illumination greater than the width of the geometrical projection of the wire. Hecht and Mintz (1939) calculated that, for a wire subtending 0.05 second of visual angle, the minimum visible would cause the core cone to be illuminated at 98.83 per cent of the general retinal illumination, and the two adjacent cones by 99.73 per cent. The difference of 0.95 per cent agrees closely with the difference threshold for intensity.

Motor Systems

T. C. RUCH

University of Washington

Apart from a few forward-looking observations the motor systems originating in the cerebral cortex were until about 1930 treated in an oversimplified fashion. Thus as recently as 1945 an influential textbook of physiology described the "pathways for voluntary motor impulses" as follows:

The pathway taken by an impulse in passing from the cerebral cortex to a muscle innervated by a spinal nerve consists of two sections: (a) a fiber of the corticospinal tract and (b) a peripheral motor neuron, i.e. a cell of the anterior horn of the spinal cord and its axon which, of course, reaches the muscle via a ventral root and a motor nerve. The corticospinal fibers pass from their cells of origin (Betz cells of the motor area of the cortex) through the white matter of the hemisphere . . .

As a result of two decades of research this concept has been modified in many respects. For example, the corticospinal tract does not end primarily upon anterior horn cells but connects with them through an elaborate system of internuncials. The corticospinal tract does not originate exclusively from Betz cells, nor does it originate exclusively from the motor area; many fibers are contributed by the postcentral gyrus and other cortical areas. Moreover voluntary activity initiated from the cerebral cortex involves many fiber systems besides the corticospinal tract. Anatomical and physiological studies show that the cerebral cortex is strongly connected with the final common path by the

so-called "extrapyramidal system." This consists of all descending chains of fibers that do not pass through the medullary pyramids. Thus impulses originating in the cerebral cortex are transmitted through complex chains of fibers, interrupted synaptically in the nuclei of the basal ganglia and the brain stem, to reach the spinal cord. The cerebellum is also involved. The extrapyramidal system is so arranged that the basal ganglia and the cerebellum may influence cortical activity by reverberating or "feedback" circuits. Finally, it is now known that a large share of the pyramidal tract fibers are unmyelinated, but whether they differ in function from the myelinated ones is yet to be learned.

Thus the large fibers originating in the Betz cells, confined to a small locus in the motor area, appear to be only one component of the neural apparatus for voluntary activity. At each level of the nervous system the mechanisms of voluntary motion have proved considerably more complex than previously expected. Other cells besides those of Betz and other areas besides the motor area give origin to the pyramidal tract. Other fibers besides the large myelinated ones are found in the pyramidal tract. Other tracts besides the pyramidal tracts are involved in voluntary activity. Other than a simple relation of the pyramidal tract to anterior horn cells is definitely proved. Even the organized nuclei interposed in the extrapyramidal system, as numerous and com-

plexly interconnected as they are, are not the whole story. The unorganized material of the brain stem, consisting of clusters of cells interwoven with fibers—the reticular substance—is probably involved in voluntary activity. At present little more than the discovery of these systems can be claimed; new methods and many years of painstaking research are clearly necessary before the neural mechanism of voluntary behavior will be known in detail.

Stimulation Experiments

Functional localization* in the cerebral cortex was first demonstrated experimentally in 1870 when Fritsch and Hitzig demarcated zones in the canine cortex from which movements of single members—face, arm, and leg—are elicitable by electrical stimulation. In primates the area of greatest excitability, and the area that is most productive of discrete movement, is area 4 which lies in the precentral gyrus of the cerebral cortex and the anterior wall of the central fissure. In man area 4 is largely concealed in this fissure. Concerning the experiments on the excitability of the motor cortex the following can be said: (1) This area has been repeatedly mapped in many mammalian forms, including man, from the point of view of the topographical representation of the musculature. (2) Its response has been compared with what results from stimulation in other zones or sectors of the brain, or after sectioning the pyramidal component of its projections. (3) The area's excitability characteristics (facilitation, extinction, after-discharge, etc.) have been repeatedly investigated and to some degree correlated with its electrical activity.

The representation of the body is, in a sense, reversed in the precentral gyrus. The face is located at the bottom of the gyrus

* Dusser de Barenne has pointed out that our conventional expression, "localization of function in the cerebral cortex," is manifestly incorrect, since the function is equally localized in the corticospinal tracts, nerves, and muscles that execute the action.

(i.e. laterally), and the leg and sacral segments are located at the top of the gyrus (medially) (Fig. 1). The area of the cortical field for a given body segment varies with the discreteness and variety of movement of that segment, not with the muscular mass involved. The tongue and finger areas, for example, are absolutely greater than the

FIG. 1. Simiusculus showing the size and order of the representation of the musculature in the motor areas of the left cerebral cortex of the monkey. The area between the dashed line and the solid line above it is the anterior buried wall of the central fissure of Rolando. The area between the two vertical lines at the right is buried in the medial longitudinal fissure. The V-shaped line running through the eye of the figurine is the arcuate sulcus. The superior precentral sulcus crosses the anterior abdominal wall. (After Woolsey and Settlage.)

trunk area, and the distal segments of a limb have a more extensive cortical representation than the proximal segments (Fig. 1). These distal segments of the limb are activated by weaker cortical stimulation than are the proximal limb segments. In turn, the strength, variety, and discreteness of movements elicitable by electrical stimulation are greater for the apical musculature, as are its voluntary activities. The degree and duration of paresis from ablations of area 4 are likewise greater for the apical musculature.

These facts are based upon many observations of clinical and animal subjects and have been confirmed by an objective and quanti-

tative technique (Chang, Ruch, and Ward, 1947). Simultaneous myographic records were made of the contraction in eight muscles, activating the toes and ankle, in response to cortical stimulation. The maximal contraction elicited in each muscle in a series was tabulated and related to muscle weight. Only the portion of the leg area appearing on the free surface of the brain was stimulated. Within this area the muscles moving the toes are more available to activation by cortical stimulation than are the larger muscles of the same class which move the ankle. Extensor hallucis longus, which dorsiflexes the great toe, although weighing only 1.42 grams, gave rise to a contraction of 310 grams of tension. Tibialis anticus, which everts and dorsiflexes the foot, weighed 8.50 grams, and gave rise to 320 grams of tension. Using grams of muscle weight as a rough index of the number of motor units contained in the muscle, the tension per gram of muscle weight from cortical stimulation gives the ratio of cortically activated motor units to total motor units. This ratio was 37.0 for the ankle muscle, and 218.3 for the toe muscle, approximately six times greater. This may mean that the cortical representation is more concentrated for the toe dorsiflexor, since the number of points that will give a preponderate tibialis response is greater than the number that will give a toe dorsiflexion. However, the toe dorsiflexor is represented as the preponderate muscle throughout several square millimeters of cortex, a large area relative to the size of the muscle. As in sensory systems multiplicity of units is one way in which finely graded responses are obtained, a conclusion consistent with Sherrington's motor-unit analysis of reflex activity.

Fundamental Plan of the Motor Cortex

How the motor cortex functions in voluntary activity cannot be directly learned from electrical stimulation, which is not its natural mode of activation. Therefore much of the research on the motor cortex has been di-

rected towards questions of localization rather than towards the elucidation of its functions. However, if localization studies are carried far enough, the boundary between structure and function is passed.

What is the basic plan of organization of the motor cortex? Since the time of Hughlings Jackson (1834-1911), it has been taught that the motor cortex is organized to yield movements. This is sometimes picturesquely stated by saying that the motor cortex "thinks in terms of movements, not muscles." It is manifest that movements are not "localized" in the cerebral cortex. What is meant is that the Betz cells, synaptically connected with muscles via their motoneurons which produce a given movement, are collected within one area of the cerebral cortex. A muscle, or a fraction of a muscle, must be re-represented as many times as there are movements employing that muscle. This idea is well expressed by the phrase "multiplicity of representation," or simply "re-representation" of muscles. Following Hughlings Jackson's original formulation, this theory is that the ingredients of a movement (Betz cells) exist in each movement focus in various combinations.

Then it may be said that one convolution will represent only the movements of the arm, another only those of speech, another only those of the leg, and so on. The facts above stated show that this is not the plan of structure of the nervous system. Thus, to take an illustration, the external parts, x , y , and z [segments or limbs], are each represented by units of the corpus striatum [motor cortex]. But the plan of representation is not that some units contain x largely only, as x_3 ,* others y largely only, as y_3 , but that each unit contains x , y , and z —some, let us say, as x_3 , y_2 , z , others as x_2 , y_3 , z , etc. [Jackson, 1931, p. 27.]

It is undisputed that the first answer received by applying electrodes to the cerebral cortex is that muscle groups or the whole

* The subscript represents the number of x , y , or z units in a given area.

limb can be activated from a single cortical point. Moreover, when stimulation conditions are arranged to produce maximal excitation, even the traditional arm, face, and leg areas are not inviolate, as Murphy and Gellhorn (1945) have shown. The degree of overlap between somatotopic areas so displayed decreases as we ascend the mam-

a pattern of cortical organization, based on detailed stimulation of the leg area, consisting of rays running obliquely across the precentral gyrus. Beginning on the mesial surface, the extensor muscles (derivatives of the dorsal muscle sheet) are represented in order from hips to toes, followed by the flexor muscles (derivatives of the ventral muscle sheet) in order from toes to hips. This arrangement would make the organization of the precentral gyrus parallel that of the postcentral gyrus (see Chapter 4).^{*} In still another approach to the problem (Chang, Ruch, and Ward, 1947) the contraction of eight distal muscles of the leg were recorded polygraphically while the leg area of the cerebral cortex was stimulated systematically, millimeter by millimeter, in order to map the cerebral cortex in terms of muscle representation. It was hoped thereby to test the hypothesis of multiple representation of muscles and to provide data from which the plan of organization of the motor cortex could be deduced. The extent of cortex stimulated was not sufficient to permit attainment of the latter objective, but evidence for a concentration of the cortical representation of individual muscles was obtained.

The conclusion reached by previous workers that single muscles can be made to contract by cortical stimulation was confirmed. When such "solitary responses" were pro-

^{*} Woolsey and Settlage (1950) have extended this analysis of the monkey's motor cortex. "In essence, fingers, toes and lower face are represented within and adjacent to the central sulcus. The axes of arm and leg run rostrocaudally so that proximal parts of limbs are better represented rostrally, as are also upper face, eyelids and pinna. Binding together face, arm and leg representations is an area for axial musculature, which forms the rostral border of the pattern." This may be termed a "unitary theory of the motor areas" since it draws the classic eye fields and adversive band (see below) into the ladder of motor representation and raises the question whether differences in the latency and character of movements from areas 4, 6, and 8 may not in part reflect the type of musculature represented rather than levels of motor function. This chapter should be read with this in mind.

FIG. 2. A diagram of the right cerebral hemisphere of the macaque monkey on which is mapped the areas from which responses of the upper and lower limb were obtained by electrical stimulation selected to produce maximal responses. Note the zone of overlap giving responses in both upper and lower extremities, and that stimulation posterior to the central fissure produces movement. CF, central fissure; IF, intraparietal fissure; AF, arcuate fissure. (Murphy and Gellhorn, 1945.)

malian series, but nevertheless overlap exists to some degree in the monkey (Fig. 2). With such maximal stimulations the areas from which toes and hip can be excited greatly overlap and are, in fact, almost identical; the same is true of the areas for fingers and shoulder. Other workers (Chang, Ruch, and Ward, 1947; Hines, 1944; Woolsey, 1938), who have selected stimulus conditions to activate a restricted cortical focus and to avoid facilitation, have obtained a different result.

Boynton and Hines (1933) observed that reduction of the stimulus strength may restrict the response to a single muscle of a group that responds to stronger stimulation, a phenomenon they termed "centripetal individuation." In 1938 Woolsey described

jected onto a cortical map according to the point eliciting them, a meaningful pattern resulted (Fig. 3). The solitary response

- × M. abductor hallucis longus (AHL)
- M. flexor digitorum longus (FDL)
- △ M. tibialis posticus (TP)

FIG. 3. A plot of the leg area of the left cerebral cortex in the macaque monkey, showing the points at which electrical stimulation caused single muscles to respond. The ordinate (numbers) is approximately parallel to the central fissure, and the abscissa (letters) to the medial longitudinal fissure that separates the two hemispheres. Each square represents slightly more than 1 millimeter. Note that the points yielding solitary responses in a given muscle are grouped into a few contiguous squares, sometimes within a single square. TA and AHL appear only a few times because they usually respond together. The data from two monkeys are combined, indicating a high degree of reliability. (Chang, Ruch, and Ward, 1947.)

points for a given muscle are not scattered at random, but fall into groups. The area so found can be considered the focus of the cortical field for this muscle. On this map, tibialis anticus and abductor hallucis longus

appear only a few times because they tended to react together, which correlates with the fact that they are slips of the same muscle, differing only in insertion. When several muscles respond together, analysis based upon strength of contraction (tension) reveals further evidence of a topical representation for different muscles. Many factors affect the absolute magnitude of the cortically evoked contraction—the size of the muscle, electrode contact, and fluctuations in the physiological state of the cortex. To cancel these out, tension developed in two given muscles is plotted for each point stimulated as in Fig. 4. For each of the parallel or approximately parallel lines sloping upward to the extensor hallucis longus ordinate, a large filled circle is entered on a graph representing the motor cortex at the point stimulated. Similarly, lines sloping in the reverse direction are represented by a large open circle, and the intermediate slopes are represented by small circles, filled or unfilled, depending on the slope of the line. The important fact is that the points so graphed form a meaningful pattern, with the large filled circles forming a cluster surrounded by small filled circles. From such distributions it is concluded that the cortical representations of the two muscles, though overlapping, are changing topographically in respect of concentration of Betz cells, or some other determinant of cortical excitability.

Latency analysis also reveals a topographical dissociation of cortical points. The latencies for responses of a given muscle are graded and suitably entered on a cortical graph. The points for short-latency responses again tend to form a cluster, surrounded by points for responses of intermediate latency. Since absolute rather than relative latencies are graphed, this type of analysis is more subject to variations depending on the state of the cortex, etc.

In evaluating the degree of topographical dissociation so demonstrated, it is important

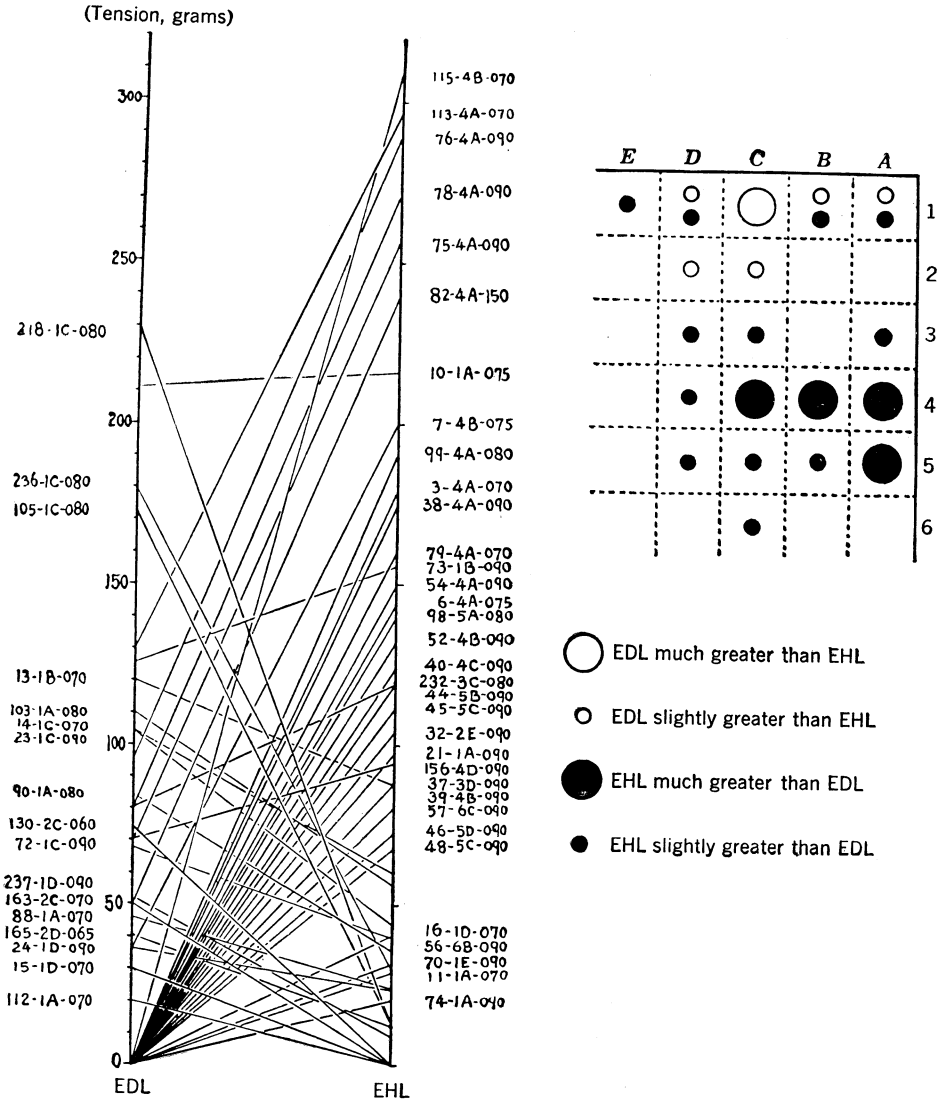

FIG. 4. An analysis of data indicating a topographical representation of muscles in the cerebral motor cortex. In the graph at the left each line shows the contraction tensions of the extensor of the toes (EDL) and the extensor of the great toe (EHL) from stimulation of various cortical points, as noted on either side of the plot. [112-1A-070 means 112th stimulation which was at point 1A (see Fig. 3) and with an intensity of 070 on the Goodwin stimulator.] The plot to the right is similar to Fig. 3, except that tension ratios are plotted in four categories determined by the slope of the lines in the graph. (Chang, Ruch, and Ward, 1947.)

to remember that the muscles that are sufficiently active to permit analysis all belong to the same class, i.e. anatomical extensors

calculated to minimize the sharpness of muscle localization. Assuming that the pattern of representation lies in the mosaic of

FIG. 5. A hypothetical distribution of Betz cells in the motor area that accounts for the data shown in the previous figures. Each muscle is represented by a field of Betz cells with a fringe that overlaps the fields of other muscles and a focus that does not overlap the focus for other muscles. Each symbol stands for a Betz cell, and the concentric circles stand for the spheres of excitation with three intensities of stimulation. Below is the expected contraction in four different muscles from stimulation of the two foci, each with three intensities. (Chang, Ruch, and Ward, 1947.)

(physiological flexors), and that the toe muscles also dorsiflex the ankle. According to Woolsey's analysis (1938) these distal muscles should be contiguously represented. Chang, Ruch, and Ward (1947) point out that the procedure of cortical stimulation is

Betz cells and in the other cells giving rise to corticospinal fibers, the following factors stand in the way of our seeing this pattern of organization: (1) Each Betz cell is potentially connected with many ventral horn cells through the internuncial neurons of the

spinal cord.* (2) Some extrapyramidal fibers arise in area 4; and, since the extrapyramidal system is diffuse, such fibers would spread excitation to a wide range of musculature. (3) Betz cells are stimulated by current passing through a dense pile of transcortical fibers, stimulation of which would spread the excitation to neighboring cortical points. Intracortical U-fibers may also be involved. By circumscription of the area stimulated, as in Murphy and Gellhorn's experiments (1945), the third factor can be controlled, though not the first or second. However, the whole area explored by Chang, Ruch, and Ward would be nearly enclosed in the small area isolated by Murphy and Gellhorn.

Figure 5 illustrates the concept that arises from these experiments, expressed in terms of Betz cell concentrations. (Other factors in cortical excitability are no doubt also involved.) The diagram indicates that the Betz cells that activate a given muscle are not uniformly spread throughout the leg area of the motor cortex, or throughout any subregion devoted to a muscle group. They are concentrated into fields that overlap those of other muscles. Within the field devoted to a given muscle is a focus of representation that is peculiar to that muscle. Thus it is believed that the pattern of the Betz layer is topographically rather than functionally organized in the sense of multiplicity of representation. Superimposed on this stable topographical pattern is an enormously complex pile of transcortical fibers by which movements may be organized. As Woolsey (1947, p. 537) has ex-

pressed it, "the whole nervous system acting dynamically makes use of stable anatomical relationships."

PHYSIOLOGY OF THE MOTOR CORTEX

The topographical features of cortical excitability were briefly outlined in the previous section. The temporal features of cortical stimulation have likewise been investigated, beginning with the pioneer researches of Bubnoff and Heidenhain (1881). The same questions are asked about the cortex as about axon and synaptic excitability. What is the time course of the response to stimulation as exhibited in latency, duration of response, after-discharge, etc.? Are there changes in excitability from a stimulus (conditioning stimulus) that reveal themselves by an altered response to a second or "testing" stimulus? The conditioning-testing procedure is the fundamental maneuver by which axon, muscle, and synapse studies have yielded information on facilitation, inhibition, refractory period, supernormal and subnormal states, etc.* The same procedure is applied to the study of the motor cortex, except that the stimuli are usually repetitive, not single shocks as with axons.

Whereas in the previous section the motor cortex was considered as a relatively stable mosaic of excitable points, in the following sections the cortex will be considered from a more dynamic point of view. Responses to stimulation of the same locus vary in degree and even in type, depending on the previous activity of this or neighboring points in the cortex. It will be shown that similar variability of response occurs from stimulation of morphological structures, such as afferent nerves, which are functionally heterogeneous in the units they contain.

* This may seem quibbling. However, if internuncial spread rather than multiplicity of Betz cell representation is involved, it would be better to speak of the internuncials rather than the cortex as "thinking in terms of movements, not muscles." On the other hand, expressions such as a "flexor Betz cell" or a "tibialis anticus Betz cell" should be understood to mean a Betz cell more strongly connected with the given motoneuron pool than with the motoneuron pools of other muscles.

* Concerning many neural processes, about all that is known is their time course, which has been learned by varying the interval between the conditioning and testing stimulations.

Latency

The period elapsing between the onset of a repetitive cortical stimulation and the onset of muscular response is often quite prolonged, as long as 5 or 10 seconds. This period, however, is not a true latent period but is more properly termed a "*summation period*." It is briefer, the more rapid the rate of stimulation, and fewer shocks are required to elicit the response when, for example, the rate is increased from 6 to 13 per second (Cooper and Denny-Brown, 1927). The summation period of a cortically evoked response can be shortened by facilitation from previous stimulation (see below), or by strychnine, which lowers the threshold of neurons to synaptic stimulation.

After contraction commences, summation continues and is manifested by an increased muscular response to successive members of a slow series of stimuli. Since the muscle action potentials are simple at this point in the response and therefore not indicative of repetitive firing of motoneurons, the phenomenon is one of "recruitment," in which additional motoneurons are successively brought above neuron threshold and made to discharge (Cooper and Denny-Brown, 1927).

During the actual response of a muscle to cortical stimulation, the time elapsing between the occurrence of a break shock and the occurrence of the action potential of the resulting contraction can be made out, provided the stimulus rate is low. This latency averages 14 to 16 milliseconds and is compounded of conduction times, a period of summation and true synaptic delay. It can be reduced to 8.8 milliseconds by strychnine. Less dramatically, the latent period shortens progressively as the contraction proceeds, a further evidence of summation. It is unlikely that summation times of several seconds represent solely the inertia of internuncials linking corticospinal fibers and motoneurons. Prolonged latency and a slow tension rise, characteristic of certain spinal reflexes, are due not simply to the necessity for summation to reach the threshold of

motoneurons, but to an intermixture of inhibitory and excitatory effects arising from the fact that spinal nerves contain the afferent limbs of antagonistic reflex arcs. Thus an increase in the stimulus may prolong rather than shorten the latency and the period of recruitment of the crossed extensor reflex (Matthes and Ruch, 1932). Certain features of the response to cortical stimulation are suggestive of inhibition intermixed with excitation, e.g. the rapid decline of contraction when stimulation is stopped.* In fact, little or no contraction may occur during a 10-second stimulation of the motor cortex, only to set in as a "rebound" phenomenon at the end of stimulation. In spinal reflexes rebound is interpreted to mean an admixture of excitation and inhibition. It will be shown later that cortical stimulation must be viewed as stimulation of a mixed population of units, some ultimately excitatory and some inhibitory to the motoneurons of the muscle observed. This, in turn, means that electrical stimulation is an unphysiological method, and data resulting from it must not be accepted at face value but must be subjected to careful analysis.

Another question is whether the motor cortex itself is the site of inertia and summation and is contributory to the summation

* "... The whole form of the response to stimulation of the motor cortex, and the clonic after-discharge characteristic of that response, are the outward signs of a conflict of summated excitation and inhibition. This conflict, which is not obviously a feature of normal voluntary movement, is not unlikely the result of artificial provocation to concurrent activity of two naturally opposed groups of minute cells in the mosaic of the motor area. One of these groups produces excitation at the final motor neurone and the other inhibition. The inhibition so rapidly developed is not merely the expression of activity of the antagonist, indeed our double records show the resulting impedance in both antagonists at the same time. The inference from this we think is clear, that for a given movement the excitatory units and the inhibitory units lie microscopically intermingled in the cortex, and, further, that representatives of movements in opposite directions are often closely enough related anatomically to be excited by the same stimulus." (Cooper and Denny-Brown, 1927, p. 233.)

period and true latency of the responses to cortical stimulation.

Adrian and Moruzzi (1939), taking advantage of the fact that the pyramidal tract breaks up into fine bundles prior to decussation, were able to record series of action potentials, alike in size and resembling single unit discharges or the synchronous discharges of a group of fibers. During the first few

effective in activating the spinal internuncials and, in turn, the motoneurons. As brought out in the previous chapter, the briefness of the excitatory effect at individual synapses makes a high-frequency input favorable for summation.

The experiments of Adrian and Moruzzi indicate that latency, summation, and recruitment are in part determined at the

FIG. 6. Oscillographic records from a single pyramidal tract fiber at varying intervals during continuous repetitive stimulation (30 per second) of the motor cortex. The large downward excursions which appear to cut the record into segments are the shock artifacts; the smaller downward excursions are the action potentials.

A. 4 seconds after beginning of stimulation—occasional impulses.

B. 1 second later—single or double impulses to each shock.

C. 3 seconds later—three to four impulses to each shock, and movement begins. (Adrian and Moruzzi, 1939.)

seconds of stimulation of the motor cortex at 30 per second, a discharge does not occur in response to each shock (Fig. 6). Later, each shock is followed by an impulse in the pyramidal tract, and, finally, each shock produces a group of three or four impulses spaced at 1.75 milliseconds. When such groups appear, limb movement is first observed. In one experiment strengthening the stimulus reduced the interval between the shock and the pyramidal impulse from 4.5 to 2.3 milliseconds and caused a double discharge in place of a single one. Thus, by summation or increase in stimulus strength, corticospinal fibers are forced into a very high rate of discharge. A high-frequency discharge, in turn, appears to be especially

cortical level. Much remains to be learned about the excitable properties of cortical tissue in response to electrical stimulation. For example, does the summation between shocks of a series represent activities of the intracortical fibers or of the Betz cells? Does the Betz cell, because it is a cell body, or because it is large, have properties different from axons, or the same properties in exaggerated degree? The multitude of questions that arise will probably be answered when single unit techniques, analogous to those of Adrian and Moruzzi, are applied in detail.

Discovery of Facilitation

Bubnoff and Heidenhain in 1881 carried out the first systematic experiments demon-

strating the facilitation phenomena of the motor cortex. They recorded myographically and kymographically the latency of limb-muscle responses to a variety of cortical stimulations. Increase in the strength of stimulations increases the size of the contraction and decreases the latency. Even strong single shocks (except those of long duration) applied to the motor cortex do not evoke muscular contraction. Subliminal stimuli, those producing no visible motor response when delivered singly, do so on repetition. The shorter the interval between stimuli, the more easily summation occurs. With repetition of a minimal current, unchanged in intensity, the height of the contraction gradually increases to a maximum. In all these cases it is clear that "each preceding stimulus therefore leaves an after-effect which increases the effect of the following one" (Bubnoff and Heindenhein, 1881). Such continued stimulation of a given point also results in a spreading of the response to include a wider range of musculature. This is called "irradiation," but the underlying mechanism is facilitation. Even a cutaneous stimulation of the limb, not in itself sufficient to evoke a visible reflex, will augment the response to a subsequent cortical stimulation.

For one stimulus to facilitate another, it is not necessary that the testing stimulus fall on the same cortical point. Such facilitation is termed "secondary." Secondary facilitation may be defined as the augmentative effect of an antecedent stimulation of a cortical focus upon the response to subsequent stimulation at a different point yielding a different but not antagonistic response. The interaction between two cortical points is strongest when they lie within the same somatotopic area, but the two points need not lie in the motor area. For example, stimulation of the postcentral gyrus will facilitate the response from a point in the motor area, and vice versa. The facilitation phenomena of the motor cortex present at least a superficial analogy to activation of reflexes by afferent

nerve stimulation. When the same nerve is stimulated successively, the resulting interaction is termed "temporal summation" and is analogous to primary facilitation. When two nerves or nerve branches are stimulated, the summation is termed "spatial" and is analogous to the stimulation of two cortical points (secondary facilitation).

McCulloch (1944) has formalized the two types of behavior that are grouped under secondary facilitation as follows:

... if two points are selected such that excitation of the first point, a , evokes a motor response, A ; and excitation of the second point, b , evokes B : and if a and b belong to the same [somatotopic] subdivision and if A and B are not antagonistic, then appropriately timed successive stimulation of a and b will cause either (1) a repetition of A when b is stimulated [$ab \rightarrow A$], or (2) an exaggeration of the response B [$ab \rightarrow B$]." [P. 216.]

The response $ab \rightarrow B$ means that the discharge from the a point intensifies the response typical of the second point. The B response tends to occur when a is undergoing extinction (see below). According to the analysis carried out by McCulloch and Dusser de Barenne, the $ab \rightarrow B$ sequence is associated with an electrical change in the cortex at point b and fails when the cortico-cortical connections between the two points are sectioned or when such connections do not exist. Their analysis has shown that area 6 is strongly connected by fibers running to area 4, and, when point a is in area 6 and point b in area 4, the sequence is $ab \rightarrow B$, never $a_6b_4 \rightarrow A$. Since the two areas are not connected by fibers running from area 4 to area 6, the sequence a_4b_6 always results in response A . This is perhaps further evidence that $ab \rightarrow B$ is dependent on cortico-cortical connections, although the fact that the response is that of the more excitable area might be a factor.

The second type of secondary facilitation $ab \rightarrow A$ is a repetition of the a response when b is stimulated. This sequence can occur and,

in fact, tends to occur when b is located in the postcentral gyrus or in area 6, and a is a point in area 4. Dusser de Barenne and McCulloch's analysis, based on section of corticocortical fibers connecting the two points, indicates that such connections are not necessary to the response, though some transcortical facilitation may be involved. It is believed to depend "chiefly upon excitation persisting in the subcortical structures affected by the first stimulation." The sequence $ab \rightarrow A$ is more easily elicited if both points lie on the same somatotopic division, for these must project to the same or closely related portions of the spinal cord. The detailed organization of the motor cortex bears upon this question. In addition to overlap between spinal terminations of the pyramidal tract fibers arising from the two points stimulated, there is probably some overlap between the Betz cells giving the two movements (Fig. 5). In any case the excitatory residuum of the first stimulus apparently is reinforced by the discharge from the second, so that in total it preponderates over the response typical of the second volley.

The second type of facilitation ($ab \rightarrow A$) differs from the first type because the response typical of the second volley is changed from B to A . This was observed by Leyton and Sherrington (1917) and described under the term "deviation of response." They state, "a cortical point can also influence the motor response of another whose response is neither diametrically opposed to nor identical with or very closely similar to its own."

Deviation of response is a change that alters the character of the response, so that some other movement — e.g. of another joint or part — appears in place of the original. Beginning in the arm area, stimulation of a descending series of points, i.e. extending towards the sylvian fissure, gave elbow flexion to a boundary beyond which facial movements abruptly appeared. After an ascending series of stimulations of the face area, the lower points which had yielded elbow flexion

in the descending series now yielded thumb and index movements. The response of the points within an area of overlap between face and arm area were, therefore, altered on the basis of antecedent stimulation. Similarly, within somatotopic areas an ascending or descending series of closely spaced stimulations will cause a movement to appear from an area not yielding that movement in the absence of facilitation.

The mechanism of facilitation will be discussed in a later section in conjunction with the phenomena of extinction and suppression.

Instability of the Motor Point

Facilitation is a factor in the functional plasticity of the cerebral cortex, a concept expressed by Graham Brown and Sherrington (1912) as the "functional instability of a cortical motor point." The instability of the motor cortical mosaic was overemphasized in the early literature, partly because of the inadequate stimulation devices then available. Modern use of thyratron or other electronic stimulators, the employment of fixed rather than hand-held electrodes, etc., minimize the variability of responses to cortical stimulation. Yet, when all known precautions are taken, there remains a definite functional instability of the cortical point. This instability is manifested, according to Sherrington, in (1) facilitation of the type $ab \rightarrow B$, (2) deviation of response $ab \rightarrow A$, and (3) reversal of response. The last is a change in the direction of a movement of a joint, so that extension may be replaced by flexion, i.e. the sense or direction of the movement is reversed. Like the first two phenomena, reversal is temporary, and the result of antecedent stimulation. Since reversal of response is perhaps the most dramatic instance of the functional plasticity of the motor cortex, it will be examined in detail after we consider the phenomenon of reciprocal innervation as manifested in cortically initiated movements.

RECIPROCAL INNERVATION AND REVERSAL OF RESPONSE

Soon after his discovery of reciprocal innervation as a principle governing the behavior of spinal reflexes, Sherrington [and Hering] (1897) described reciprocal excitation and inhibition of limb antagonists under cortical stimulation. When a monkey or a cat was in the stage of ether anesthesia at which the legs maintain a position of flexion at the elbow or hip, a cortical point previously determined to produce extension of the elbow joint or hip joint was stimulated. Concurrent with the resulting extension, the antagonistic flexor muscle became suddenly flabby to palpation, while the extensor muscle became tense in contraction. In a stage of narcosis when an extensor posture of the limbs obtained, relaxation of the extensor muscle resulted from stimulation of the cortical point yielding contraction of the antagonistic flexor muscle. In order to determine whether the interaction was between cortical neurons, the cortex was removed, and the fibers of the internal capsule were stimulated. Reciprocal innervation was maintained.

Several years earlier Sherrington (1893) demonstrated reciprocal innervation of the eye muscles. By nerve section, all the external muscles of one eye were paralyzed except the external rectus which moves the eye to the side. The area of the ipsilateral hemisphere, which prior to nerve section yielded conjugate movement to the opposite side, was then stimulated. The eye moved in the lateral direction. The movement of the ipsilateral eye could only be due to inhibition of the tonus in the innervated lateral rectus.

Reciprocal innervation from cortical stimulation, like that from afferent nerve stimulation, has been challenged from time to time on the basis of evidence of co-contraction of antagonistic muscles. The latter without question does occur, and it was observed by Sherrington himself. The issue is how the fact of co-contraction is to be interpreted.

As with the problem of latency, much is to be gained by approaching the pyramidal system with the experience gained in the study of spinal reflexes. It is profitable, therefore, to examine briefly how the same problem was met and solved in the study of these reflexes. The experiments are detailed and technical and can only be briefly sketched. In the sphere of spinal reflexes, departures from reciprocal innervation are usually accompanied by poststimulatory inhibitory and excitatory rebound phenomena, and adequate explanation is found in the unphysiological character of nerve trunk stimulation. Mixed nerves contain the afferent limbs of many reflexes. Their collective stimulation yields a dominant and a concealed reflex, often antagonistic. By manipulating the intensity, the frequency, and the duration of the stimulation, the concealed reflex can often be made dominant. Evidence adduced in a later section indicates that the territory stimulated directly and by intracortical facilitation contains intermingled "flexor Betz cells" and "extensor Betz cells." This circumstance is adequate to explain co-contraction, especially when it follows a period of reciprocal relationship, is favored by strong and prolonged stimulation, and is followed by poststimulatory rebound, as in the observations of Bosma and Gellhorn (1946). It is often not appreciated that Sherrington's generalizations are the result of analysis, not mere observations; that he thought in terms of single units before enunciating that concept; and that he was well aware of, and often discarded, those situations in which complexity of anatomical arrangement and the bluntness of experimental tools obscure simple and fundamental relationships. The stimulating electrode applied to the cortex stimulates many units *en bloc* and without regard to their function, i.e. the synaptic connections in the spinal cord of the Betz cells lying beneath the electrodes. These same elements, grouped together morphologically, are unquestionably activated selectively by synaptic excitation in normal voluntary action.

The electrode is an unnatural mode of stimulation, and the responses mirror nature only when the stimulus can be confined to a functionally homogeneous group of neurons or when the response of a single unit can be studied.

In 1912 Graham Brown and Sherrington described, as exceptions to the usual stability of the cortical mosaic, instances in which the responses from a given cortical point differed on successive stimulations. Specifically they were concerned with "reversal of a response," i.e. instances in which a point regularly yielding flexion can be made to yield extension, and vice versa. This phenomenon differs from "deviation of response," which is a change to a different but not antagonistic muscle group. Reversal of a response is restricted to a change to response of the antagonist. Although serial stimulation usually augments the response (so-called "intensification of response") because of facilitation, it sometimes results in a reversal of the response.

Interpolating a stimulation of a flexion point in a series of stimulations delivered to an extension point will often temporarily "convert it" to a flexion point, i.e. reverse its response.

One of the factors for reversal is stimulus intensity. In exploring the motor cortex during polymyographic recording from muscles acting over the ankle joint, excitation of flexor muscles (physiological extensors) was rarely obtained (Chang, Ruch, and Ward, 1947). Figure 7 shows a series of responses from a flexion point for the toes, obtained by careful adjustment of the stimulus intensity. A moderately weak stimulus produced contractions of the toe flexor and the toe extensor, larger in the latter (obs. 110 and 111). Reducing the strength of the stimulus *increased* the contraction of the flexor and decreased the contraction of the extensor (obs. 112). Strengthening the stimulus strengthened the extensor contraction and weakened or inhibited completely the flexor response (obs. 116 and 118). A

response confined to the flexor was produced when the stimulus was again reduced to near threshold strength (obs. 119). Thus the stimulus strength determined whether flexor or extensor contractions would result from stimulation of the same point on the cortex.

Perhaps the simplest explanation of such phenomena is gained by viewing a cortical point* as a mixed population of Betz cells, as indicated in Fig. 5. A flexion point is one containing a preponderance of the Betz cells that activate flexor motoneurons. A second assumption is that there is an average threshold difference between the two categories of cells, in this case that those activating the extensor have the lower threshold. Further it is assumed that flexor-connected cells are more numerous in the cortex at the point stimulated or are preponderant in spinal synaptic connections. Finally, if the pyramidal tract fibers from the flexor and extensor Betz cells act reciprocally on the spinal motoneurons, we have a model that would adequately account for reversal of response through change in stimulus intensity.

Frequency is also a factor in the reversal and deviation of response to stimulation of a single cortical point (Boynton and Hines, 1933). Many instances can be cited in which frequency-determined reversal follows stimulation of peripheral and central neural structures. The mechanisms for frequency and for intensity reversal may not be the same. Whereas intensity determines, on the basis of threshold, which cells of the cortex are stimulated, frequency can be selective at subcortical levels if the internuncial bombardments set up by "flexor" and "extensor" pyramidal tract fibers have different time characteristics. Assume that the internuncial system interpolated between the pyramidal tract and the extensor motoneurons produces an internuncial bombardment briefer than that of the

* A cortical point is that area beneath the stimulating electrode, or within the electrical influence of the electrode. A flexion point is one from which a flexion of some joint is the usual response.

internuncials of the pyramidal flexor motoneurons. A faster rate of cortical stimulation would then be required to obtain sufficient summation to discharge the extensor motoneurons and might reciprocally inhibit

can determine the response when a heterogeneous population of cells is excited.

Where there is no reason to assume a reciprocal inhibitory relationship between the two responses, it is more difficult to explain

FIG. 7. A record showing reversal of response from a *single* cortical point, obtained by varying the stimulus strength. The upper two lines are kymographic tracings of two muscles whose tendons were attached to two semi-isometric myographs. The stimulus was repetitive and lasted 4 seconds. Observations Nos. 110 to 119, inclusive, are shown. The notation 4E-060 means that point 4E was stimulated with an intensity of 060 (cf. Fig. 4). EHL is extensor hallucis longus, which dorsiflexes the great toe and is a physiological flexor. FDL is flexor digitorum longus, which plantar flexes the toes and is a physiological extensor. Note that strong stimulation increases EHL response (obs. 110, 111, 116), whereas weakening the stimulation increases FDL and decreases EHL. (Chang, Ruch, and Ward, 1947.)

the flexor motoneurons. Another adequate assumption is that physiological flexors, which execute relatively active and fine movements, have a lower motoneuron threshold, a richer internuncial system, or, for that matter, simply receive more pyramidal tract fibers. Any of these conditions would result in less necessity for summation and in a greater ability to respond to slow rates of stimuli. Therefore frequency, like intensity,

deviation of response produced by changes in frequency. Bailey and von Bonin (personal communication) have given a clear-cut example of a frequency-induced change in the somatotopic distribution of response. At low frequencies (below 10 per second) stimulation of the face area of the motor cortex yielded movements of the tongue and vocal cords; at higher frequencies of stimulation facial movements *alone* were obtained. Mc-

Culloch (1947), in explaining this phenomenon, speaks of lower structures acting as "filters," accomplishing "diversion" of cortically initiated impulses from the 7th to the 12th nerve at low rates of stimulation.

A model of an internuncial filter might be as follows: Suppose the internuncial pools contain closed chains of fibers or reverberating circuits. The simplest model would be a pyramidal tract fiber and an interneuron, the axon of which gives off a collateral that returns to the interneuron cell body. With such a single loop, the moment that the recurrent impulse, initiated by the first pyramidal volley, returns to the interneuron cell body is the optimal time for the arrival of a second pyramidal volley, if summation is to occur. The pyramidal system is not so critically timed, since summation is obtained throughout a wide band of frequency, and neither were the circuits in Bailey and von Bonin's experiment. However, their results can be explained by assuming multiple loops, each with a different circuit time, the statistical distribution of which determines the optimum frequency for summation and hence the optimum frequency of cortical stimulation. If the statistical distribution of circuit times is different for facial and hypoglossal interneurons, a result like Bailey and von Bonin's can be expected.

The phenomenon of the instability of the cortical point should be viewed conservatively. When we stimulate a morphological unit (cortical point, afferent nerve, gray ramus), we are stimulating a functionally heterogeneous structure. Only when such structures are reduced to single units, or to groups of functionally homogeneous units, are we on safe ground. Nor should instability of total response be taken to support a concept of field theory until instability, reversal, etc., have been demonstrated for the individual units.

Extinction

The same technical maneuver that demonstrates facilitation — conditioning-testing se-

quence — demonstrates the phenomenon that Dusser de Barenne and McCulloch described in 1934 under the term "extinction." In fact, facilitation and extinction are intermingled and must be separated by analysis. Extinction is defined as a *diminution or absence of response to stimulation of a cortical motor focus following antecedent stimulation of that same focus* (1939). The phenomenon of extinction is cortical, not spinal, in origin, since it is not seen after thermal destruction of the cortex; neither is it due to the physical spread of current as opposed to the excitatory results of stimulation. The time course and other features of the response show that facilitation and extinction are dissimilar in other ways than the sign of the effect of the precedent stimulation on the testing stimulation.

1. *Time course.* Whereas facilitation is strongest immediately after the testing shock, extinction is maximal about 13 seconds after this stimulation (Fig. 8). Its point of maximum and its duration depend on the depth and type of anesthesia and upon other factors affecting the physiological state of the cortex.

2. *Extensivity.* Although not strictly local, in the sense of being confined to the area immediately subjacent to the stimulating electrode, extinction is much more a local phenomenon than is facilitation. When the conditioning and testing shocks are delivered through electrodes 1.5, 3.0, and 4.5 millimeters apart, there is a sharp spatial decrement in the degree of extinction.

3. *Stimulus parameters.* Extinction is favored over facilitation by prolonged stimulation, high frequency, long pulse duration, and high voltage of the conditioning stimulation. The fundamental difference between the two phenomena is that facilitation appears to be the consequence of neuron impulses, set up locally and at a distance by the stimulus, which render nerve cells more responsive, whereas extinction appears to be a consequence of the fact that nerve cells

have fired and are thereby rendered less excitable. The duration of extinction precludes its being identified with refractory period, which, by analogy with motoneurons, is a matter of milliseconds. Nor is fatigue or exhaustion an attractive explanation, since extinction follows stimulations that do not cause overt responses.* Further differences between extinction and facilitation will be presented when the correlates of extinction and facilitation are discussed.

tion alone. This formulation overlooks the possibility that a cortical focus may represent a mixed population of cells, one class of which preponderates, as shown in Fig. 5. One group of cells may be antagonistic in its action on motoneurons to the preponderate group of cells that gives the point its name. The inhibition resulting from stimulation of a heterogeneous population of cells might, by analogy with spinal reflexes, be termed a "concealed inhibitory component." The dis-

FIG. 8. Kymographic records showing the phenomenon of extinction. Wrist extension induced by repetitive stimulation of the motor area of a macaque monkey was recorded under Dial anesthesia. Lower lines show stimulus and time in 2-second intervals. Responses 2, 4, and 6 suffer extinction because of the short interval (13 seconds) following the antecedent stimuli (1, 3, and 5). The latter are fully effective because of the long preceding interval for recovery. (After Dusser de Barenne and McCulloch, 1934.)

Extinction versus Inhibition

Both extinction and inhibition result in a diminution of response, but there the parallel ends. Dusser de Barenne and McCulloch (1939a) state the distinction succinctly:

Inhibition in the physiology of the cortex is, as far as it is known at present, the disappearance of an existing muscular contraction on stimulation of a cortical focus from which an antagonistic response may be elicited. Extinction is the diminution or absence of response to stimulation of a motor focus following antecedent stimulation of that same focus.

The dichotomy between inhibition and extinction cannot be made on the basis of defi-

tion between a point yielding the same and a point yielding a different and antagonistic response is, therefore, a matter of degree.

Assume that the reciprocal inhibitory aspect of a cortical stimulation has a more prolonged time course than the excitatory aspect. This assumption would account in part for the different time relations of extinction and facilitation. Such delayed inhibitory components in spinal reflexes are well documented where there are latency differences between various reflexes, but the same assumption may not be justified for the pyramidal systems. Furthermore, reciprocal inhibition is not necessarily the only type of cortically initiated inhibition of the motoneurons. Perhaps the slow-conducting, unmyelinated fibers of the pyramidal tract

* However, Adrian and Moruzzi (1939) have shown that the pyramidal tract is conducting impulses prior to overt response.

and/or the extrapyramidal system, arising from area 4, supply a delayed inhibitory component. If the extrapyramidal system is involved, no time limitation need be placed

not suggested, for reasons given above, that delayed inhibitory components are the explanation of extinction, but they might be confused with true extinction phenomena.

FIG. 9. Diagram showing facilitation (Fac.) and extinction of limb response due to stimulation of the motor cortex (upper record), together with electrical activity (second record), voltage drift, i.e. sustained surface positivity and negativity (third record), and the pH of the cortex (bottom record). All determinations were made at the site of stimulation. The stimulus was a 60-cycle current lasting 5 seconds. Note coincidence of the return of the response to normal with the return of spontaneous electrical activity, labeled alternating-current potential. Note also that the voltage drift (direct-current potential) ends while extinction still persists. Voltage drift and acidity, when summated, correlate well with the first and second records. (After Dusser de Barenne and McCulloch, 1939a.)

upon the delayed inhibitory component because multisynaptic arcs are involved, and there arises the possibility of reverberating circuits within or between subcortical nuclei.

An effect of a delayed inhibitory component, arising from an intermixture of diverse functional units in a cortical point, would be to reduce the response to a subsequent stimulation of the same point. It is

These considerations are, however, urged as a criticism of the definition of extinction.

Correlates of Extinction and Facilitation

By correlates of extinction are meant changes in spontaneous electrical activity and changes in potential and pH in the neighborhood of the stimulated neurons. These are summarized graphically in Fig. 9.

Electrical activity. Resulting from an electrical stimulation that causes extinction, even one producing no overt response, there is a diminution, or stilling, of the "spontaneous" electrical activity at or in the immediate neighborhood of the point stimulated. With certain stimuli the period of electrical silence may be preceded by a period of increased electrical activity coinciding with the period of facilitation and interpreted as cortical after-discharge. This discharge also occurs in neighboring foci after a delay of 10 milliseconds or more, depending on the distance. This suggests a slow spread of excitation through the cortex. During the state of facilitation and electrical after-discharge, electrical activity is observed in the spinal cord, even when the cortical stimulation is subliminal. This is evidence of a spinal component in facilitation.

Voltage drifts. These are demonstrated with an apparatus that amplifies slow potential changes as opposed to the relatively rapid "spontaneous" electrical activity of the cortex. The region at or close to the point stimulated is first surface negative, then slowly shifts to surface positive, and finally returns in a few seconds to zero potential, as shown in Fig. 9. At the point of the shift from negativity to positivity the excitability of the cortex shifts from facilitation to extinction. Since the positivity does not persist throughout the entire period of extinction, some other correlate of extinction must be sought.

Cortical pH. A glass electrode applied to the cortex detects a wave of acidity (low pH) that outlasts the positive voltage drift and terminates at about the time spontaneous electrical activity resumes. Preceded by a brief alkaline shift, this acid shift is regarded as the result of intense cortical activity, however caused. The direction of the pH changes are consistent with their being factors in the cortical excitability represented by facilitation and extinction. The association of negativity with increased responsiveness, and of positivity with decreased excitability, is also found in peripheral nerve.

Dusser de Barenne and McCulloch (1939a) believe that both factors, voltage drift and pH, combine to determine the phenomenon of extinction.

Suppression

Like facilitation and extinction, this phenomenon is demonstrated by the conditioning-testing stimulation technique. Suppression exists in two forms. The first is termed "suppression of motor activity" (Fig. 10), and the second form is "suppression of electrical activity" (Fig. 11). The latter is seen as a depression of spontaneous electrical activity throughout the cerebral cortex.* Suppression of motor and suppression of electrical activity must be carefully distinguished because they have quite different subcortical mechanisms. Suppression of electrical activity was first observed in 1938 by Dusser de Barenne and McCulloch (1938a, b) when strychninizing the anterior border of area 4, the "strip area" which Marion Hines (1937) had earlier shown to exert an inhibitory action on movements and reflexes. Later Dusser de Barenne and McCulloch studied the suppression of motor activity from this region (1941). Other "suppressor" areas or strips have since been discovered and will be described later.

Antecedent stimulation of area 4s will suppress the responses to stimulation of area 4. This suppression of motor activity is differentiated from extinction for several reasons.

* Since this chapter was written, several workers have questioned the suppression phenomena. Sloan and Jasper (1950) found many similarities between the suppression of electrical activity and the spreading depression described by Leão (1944a, b, 1947) which, according to Marshall (1950), is fundamentally non-neural in origin and caused by dehydration. Clark and Ward (1948) failed to observe suppression of motor activity in monkeys stimulated with the cranium closed and without anesthesia. Other workers have verified the phenomena of suppression but have found a latency, duration, and refractoriness that are shorter, and hence more consistent with other known neural phenomena. The degree to which spreading depression has confused observations on the suppression of electrical and motor activity has not yet been fully determined.

Time course. In the record shown in Fig. 10, the cortical responses were abolished 4 minutes after delivery of the stimulus to area 4s. Latencies as long as 10 or 12 minutes have been observed. The suppression

is demonstrable only for those within a narrow band of the motor area (4s) and other similar suppressor bands.

Extensivity. Suppression of motor response is not confined to the neighborhood of the

FIG. 10. "Suppression of motor activity" (for the arm) by stimulation of area 4s in the macaque monkey under Dial anesthesia. The upper tracing is the extension of the wrist in response to brief stimulation of the arm area at 1-minute intervals. At the arrow area 4s was stimulated for 5 seconds. Note that suppression is not fully developed until 4 minutes later and is evident for at least 10 minutes. The time line marks 1-minute intervals. (After Dusser de Barenne and McCulloch, 1941.)

FIG. 11. Electrocorticograms of the motor area (arm), showing "suppression of electrical activity" from strychnine stimulation of area 4s (face). Observations on a macaque monkey under Dial anesthesia. Note that suppression is complete in 5 minutes after the application of strychnine; electrical stimulation gives a shorter latency of effect. (McCulloch, 1944.)

lasted for 4 minutes on this record, but it may be shorter or it may endure as long as 20 to 30 minutes, depending on stimulus strength and depth of narcosis. Once elicited, suppression cannot be reinduced immediately, but only after a pause of 15 to 45 minutes.

Specificity. Whereas extinction is a property of all neurons within the motor area,

point stimulated, nor is it limited to the corresponding somatotopic area of area 4.

Site of suppressor action. The interaction between areas 4s and 4 is not by intracortical or intercortical connections, because a deep incision between the two areas does not prevent either form of suppression. The suppressor impulses pursue a descending course, because suppression is ended by undercutting

area 4s. The caudate nucleus is not a link in the chain for suppression of motor response, wherein it differs from the simultaneously developed suppression of electrical activity, which employs corticocaudate connections. The putamen, the globus pallidus, the thalamus, the substantia nigra, and the cerebellum are also excluded as a part of the pathway for suppression of motor activity. Subsequent to the discovery of a bulbo-inhibitory area by Magoun and Rhines (1946), evidence was adduced that area 4s projects to this region (McCulloch, Graf, and Magoun, 1946). Through the bulbo-inhibitory center, a part of the reticular substance, the impulses are presumably relayed to the spinal cord where they inhibit the motoneurons or the internuncial neurons. Employment of multisynaptic pathways is consistent with the long latency and duration that are characteristic of the two suppressor phenomena.

Distribution of suppressor areas. Systematic exploration of the cerebral cortex by topical application of strychnine (to avoid spread of current) has demarcated those areas in monkey (Dusser de Barenne, Garol, and McCulloch, 1941b) and chimpanzee (1941a) from which suppression of motor and cortical electrical activity is elicited. The location of these bands is shown in Fig. 12, with the exception of one on the mesial surface of the hemisphere at the anterior end of the cingular gyrus, area 24 of Brodmann (Ward, 1947). It is characteristic of these areas that stimulation of them suppresses the excitability of the motor cortex and suppresses electrical activity over the whole of the cerebral cortex, beginning in areas adjacent to those stimulated and spreading slowly across the cortex (15 to 20 minutes).

Significance of suppressor areas. The accumulation of detailed information on cortical physiology within the past decade has outstripped our ability to evaluate its functional significance. The suppressor areas are a case in point. The data on which an hypothesis of suppressor function can be based

are still limited and, in brief, consist of (1) what can be deduced from the position of the bands in relation to the other areas of known function, and (2) the nature of the descending pathways responsible for the suppression. The distribution of the suppressor areas is such that three of the major thala-

FIG. 12. Suppressor bands (areas 8s, 4s, 2s, and 19s) on the cerebral hemispheres in the macaque monkey. The numbers are Brodmann-Vogt cytoarchitectural areas. L, A, and F are leg, arm, and face areas of the sensorimotor cortex, and the dashed lines mark the boundaries between these areas. Area 24, a suppressor area of the cingular gyrus, is not visible on this view of the cortex. The mapping is based on suppression of electrical activity. Area 8s, largely buried in the arcuate fissure, is wider than the figure suggests. Later studies have shown that area 2s extends throughout the face area as well. (Dusser de Barenne, Garol, and McCulloch, 1941.)

mocortical projection areas are bounded by them; the auditory projection area is not so bounded, nor does the strong suppressor of the cingular gyrus form the boundary of a projection area. The occipital projection area of the lateral geniculate body, being polar, is bounded by area 19s; the frontal projection area of the dorsomedial nucleus, being similarly polar, is bounded by area 8s and perhaps by area 24. The central sector, the projection area of the posteroventral and lateroventral thalamic nuclei, is bounded by area 2s, area 8, and, in a sense, area 4s. This relation has suggested to some (Ward, 1949)

that the suppressor areas act as dikes or barriers, preventing the spread of activity set up by impulses arriving by the thalamocortical projection systems. However, the auditory area is not so bounded, nor is there a barrier between the postcentral sensory area and the motor cortex. For area 4s a possible significance will be indicated in the discussion of the extrapyramidal system.

Marion Hines (1947) has made the interesting point that three of the major divisions of the cerebral cortex have an adverse * as well as a suppressor area. The posterior adverse zone, lying at the junction of the parietal and occipital lobes and including a portion of the superior temporal gyrus, is more concerned with movements of the eyes, and less with those of the head and body. Conjugate eye movements are elicited from the posterior part of the parietal lobe and the anterior part of the occipital lobe and throughout the striate area. This is a unique situation in that motor effects ensue from stimulation of a primary sensory area for vision. The direction of the conjugate eye movement elicited from a given point in the striate area, relative to the portion of the retina represented at that point, is such that the movements can be interpreted as visual fixation. Weak and inconstant pupillary constriction and lid movements also occur. From occipital and parietal stimulations limb movements are elicited that can be interpreted as reaching and grasping.

The frontal lobe also possesses an adverse area in close conjunction with a suppressor band, area 8s. Stimulation of area 8 and of the immediately adjacent areas causes lateral deviation of the eyes and a turning of the head and trunk on the long axis of the body away from the side stimulated. Pupillary dilatation and lid opening also occur from stimulation within area 8. Epileptic seizures beginning from a focus in this area start with lateral rotation (adversion) of

the eyes, head, and trunk. This region is therefore termed "frontal eye fields" and was termed the "frontal adverse field" by Foerster.

Considerable controversy exists about the effects of ablation of area 8, probably because much of it is buried in a deep sulcus which presents the hazards of subtotal lesion on the one hand and of invasion of underlying projections to the prefrontal lobe on the other. Ablation of this area on one side, according to Kennard (1944c), induces a disturbance consistent with the results of stimulation experiments. The head is turned toward the side of the lesion ("the animal looks at the lesion"), and, in moving about, the animal tends to circle to the side of the lesion. There is initially some paralysis of conjugate lateral deviation of the eyes to the opposite side. That something more than a pure motor phenomenon is involved is suggested by the curious observation that the animal is pseudohemianopic, tending to neglect or failing to recognize objects on the side opposite the lesion.

If we assume that the left side of the cerebral cortex is at the command of sensory impulses from the right side of the body, the adverse movements due to stimulation of the left cortex are actually an *orientation* to the side of a sensory stimulation. Therefore some such term as an *orientational field* would better denote the probable significance of this area. Furthermore, the adjective "adverse," meaning turning towards, does not specify the point of reference and is often understood to mean turning away from.

Despite the dangers of mentalistic interpretations, it is tempting to speculate that we are dealing here with a neural substrate of attention. The so-called "adverse movements," whereby the sense organs and the body as a whole are directed towards a stimulus object, may constitute a motor aspect of attention. Assuming that the adverse field is normally activated by sensory stimulation, a positive feed-back mechanism can be envisaged. A sensory stimulus on one

* An adverse movement is one that causes a rotation of the eyes, head, or trunk about the long axis of the body.

side causes the sense organs of the head and hands to be brought into a position for more effective stimulation and for effective manipulation of the stimulating object.

The relation between orientation (adversion) and suppressor activity is topographically close, and an equally close functional relation may be hypothesized. Hines (1947, p. 442), in describing the effect of stimulation of these regions, said: "The quieting effect, causing cessation of spontaneous movement, conferring upon the animal a curious appearance of attentive repose, was a generalized effect. This effect was most easily obtained from the anterior field on the lateral surface of Brodmann's area 9 and from the three posterior fields." These functions are presumably subserved by the extrapyramidal system.

The linkage of generalized suppression of motor activity with movements that orient the eyes and body towards a stimulus object seems best explained as a mechanism of attention. In addition to the generalized suppression of motor activity exercised through projections from area 4s to the reticular substance, the suppressor areas exert their action upon cortical areas via the corpus striatum and the thalamus, as shown by a reduction of spontaneous electrical activity of the cerebral cortex. Several indications prompt the speculation that suppression of cortical electrical activity is the third member of a triad, along with orientation and suppression of motor activity.

In the electroencephalogram of the resting cerebral cortex, a regular ten-per-second alpha rhythm is preponderant. Sensory stimulation replaces this rhythm with a faster one of smaller amplitude. Analysis has shown that attention to the stimulus is a requisite for this effect. Various explanations for this phenomenon have been given. But it is suggested here that suppression of cortical electrical activity is in some manner a device by which the reverberating thalamo-cortical circuits are brought under control

and prepared for the singleness of activity represented by attention.

Several difficulties present themselves in this as well as in the barrier theory. One is the extraordinary latency and long duration of the phenomenon, which would seem inappropriate to a mechanism having a quick play over environmental stimuli. But suppression, as elicited by electrical or strychnine stimulation under anesthesia, may be a poor indication of how the suppressor areas actually function in the intact animal. The latency is known to be less under light than under deep anesthesia. Another difficulty common to both hypotheses is that suppression falls first and most heavily upon the cortical fields with which the suppressor area is associated. One can conclude only that further research is needed to discover the role of suppression in the cortical processes of the intact animal.

In summary, the so-called "adversive" movements to electrical stimulation can be interpreted as *orientational* movements in the intact animal, and, therefore, as a motor component of attention. Suppression of motor activity and suppression of electrical activity may also prove to be, in some manner, concerned with attention. Another hypothesis is that the suppressor areas act as barriers to the spread of corticopetal impulses throughout the cortex.

PYRAMIDAL TRACT

Historically the pyramidal tract was defined as those fibers passing through the medullary pyramids (Türk, 1851).* Because degeneration of the large axons of injured Betz cells can easily be traced through the

* Excluded by this definition are those fibers that have the same relation to the motor cranial nerve nuclei that the pyramidal tract bears to the motoneurons. By usage these are sometimes called "pyramidal," though they terminate rostral to the pyramids and therefore do not pass through the pyramids. There is no harm in this convention, since it does not obscure the vital distinction between the pyramidal and the extrapyramidal systems.

pyramids and because section of the pyramids causes retrograde degeneration in the pyramid-shaped Betz cells, the term "pyramidal tract" gradually became synonymous with corticospinal fibers arising in the Betz cells of the motor area. Later studies have emphasized the necessity for adhering to the historical definition. The medullary pyramids are the only point at which pyramidal tract fibers are not intermingled with fibers of the extrapyramidal system, and here they can be separately sectioned for physiological study. Moreover, it is indisputably proved that the pyramidal tract fibers originate in many cortical areas besides area 4, and within area 4 many fibers originate in other than Betz cells.

That the oversimplified view of the origin and composition of the pyramidal tract was universally accepted illustrates the fact, pointed out in Chapter 4, that neuroanatomy has been largely the study of large, myelinated fibers, collected into well-defined tracts. In 1932 McKibben and Wheelis pointed out that the medullary pyramids are largely composed of unmyelinated fibers. In 1939 Lassek and Rasmussen inaugurated a series of painstaking quantitative studies that have considerably revised the conception of the pyramidal tract. Application of the silver technique enabled them to count roughly one million axis cylinders, myelinated and unmyelinated, in the human pyramid of one side. Two-fifths of the total are unmyelinated, and the remaining three-fifths, though myelinated, are mostly of small diameter.

By actual measurement and counts of a population of 30,000 *myelinated* pyramidal tract fibers, over half were found to be exceedingly fine, about 1 micron in diameter (Lassek, 1942a). Ninety per cent of the myelinated fibers of man are below 4 microns in diameter; about 8 per cent are 5 to 10 microns; and less than 2 per cent are fibers of large diameter, 10 to 20 microns (see Fig. 13). The large-diameter fibers contribute only some 30,000 of the total of one million

fibers. A later study (Lassek, 1940) showed that the number of cells larger than 900 to 4100 square microns in area,* situated in the intragranular layer of area 4, is about the same (34,000). Since cell body and fiber size are roughly correlated, the large Betz cells are sufficient to account for only the largest myelinated fibers (>10 microns). In any case the figures prove conclusively that the myelinated pyramidal tract fibers must arise in other than giant Betz cells. This conclusion is further supported by experiments on monkeys and chimpanzees (Lassek, 1941).†

By the method of experimental degeneration many observers have traced fibers into the pyramids from cortical areas other than area 4. Lassek's statistical method of fiber counts also proves that the pyramidal tract does not arise only from area 4. Ablation of area 4 eliminates all but a few of the large fibers in the pyramids and reduces the total number of fibers by 27 to 40 per cent (Lassek, 1942b; Mettler, 1944). That 60 per cent of the pyramidal tract fibers originate outside area 4 is in agreement with a large number of studies by other techniques. The parietal area contributes to the pyramidal tract some large fibers, presumably from the occasional giant pyramidal cells, and many smaller fibers. However, according to Lassek, large, though not complete, ablations of the pre- and postcentral regions leave intact, and hence unaccounted for, some 50 per cent

* Since there is no way to define accurately what constitutes a Betz cell, this figure will vary, depending on the size chosen as demarcating Betz cells. A smaller figure is used for the monkey because the size of Betz cells bears some relation to the size of the animal.

† The corresponding figures for the monkey are 554,000 pyramidal tract fibers and 18,845 Betz cells larger than 600 square microns, in each case about half the figure for man. The chimpanzee takes an intermediate position with 28,045 cells larger than 800 square microns and 750,000 myelinated pyramidal tract fibers. The minimum figure varies because the Betz cells are largest in man, next largest in chimpanzee, etc. These figures are an interesting quantitative demonstration of the increased encephalization of motor functions in the primate series.

of the fibers in the pyramids. This would make the postcentral contribution small but definite.

Many observers have reported degeneration in the pyramids due to ablation of the premotor area, though some dispute this finding. The possibility that some of the

tine fibers, before terminating on the pontine nuclei, give rise to a long, descending, unmyelinated fiber which may traverse the pyramids. Should this suggestion be confirmed, it would constitute further evidence of the close linkage of pyramidal and extra-pyramidal systems.

FIG. 13. A graph showing the size distribution of the myelinated fibers of the pyramidal tract in two adult human brains (solid and broken lines). It is evident that the bulk of these fibers are of small diameter (less than 0.004 millimeter). (Lassek, 1942.)

pyramidal tract fibers are of subcortical origin seems ruled out since in man (Mettler, 1944) and in monkey (Lassek and Evans, 1946) all fibers of the pyramid degenerate after hemidecortication. Therefore, allowing for the possibility of a contribution from the premotor area and a greater contribution from the postcentral gyrus than Lassek's present figures indicate, there still remains a considerable fraction of pyramidal fibers that originates elsewhere than in the sensorimotor area. Tower (1944) suggests that fibers of the corticopontine system from the frontal, parietal, and temporal lobes may contribute fibers to the pyramids. According to an observation by Cajal, corticopon-

Tower summarizes as follows the present and future problem presented by the newer work on the components of the pyramidal tract.

... it is clear that a new outlook is required on the nature of the pyramidal tract. Certainly it is not the simple motor pathway from the large cells of the precentral gyrus to the cord that it was so long considered. Nor may "pyramidal" continue to be synonymous with "corticospinal." It is even possible that the tract may not be entirely motor. With the probability looming that a considerable proportion of the corticospinal fibers arise outside the main motor area, and some from parts of the cortex which exercise

little or no known motor function, Peele's suggestion that the component of corticospinal fibers from the parietal lobe might be considered, as others have considered the corticothalamic fibers, as a sensitization mechanism for cord sensory neurons, merits experimental investigation and serious consideration. In the end it may be necessary to redefine the pyramidal tract. [1944, pp. 155-156.]

Termination

The manner in which the pyramidal tract terminates in the spinal cord is a matter of fundamental importance. Throughout the following pages it will be repeatedly necessary to distinguish between events within the cortex and events at the spinal level. Cortical excitation presents all the complexity of reflex action of the spinal cord, plus the added complexity of stimulating, not a peripheral nerve, but an intricately organized neuronal structure, the cerebral cortex. The relation of the pyramidal tract to the final common path represented by the motoneurons, a vital link in the neural mechanism of cortically induced movement, has proved singularly difficult to investigate both anatomically and physiologically. Because the pyramidal tract fibers lose their myelin sheaths shortly before terminating synaptically, their exact termination cannot be learned from myelin sheath stains (e.g. Marchi's method). Obviously, the better method is one that differentially stains normal and degenerating synaptic terminals. Although several attempts have been made to discover the exact termination of pyramidal tract fibers by using silver methods, whether degenerating boutons can be critically differentiated from normal ones is in dispute.

With the Marchi technique, degenerating fibers of the pyramidal tracts can be traced into the external intermediate zone of the gray matter of the spinal cord close to the pyramidal tract. E. C. Hoff (1932), using Cajal's silver method to study the distribution of degenerating boutons after cortical

ablation, concluded that the corticospinal tract terminates mainly at the base of the posterior horn and in the intermediate gray region, but that some degenerating boutons are found on the cells of the anterior horns.

The relation of the pyramidal tract to the spinal mechanism, internuncials, and motoneurons of the spinal cord has been studied by Lloyd (1941). To do this it was necessary to stimulate the medullary pyramids, since cortical stimulation inevitably involves extrapyramidal fibers and its own facilitation phenomena. To insure that no other descending fibers were stimulated, the medulla was transected, sparing the pyramids; and, to prevent the spread of impulses to the cortex by way of ascending systems, the brain stem was completely transected at the mesencephalon. Microelectrodes were then inserted into various regions of the spinal cord to dissect the electrical activity of the spinal mechanism.

The main result of Lloyd's analysis was to establish that the pyramidal tract does not discharge the motoneurons directly but instead activates a complex system of internuncials. The earliest response to a pyramidal volley is seen in the gray matter adjacent to the pyramidal tract (the external basilar region of Cajal, Fig. 14). This region sometimes responds to a single volley, but its response is greatly augmented by repeated volleys. With repeated pyramidal volleys activity is seen in the penultimate or premotoneurons (1) in the solitary cells of the dorsal horn (latency, 9 to 10 milliseconds) and (2) in the intermediate region between the dorsal and ventral horns (latency, 12 to 20 milliseconds). In both instances several shocks are required to activate these internuncial neurons; and the rate of discharge does not follow the rate of pyramidal tract stimulation, suggesting that these interneurons are largely activated from those in the external basilar region. Figure 15 shows electrical responses from single cells in the intermediate region of the gray matter of the spinal cord. Three volleys are necessary to

obtain the first response of the unit. With four, five, and six shocks more responses are obtained; and there is little tendency to after-discharge.

FIG. 14. A cross section through one-half of the spinal cord, showing the connections of the pyramidal tract fibers, of collaterals from the posterior root fibers with cell groups in the gray matter, and the interconnections between the latter. The drawing is based upon microelectrode recordings of electrical activity during pyramidal stimulation. The dotted area P is the area of the pyramidal tract in the white matter from which fibers make direct connection with E, the "external basilar region" (Cajal). S is a "solitary cell" of the dorsal horn; I₂, the intermediate cells of the gray matter; I₁, the intermediate gray nucleus of Cajal; and MN, the motoneurons, the axons of which pass into the ventral root (VR) and ultimately reach the muscles. PA is a collateral of a posterior root fiber with terminal collaterals 2, 3, and 3a. Note that the collateral connections of the neurons in E make a closed circuit. (From Lloyd, 1941.)

Further evidence of interneuron play is that the excitability of motoneurons is not increased by pyramidal facilitation (as tested by the excitability of two-neuron reflex arcs) unless more than two pyramidal vol-

leys are instituted. The latency of such facilitation is 12 to 20 milliseconds. The time course of the facilitation parallels the electrical signs of internuncial activity in the intermediate region, suggesting a causal relationship.

By recording from ventral roots, it was determined that the latency of discharge due to pyramidal tract stimulation was 20 to 30

FIG. 15. Electrical activity recorded by microelectrodes in the intermediate region of the gray matter (see Fig. 14) of the spinal cord. In records A to F (lumbar region) and G to L (cervical region) the pyramids were stimulated with one to six shocks, as is seen by the small shock artifacts to the left of each tracing. Note that one and two pyramidal tract volleys were without effect (A, B; and G, H), and that the discharge increases in number and frequency, and decreases in latency, with more pyramidal volleys (C, F; and I, L). Time: 5-millisecond intervals. (Lloyd, 1941.)

milliseconds, with an after-discharge of several hundred milliseconds. This again is consistent with activation through summation in interneuron pools and establishes that some of the latency of pyramidal tract stimu-

lation is due to the inertia of the spinal mechanism.

The fact that the pyramidal tract fibers act predominantly upon internuncial neurons has implications with respect to the supposed inhibitory actions of that tract. "Direct inhibition" exerted upon the motoneurons was not seen. In several instances pyramidal tract volleys suspended spontaneous activity in the internuncials under observation. Reciprocal innervation by the pyramidal tract, as described by Sherrington, probably is gained by the tract's dealing reciprocally with interneuron systems, or, in other words, by its working through the spinal mechanism for the reciprocal activation of motoneurons.

It should come as no surprise that the higher levels of motor activity have proved anatomically and functionally more complex than the pyramidal fiber-motoneuron chain of the diagram makers. It is a complex system even when the pyramidal tract is excited electrically, thus short circuiting the rich interneuronal system of the cerebral cortex, as described by Lorente de Nó, through which corticopetal impulses must pass to gain access to the pyramidal tract neurons. The complexity has two dimensions: the nexus between cortex and muscle is multisynaptic, and the tract itself is heterogeneous with respect to fiber composition and cortical origin. Finally, it is but one of many potential pathways between the cortex and the motoneurons. The extrapyramidal systems originating in the motor cortex will be discussed in the next section.

Functions of the Pyramidal Tract and Cortical Motor Areas

Until 1932 the functions attributed to the pyramidal tract (and to the motor area) included many that subsequent analysis has proved are those of the extrapyramidal systems. Since the degree to which the extrapyramidal system takes origin in the cerebral cortex was not appreciated, disturbances now known to be due to extrapyramidal damage were ascribed to the pyramidal sys-

tem. Injury to the pyramidal system was (and still is in many textbooks of neurology) described as producing, in addition to paralysis (or paresis) of voluntary activity, spasticity and exaggeration of tendon reflexes. Fulton and his co-workers (Fulton, Jacobsen, and Kennard, 1932; Fulton and Kennard, 1934; Kennard, 1944c) demonstrated that lesions of area 4, exclusive of its anterior border, produce not a spastic paralysis, but a flaccid paralysis; whereas lesions farther anterior (area 6 and the anterior border of area 4) produce spasticity and the grasp reflex.* In these early experiments the anterior border of area 4 was probably included in the lesions of area 6. Damage to this region, termed the strip area or area 4s, was shown by Marion Hines (1937) to be largely responsible for the spasticity, clonus, and brisk irradiating tendon reflexes previously ascribed to area 6. Later it became clear that this region gives rise to extrapyramidal fibers and is one of a series of so-called "suppressor areas" discussed above. It was gradually learned that the activities of area 4, exclusive of 4s, are predominantly, though not exclusively, executed through the pyramidal tract, whereas those of the more anterior areas are predominantly concerned with extrapyramidal function. Because the dichotomy is not complete, analysis at the cortical level is difficult. Concurrently, Tower (1935, 1936, 1940, 1944) attacked the same problem by the technically difficult maneuver of sectioning the medullary pyramids. As pointed out above, only at this point does a section interrupt only pyramidal tract fibers, because at all levels above and below the pyramids the two systems are inextricably mingled.

Tower performed two fundamental experiments to display the respective roles of the

* Spasticity consists of a heightened resistance to passive flexion or extension of a joint. Flaccidity is less than normal resistance. Spasticity is an exaggerated proprioceptive reflex to muscle stretch, due to changes in the play of facilitatory and inhibitory impulses from the brain on the motoneurons.

pyramidal and extrapyramidal systems: (1) section of the medullary pyramids, and observation of the resulting defects of movement and changes in reflexes; and (2) stimulation of the motor areas subsequent to pyramidal section. Certain types of responses to cortical stimulation are lost when the stimulation is applied subsequent to pyramidal section, and these responses correlate with the defects in voluntary movement from pyramidal section. The responses retained are similarly correlated with the type of voluntary activity retained after ablations in the posterior portion of the motor areas.

Traditionally, spastic paralysis was considered the consequence of "pyramidal tract damage," but Tower has conclusively demonstrated by pyramidal section in cat, monkey, and chimpanzee that "hypotonic paresis," i.e. flaccidity and partial paralysis, is the actual result. After pyramidal section there is a loss of fine, discrete movements such as the opposition of thumb and index finger in picking up small objects. Isolated movements tend to default. Grosser movements involving a wide range of musculature persist but lack "all the finer qualities which make for aim, precision and modifiability in the course of execution." These movements, though defective in quality, are clearly "purposeful" and are executed with an appearance of great attentiveness and effort. It is, therefore, erroneous to associate voluntary movement exclusively with the pyramidal system.

Wanting after experimental pyramidal section are the spasticity, exaggerated deep reflexes, and clonus previously ascribed to pyramidal tract damage. Diminished resistance to passive flexion or extension of a joint obtains. The hypotonia was relatively greater in monkey, and the loss of fine movement relatively greater in the chimpanzee. Atrophy of muscle, rather than contraction (which accompanies fixed spastic position of limbs), follows pyramidal section. The up-going toe resulting from plantar stimulation (the positive Babinski reflex)

seen in the chimpanzee survives as a sign of pyramidal tract damage. The hopping and placing reactions are abolished.

The intermingling of the cortical representation of the pyramidal and extrapyramidal systems is well illustrated by the fact that section of the medullary pyramids does not abolish cortically induced movements to electrical stimulation of the motor areas. Such movements resulting from stimulation of area 4 are to some degree "somatotopically organized," i.e. movements are confined to the arm, trunk, or leg. They differ from movements induced prior to pyramidal section by involving a wider range of musculature. Discrete responses confined to a muscle or a muscle group are no longer seen when the pyramids are sectioned.

With the pyramids sectioned, stimulation of the motor cortex has another conspicuous result — chhalasis, or the inhibition of posture and movement. In the anterior region of area 4 this tends to be an inhibition of tonic extensor posture, whereas, more forward, in area 6, the response tends to be a relaxation of tonic flexion, including inhibition of grasp. The latter is consistent with the observation of Fulton, Jacobsen, and Kennard (1932) and Richter and Hines (1934) that ablation of this area induces forced grasping.

Section of the pyramids intercepts many corticospinal fibers besides those originating in area 4. The portion that arises in the postcentral gyrus is also concerned with voluntary activity. Welch and Kennard (1944) have shown that postcentral lesions increase the paresis consequent to a lesion of the motor areas and increase the severity of spasticity. The postcentral area, even to a greater degree than the precentral area, exhibits an intermingling of pyramidal and extrapyramidal functions.

In summary, the function of the pyramidal tract projections from the classic motor area (area 4, exclusive of area 4s) and elsewhere in the cerebral cortex is the execution of discrete, fine, voluntary movement and the execution of the so-called "cortical" reflexes

(hopping and placing reactions). Grosser movements and the inhibition of movements are served by the extrapyramidal fibers originating in the motor and other areas of the cortex. Spasticity, exaggerated reflexes, the Babinski reflex, and forced grasping are not related to pyramidal tract section. Voluntary movement, therefore, appears to be a conjoint action of pyramidal and extrapyramidal systems and also involves corticopetal systems and cerebello-cortical interaction. The extrapyramidal system and the cerebellum will be discussed in the next sections.

Recovery of Function after Lesions of the Motor Cortex

Perhaps the most ubiquitous and the least understood phenomenon in neurology is the recovery of function that follows all but a few experimental lesions of the nervous system. The problem of recovery, because of its gross similarity to the problem of learning, falls in the border zone between neurology and psychology, and perhaps for that reason the mechanism of recovery is still not analyzed. Where multiplicity of pathways exists, recovery is conspicuous; only where a bottleneck exists and all the fibers in a functional category can be sectioned is recovery wanting. Thus lesions of the motoneuron are definitive (apart from regeneration). So is section of all the posterior root supply of a limb (though vision can compensate to some degree). Section of the spinal cord ends all activities that depend on conduction through long spinal pathways connecting the brain with segments below the level of the lesion, and no recovery is possible (nor does regeneration occur).

The situation is different for reflex action, since spinal transection severs not the segmental reflex arcs but only the descending facilitatory and inhibitory tracts, and the long-circuits through the brain. After a period of abolition or severe depression certain reflexes of the spinal cord, especially flexion, return and some become exaggerated. Similarly, after lesions of the cerebral motor

systems the period of spasticity and exaggerated reflexes is preceded by a period of flaccidity and depressed reflexes. These two periods are termed the phase of "shock" and the phase of "release of function." Shock is, of course, a complete misnomer, because the depression of reflexes arises solely from interruption of descending fibers, not from any stimulation due to the trauma of the section. In lesions of the cerebral cortex trauma is a factor. Thus some of the immediate effects of cortical extirpations—so-called "neighborhood" symptoms—are artifacts due to damage of surrounding areas by trauma, interference with blood supply, edema, exposure, etc.

Such factors, being evanescent under carefully executed neurosurgical procedures, do not explain the severity of deficits in the early postoperative period. Although the intimate mechanism of recovery is not known, the factors affecting it have been worked out in some detail for voluntary motion (Kennard, 1940; Kennard, 1944a, c; Welch and Kennard, 1944). The first factor follows from facts presented in the previous section, namely that cortical areas other than area 4 give rise to pyramidal tract fibers and to extrapyramidal fibers and therefore can support some degree of recovery when the principal motor area is removed. Some of the other factors are the following:

Size of lesion. Ablation of the arm area alone has less effect on arm functions than if the arm and leg areas are both removed. This may well be due to some intermingling of arm and leg representation. Ablation of areas 4 and 6 limits voluntary movement more than ablation of only area 4. Bilateral lesions of areas 4 and 6 have a greater effect than unilateral lesions, which correlates with the observation that some ipsilateral movements are elicited by electrical stimulation of the motor areas.

Kind of lesion. Sperry (1947) has shown that crisscrossing the cerebral cortex with the scalpel has surprisingly little enduring

effect on voluntary movement. This suggests that movements are integrated by an interplay between the subcortex and the cortex through the circular mechanisms described above.

Time elapsing between lesions. If areas 4 and 6 of both hemispheres are removed in four stages with time for full recovery between, the final paresis is very much less than if the same amount of cortex is removed at one time.

Age. Young animals suffer slighter defects after the removal of a given cortical area than do mature animals. Similarly the effects of spinal transection are less severe in embryos or young animals.

Phylogenetic position. In general, the higher the animal is in the evolutionary scale, the greater the degree of functional impairment from equivalent cortical lesions or decortication. This is one of several evidences of the corticalization of function.

Use. Use promotes recovery of function and is one of the main resources in the treatment of spastic paralysis and other organic disorders of the nervous system. This factor is especially important in experimental lesions of the motor cortex which cause the animal to "neglect" the limb. When binding the normal arm forces the animal to use the affected arm, an unsuspected variety of movements are seen, and recovery of function is promoted.

Motivation. During excitement an animal displays greater voluntary power and skill than it does during cage life.

Drugs. Ward and Kennard have shown that the administration of a stable cholinergic drug, i.e. one resembling acetylcholine in action, increases voluntary capacity in monkeys with cortical lesions, and with daily administration the effects outlast the presence of the drug in the blood stream. On the other hand, recovery is retarded by phenobarbital which depresses cortical function.

The necessity for making a complete lesion of a given cortical area in order to display

its functions is well recognized. A small fragment of the arm area 4 will support a surprising degree of recovery of voluntary capacity. A quantitative issue is involved. We have seen that variety and delicacy of finger movements are gained by the evolution of a large cortical representation, i.e. multiplicity of units. Should the law of diminishing returns apply so that the curve relating neural units to performance is negatively accelerated, certain recovery phenomena can be explained. For example, if a large amount of cortical tissue is required to gain the highest levels of motor skill, a severe cortical insult would appear to produce little permanent deficit unless the examination methods actually test the highest levels of motor skills, which they rarely do. Added to this factor is the presumed ability of remnants of the total neural mechanism to increase their level of activity. Whether this involves any true "reorganization" in the sense of establishing new connections is an open question. But it is worth noting that "reorganization" is closely akin to "vicariation of function." There is a reluctance to believe that a cortical area can acquire a new function after the main area of representation for that function is ablated. Rather, the tendency is to believe that a small component area can increase the level of its activity, i.e. reorganization rather than vicariation.

Finally, quite a different view of recovery is held by those who accept von Monakow's doctrine of *diaschisis*.^{*} How one views re-

^{*} *Diaschisis* literally means splitting, the thought being that the sudden withdrawal of impulses normally received from the extirpated tissue adversely affects synaptic conduction in functionally related structures, temporarily reducing their activity. Thus, temporary underactivity will be felt throughout the whole of a system of functionally related fibers. The anatomically fractional extirpation amounts to a total functional ablation. The postulated synaptic change has not been proved, but neither has the mechanism of the postulated reorganization process. The *diaschisis* theory avoids some of the quasi-vitalistic connotation of reorganization or vicariation.

covery depends on how one views the original deficit. The diaschisis theory is that a fractional loss of the neural apparatus for a given function temporarily puts the total neural apparatus for the function out of action by an unknown mechanism. Recovery then becomes, not the attainment of new levels of activity through reorganization of the surviving neural components, but their return to normal levels of activity. Actually, diaschisis and reorganization are not mutually exclusive, and both may be involved in sequence. Certainly no critical experiment has been devised that discriminates between the two hypotheses.

EXTRAPYRAMIDAL SYSTEM

The extrapyramidal system consists of a series of complexly interconnected nuclear masses lodged in the cerebral hemispheres and brain stem. It is sometimes convenient to include the cerebellum in a discussion of this system. The neuroanatomy of the extrapyramidal system is too large a subject to describe in this chapter. Figures 16 and 18 and a neuroanatomy text should be studied. Injury to the extrapyramidal system produces widely varied disturbances of movement and posture, but clinical studies have done little to solve the localization problem because of the diffuse character of

FIG. 16. A highly schematic diagram, showing cortical and other connections of the basal ganglia of the left hemisphere (left is lateral, right is medial). Cell bodies are represented by circles, and the terminations of axons by a fork. Conduction between neurons is from termination to cell body. The large fiber represents the pyramidal tract. The pathway for motor and electrical suppression from 4s is marked by fine solid axons and is 4s → caudate → globus pallidus → thalamus → areas 4, 4s, and 6. Other connections are indicated by dashed lines, and some have been omitted. H₁ and H₂ are the fields of Forel. For simplicity collateral fibers have been used where separate fibers probably exist. (Modified from Kennard, 1944.)

the lesions seen at autopsy. However, some insight into the extrapyramidal system has been gained from laboratory and neurosurgical studies of the past two decades. Progress in three directions is notable: (1) discovery that the extrapyramidal system is anatomically and functionally connected with the cerebral cortex, (2) isolation of a cerebrotocerebellar circuit, and (3) discovery in the reticulum of the brain stem of links belonging to the extrapyramidal system.

Much of our knowledge of the extrapyramidal system pertains to the abnormalities that follow disease of it; little is known of what it contributes to normal voluntary and postural activities. The disorders of the extrapyramidal system are best considered from the point of view of signs rather than the syndromes into which the signs are grouped. Disturbances of the extrapyramidal system, including the cerebellum, fall into three broad categories: (1) posture, (2) movement, and (3) emotional expression; and in each category the alteration may be either one of excess or one of deficit.

- I. Disturbances of posture.
 - A. Spasticity and rigidity.
 - B. Hypotonia.
- II. Disturbances of movements.
 - A. Hypokinesia (poverty of movement).
 - B. Hyperkinesia.
 1. Tremors.
 - a. Of rest.
 - b. Of intention.
 - c. Of posture, i.e. static tremors.
 2. Athetosis (sinuous, slow, twisting or writhing movements of the arms and legs, grimacing of the face).
 3. Choreo-athetosis (involuntary jerking of the limbs).
 4. Hemiballismus (repeated, sudden excursions of the arm as though flipped away from the body).
- III. Disturbances of emotional expression.
 - A. Overactivity of emotional expression (involuntary laughing or crying not accompanied by appropriate emotional feelings).

- B. Diminution of emotional expression (e.g. masked facies in paralysis agitans).

A cursory examination of this list or of the neuroanatomy of the extrapyramidal system suffices to show that "extrapyramidal system" is a term of convenience not unlike the terra incognita of the early Renaissance map makers. It is obviously not a unitary or homogeneous system that does some one thing. Yet there is reason to hope that recent researches have established some of the main routes and continents of this terra incognita.

It has already been pointed out that spasticity results from destruction of certain of the cortical origins of the extrapyramidal system, and that posture as well as movement can be inhibited by stimulation of them. One of the extrapyramidal components concerned with posture arising from area 4s has been traced to the reticular formation of the medulla oblongata. It will be considered in detail.

Brain Stem Reticular Inhibitory and Facilitatory Areas

The ubiquitous reticular substance of the brain stem* has come into prominence with the discovery by Magoun and Rhines (1946) that its bulbar portion, specifically the ventromedial area superior to the inferior olivary nucleus, has widespread inhibitory actions (Fig. 17). Tested against sample reflexes—the ipsilateral flexor reflex of the forelimb (forelimb and nociceptive), the knee jerk (hind limb and proprioceptive), and the blink reflex (cranial and tactile)—stimulation of the reticular area was found to inhibit them all. Such stimulation also

* "The formatio reticularis fills the interspaces among the longer tracts and their nuclei. It is composed of small islands of gray matter, separated by fine bundles of nerve tracts which run in every direction, but which are for the most part either longitudinal or transverse . . . The nerve-cells of the reticular formation are scattered through the mesh of interlacing fibers. In certain localities they are mostly grouped and form fairly well defined nuclei." (Ranson, 1943.)

inhibits the responses to stimulation of the motor cortex, and the interaction is at a spinal level. The latter effects are usually bilateral, and stimulation of a single point in the reticular area inhibits decerebrate rigidity in all four limbs. The inhibition is therefore widespread with respect to topo-

hood of area 4s. Action potentials synchronous with the strychnine spike from the cerebral cortex were recorded from two sites, the pyramidal tract and the bulbar inhibitory area. At the latter site the potentials were triphasic—positive, negative, positive—indicating, according to volume conductor theory, electrical activity at the site of the electrodes. Electrical activity from the pyramids consisted of diphasic waves, positive-negative, indicative of activity at a distance from the electrodes. Thus it was concluded that area 4s projects to the bulbar inhibitory area. Activation of the bulbar inhibitory area by stimulation of 4s was prevented by a section through the basis pedunculi of the midbrain, which contains both pyramidal and extrapyramidal fibers, but it was not prevented by section of the pyramidal tract more caudally, just above the bulbar inhibitory area. This indicates that the fibers from 4s to the bulbar inhibitory area diverge from the corticospinal tract at a pontile level. The suppressor area of the cingular gyrus (area 24) also discharges into the bulbar reticular area. Whether other suppressor areas do likewise remains to be learned. From the bulbar reticular inhibitory area, the reticulospinal tracts descend the spinal cord, mainly in the ventral columns (Niemer and Magoun, 1947). Lesions of the spinal cord, designed to interrupt the reticulospinal tracts and spare the pyramidal tract, produce spasticity without impairing voluntary movement. Thus the reticulospinal tracts complete a pathway from the cerebral cortex to the motoneurons. The links in this pathway have been worked out by several independent groups of workers, starting at different points and using different techniques. The piecing together of the chain constitutes one of the major achievements in neurophysiology in recent years.

Hughlings Jackson laid down as a heuristic principle in neurological thinking that positive symptoms, e.g. spasticity, cannot result from a negative event represented by corti-

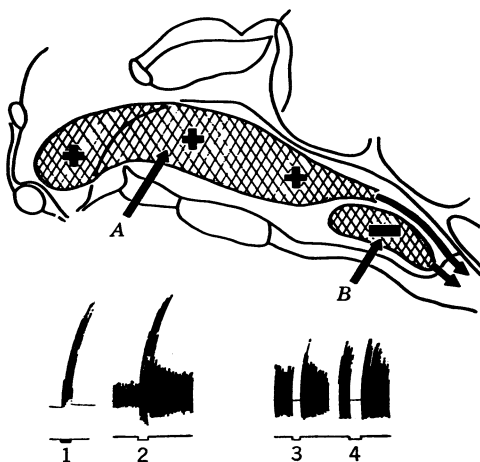

FIG. 17. A mid-sagittal plane of the cat's brain stem, showing by crosshatching the facilitatory (+) and inhibitory (-) areas of Magoun and Rhines. Below are typical records showing facilitation (A) and inhibition (B) of the patellar reflex (1 and 3) and of cortical motor response (2 and 4). The lowest line is a stimulus signal. (Niemer and Magoun, 1947.)

graphical distribution and to the type of reflex affected, and the conduction pathways must be correspondingly diffuse.

Discovery of a bulbar inhibitory area has further illuminated the suppression of cortical motor response elicited by stimulation of area 4s. Unlike suppression of electrical activity, suppression of cortical motor excitability does not depend upon a circuit through the corpus striatum and the thalamus but is exerted by a pathway descending into the brain stem. That the bulbar inhibitory area is a link in the suppression of motor activity was shown by McCulloch, Graf, and Magoun (1946) by strychninization in the neighbor-

cal or other lesions. The cortical lesion can "release" but cannot produce the over-activity. As Magoun (1947) picturesquely puts it, if the cerebral cortex is the lid on the jack-in-the-box, where is the spring that makes Jack jump when the lid is raised? The spring is not the segmental reflex arcs of the spinal cord. Those serving postural reflexes in animals higher than cat and dog have become so dependent on facilitation from, or long-circuiting through, the brain stem that they cannot even support normal postural activity, much less spasticity, when acting in isolation following complete transection of the spinal cord.

The spring of the jack-in-the-box is then to be sought in the brain stem. Since a transection passing through the lower part of the midbrain of a cat or a monkey results in hyperactivity of stretch reflexes (decerebrate rigidity), an upper limit is established. It has long been known that destruction of the vestibular nuclei in the cat abolishes or greatly reduces decerebrate rigidity, as does severance of the anterior columns of the spinal cord which contain the vestibulospinal and the ventral reticulospinal tracts. However, there has been considerable doubt whether the vestibulospinal system plays the same role in man that it does in lower animals. Therefore it has been a welcome disclosure that the reticular substance also appears to act as a facilitatory mechanism.

This was shown by experiments similar to those that disclosed the existence of the bulbar reticular inhibitory area (Rhines and Magoun, 1946). Stimulation of the brain stem with the Horsley-Clarke apparatus was played against the patellar reflex, or against stimulation of the pyramids or of the motor cortex. In some cases the sensory motor cortex was removed to insure that the interaction was not at a cortical level. The facilitatory area is not so circumscribed as the reticular inhibitory area (Fig. 17). The former extends from the ventral diencephalon (subthalamus and hypothalamus) caudally

through the central gray matter and the tegmentum of the midbrain and the reticulum of the brain stem. The facilitation is not exerted through the vestibular nuclei, for it persists after their destruction (Bach and Magoun, 1947).

Slowness and poverty of movement are conspicuous elements of one extrapyramidal syndrome, paralysis agitans or Parkinsonianism. Since the brain stem facilitatory area acts strongly on movements induced by stimulation of the pyramid or cortex, Rhines (1947) and Rhines and Magoun (1946) suggest that clinical hypokinesia may be the result of interference with the brain stem facilitatory system. Stated positively, this means that a component of the extrapyramidal system acts to reinforce the discharge of the pyramidal system in executing voluntary acts.

In the lower vertebrates, where the cerebral cortex is poorly developed, the basal ganglia and brain stem carry on many of the functions performed by the cerebral cortex in mammals. For this reason the hyperkinesia of extrapyramidal disease is often regarded as primitive behavior patterns released from cortical control. A more recent point of view is just the reverse of this and holds that certain of the hyperkinetic phenomena are cortically initiated activities uninfluenced by the extrapyramidal system.

The results of electrical stimulation of the basal ganglia favor the second hypothesis, since few movements result from such stimulation. However, given a background of posture or of movement induced by cortical stimulation, stimulation of the basal ganglia results in prompt inhibition of pre-existing activity. Nor do large bilateral lesions of the basal ganglia cause default of any type of movement, though abnormal involuntary movements appear. On the whole the evidence of stimulation and ablation indicates little independent activity of the basal ganglia. Rather, the basal ganglia and cerebral cortex appear to act as a unit. The close interaction between them appears to

be accomplished by the projection of the suppressor areas on the caudate nucleus from which impulses are returned to the motor cortex by way of the pallidum and thalamus. Because activation of this sys-

activities from control by the cerebral cortex, are abolished if the precentral gyrus is damaged incidentally by disease or intentionally by neurosurgery (Bucy, 1944). These abnormal movements are, therefore,

FIG. 18. Schematic diagram illustrating Bucy's view of the neural mechanism of choreo-athetosis, utilizing a suppressor circuit 4s to caudate nucleus (CN) to globus pallidus to the ventrolateral nucleus of the thalamus VL by way of the fasciculus lenticularis (f.l.) and ansa lenticularis (a.l.) and H₂ and H₁, the fields of Forel. Thalamocortical fibers return the impulses to areas 4 and 6. Parapyramidal is a synonym for extrapyramidal fibers originating in the areas 4 and 6 and are thought to be released to abnormal activity which results in the involuntary movements of choreo-athetosis. (Bucy, 1944.)

tem leads to suppression of cortical electrical activity, this circuit is believed to modulate cortical discharges. In the absence of such modulation hyperkinetic movements appear. In the next section an explanation of clinical choreo-athetosis in terms of circular systems will be presented.

Choreo-Athetosis

These hyperkinetic movements, far from being induced by the release of subcortical

cortically initiated. They might represent discharge of the pyramidal system when unaided by the damaged extrapyramidal system, or they might represent a discharge of the motor cortex through its extrapyramidal connections. The latter appears to be the case, because such involuntary movements are also abolished by section of the anterior column of the spinal cord (Putnam, 1940). Therefore, the impulses producing abnormal movements must reach the motoneurons not

by the corticospinal tract, undamaged because it is situated in the lateral columns, but by one of the more ventrally lying tracts originating in the brain stem. Whether the discharges are purely extrapyramidal is still open to question. That hyperkinetic movements are initiated cortically rather than subcortically was deduced by Kinnier Wilson, a deduction that forms the rationale for an effective neurosurgical attack on athetosis suggested by Bucy. He has shown that removal of the precentral gyrus (areas 4 and 6) effectively ends or ameliorates the distressing athetoid movements. Bucy integrates his views on the origin and conduction of impulses giving rise to athetoid movements in Fig. 18 and in the following paragraph:

Choreo-athetosis is usually associated with destructive lesions of the caudate nucleus and putamen (Alexander), less commonly with destruction of the ventrolateral nucleus of the thalamus (Schuster), and still more rarely with lesions of the globus pallidus (Papez, Hertzman, and Rundles). It appears most likely that these various destructive lesions remove a "governor," thereby releasing the precentral cortex to an abnormal state of hyperactivity which finds expression via impulses travelling to the anterior horn cells through the parapyramidal fibers in the anterior fasciculus of the spinal cord. Anatomically these various subcortical nuclei are connected in a neural circuit which passes from the caudate nucleus and putamen to the globus pallidus and thence . . . into the ventrolateral nucleus of the thalamus, and from there by thalamocortical fibers to the precentral motor cortex. [1944, p. 405.]

Tremor of Rest

This form of hyperkinesia, seen in the Parkinsonian syndrome, differs in several respects from choreo-athetoid movements. It is a regularly recurring, alternating activation of antagonistic muscle groups as opposed to the irregular, jerky movements of choreo-athetosis. The tremor of rest is not

ended by section of the anterior columns of the spinal cord, but it is abolished or greatly ameliorated by section of the lateral columns of the spinal cord containing the pyramidal tract fibers, or by extirpation of the posterior part of the cortical motor area (Bucy, 1944; Putnam, 1940). These observations suggest that the pyramidal tract conducts the impulses underlying the tremor. The undamaged extrapyramidal system, either through subcortical circuits or by interaction at the spinal level, supposedly modifies the pyramidal discharge, rendering it more continuous.

An alternating tremor of rest, believed similar to that of the Parkinsonian syndrome (paralysis agitans) has been produced by lesions, not in the basal ganglia, but in the mesencephalic and the pontine tegmentum (Ward, McCulloch, and Magoun, 1948). The tremor of rest was accompanied by hypokinesia and poverty of emotional expression (masked facies) which are characteristic of paralysis agitans. The tremor was temporarily abolished by lesions of areas 4 and 6 and returned with the recovery of motor power. Interruption of the circular system from cortex to cortex through the basal ganglia did not affect the tremor, nor could the rhythm of cortical activity be correlated with the rhythm of motoneuron discharge. The latter observations raise the possibility that the source of the tremor lies in the brain stem below the destructive lesions and is an oscillatory phenomenon of the inhibitory and facilitatory mechanisms of the reticular substance. It has long been known that the upper brain stem is prone to produce rhythmic activity, whereas the lower levels subserve sustained movement or posture. The lesion may have released some upper brain stem mechanism. In any case the experimental production of a syndrome exposes it to analysis and often marks the turning point in our understanding of the disease.

CEREBELLUM

The cerebellum and the cerebral hemispheres show many features in common. Each consists of a convoluted mantle or cortex of gray (cellular) substance and a central core of white matter (centrifugal and centripetal fibers) in which are lodged gray nuclear masses. Both are suprasegmental structures. This means that they do not give rise to sensory and motor roots, as the spinal cord and brain stem do. The cerebellum, like the cerebral hemispheres, receives a large afferent input from the sensory roots of the spinal cord and the brain stem. The cerebellum is strongly connected with the motor areas of the cerebral cortex which, in turn, are strongly connected with the cerebellum. Finally, the cerebellum projects to certain brain stem nuclei. These four classes of fibers enter and leave the cerebellum by three peduncles—inferior, middle, and superior—which form three legs attaching the cerebellum to the brain stem.

The cerebellar cortex contains a large cell with profusely branching dendrites, the Purkinje cell. These cells, like the Betz cells of the cerebral cortex, are mainly reached by incoming systems only through an inter-nuncial system. The Purkinje fibers constitute the only known exit for impulses from the cerebellar cortex. The axons of Purkinje fibers terminate within the cerebellum on the deep masses of gray matter: the large, laterally placed dentate nucleus; the smaller fastigial nucleus, lying near the midline; and two nuclei interposed between them—the globosus and emboliform nuclei. All these nuclei give rise to the efferent cerebellar systems.

Another point of similarity between cerebellar and cerebral cortex was mentioned in the previous chapter, namely, that the cerebellum receives other than proprioceptive and vestibular impulses. Oscillographic studies (Snider and Stowell, 1944) have revealed that the cerebellum receives tactile,

visual, and auditory impulses, and the cerebellar cortical areas for each have been mapped. In fact, for tactile impulses there is a double representation of the body surface—one in the anterior lobe and one in the paramedian lobule—just as there are two sensory areas in the cerebral cortex. Cerebrocerebellar connections link sensory area I (postcentral gyrus) with the anterior lobe somatosensory area, and somatic area II is linked with the paramedian lobe (Hampson, 1949). The auditory and visual areas of the cerebral cortex are connected with the auditory and visual areas of the cerebellar cortex.

A further similarity between the cerebellar and cerebral cortex is that both exert a control over visceral as well as skeletal musculature. It is clear from this newer investigation that the old concept that the cerebellum is a proprioceptive center controlling skeletal musculature must be considerably revised. Like the cerebral cortex, the cerebellum must play a part in a wide array of activities. This does not mean, however, that the two structures play the same role. The cerebellum lacks, for example, the direct connection with the final common pathway that the pyramidal tract provides.

Unlike the Betz cells, the Purkinje cells do not send fibers to the spinal cord or motor nuclei of the cranial nerves. Consistent with this lack of a direct connection with the final common pathway, the cerebellum is not believed to execute voluntary or any other type of movement. No type of movement is lost through extirpation of the cerebellum, though movement is altered in character. The role of the cerebellum appears to be regulatory rather than executory. The effect projections of the cerebellum are presumed, on an anatomical basis, to be most nearly like those of the extrapyramidal system of the cerebral cortex.

Lobulation, Projections, and Nuclei

The cerebellar cortex, though highly convoluted and divided into a number of lobes,

shows none of the fractionation into cyto-architectural areas so characteristic of the cerebral cortex. Nevertheless the various areas of the cerebellum show a diversity of function. There are definite areal differences in the afferent projections, and these differences have functional significance. In fact the guiding principles in the investigation of the cerebellum have come from the study of the afferent projections by the technique of evoked potentials which, in turn, was inspired by a disentanglement of the lobulation of the cerebellum based on phylogenetic and ontogenetic studies (Larsell, 1937; Dow, 1942a). The complex morphological terminology applied to the various lobules of the cerebellum has proved largely meaningless and is now used only when necessary for descriptive purposes.

Morphologically the cerebellum consists of the cerebellar hemispheres between which lies a distinct longitudinal fold called the vermis because of its resemblance to a worm (Fig. 19). The lateral expansions, or cerebellar hemispheres, are virtually nonexistent at the anterior end and expand greatly in passing posteriorly. At one time thought to be of functional significance, this dichotomy into vermis and cerebellar hemispheres is no longer stressed. Several transverse fissures mark off the traditional morphological lobes of the cerebellum. The comparative anatomical studies of Larsell and Dow show that only one major fissure and two minor ones demarcate functional areas and hence are significant. The earliest fissure to develop phylogenetically and ontogenetically, and hence the most fundamental one, is the *fissura posterolateralis* which divides the cerebellum into the flocculonodular lobe and the corpus cerebelli. The *fissura prima*, so named when it was considered the fundamental fissure of the cerebellum, divides the corpus cerebelli into an anterior and a posterior lobe. The posterior lobe is further divided into two areas by the *fissura prepyramidalis*. This results in four areas.

For reasons that will be given below, the anterior lobe and the portion of the corpus cerebelli that lies behind the prepyramidal fissure are collectively known as the paleocerebellum.* The portion of the corpus cerebelli lying between the prepyramidal fissure and the *fissura prima* is known as the neocerebellum because it has undergone the greatest expansion throughout the phylogenetic series. The neocerebellum has developed *pari passu* with the development of the cerebral cortex with which it is reciprocally connected. It should be noted that the neocerebellum is not synonymous with the cerebellar hemispheres, since the neocerebellum includes a portion of the vermis, namely, the folium and the tuber vermis. Note also that the "posterior lobe" is the posterior portion of the corpus cerebelli and is not the most posterior part of the cerebellum, being anterior to the flocculonodular lobe.

The justification for this division of the cerebellum is that the resultant areas have different afferent and efferent projections, a fact that has proved to have functional significance. Thus the neocerebellum receives its main afferent input from the pontine nuclei via the middle cerebral peduncle, and ultimately from the corticopontine tracts which originate in the frontal and other lobes of the cerebral cortex (see Fig. 18). It also receives impulses from the visceral and auditory receptors. The transverse sectors just rostral and caudal to the neocerebellum have preponderately spinocerebellar connections by which they are placed in contact with the somatic sense organs of the body, especially the proprioceptors of the musculature. Still more rostral (*lingula*) and caudal (*flocculonodular lobe*) are two zones having connections, by way of the vestibular nerve, with the apparatus for equilibrium in the internal ear. The flocculonodular lobe is far

* The flocculonodular lobe is sometimes included in the paleocerebellum, a poor practice because it includes two unrelated areas of the cerebellum under the same designation. The flocculonodular lobe is better termed the archicerebellum.

larger than the lingula and, unlike the lingula, receives only vestibular connections. As pointed out above, the fissures that divide the lobe areas morphologically do not sharply delimit the areas established on the basis of afferent connections. The field in which corticopontocerebellar pathways terminate overlaps that in which the spinocerebellar fibers terminate, and this overlap is especially marked in the lateral portions of the cerebellar hemispheres. The zone with spinocerebellar connections, in turn, overlaps to some degree the vestibular fields, since some vestibular fibers are found anterior to the *fissura posterolateralis* in the uvula and in the lingula.

Several studies have indicated that the division of the corpus cerebelli into a pontocerebellar and a spinocerebellar field is overly schematic. Thus, a study of the pontocerebellar projections suggests that they reach all parts of the cerebellar cortex except the flocculonodular lobes (Brodal and Jensen, 1946). The absence of spinocerebellar fibers to the neocerebellum may mean only that this region, especially its vermal portion, is concerned with head functions and receives impulses not from the spinal nerves but from cranial nerves (Hampson, 1949). Thus Woolsey (1947) says: "It seems likely then that the neo- and paleocerebellum no longer define in mammals separable portions of the cerebellum unless an exception exists in the flocculonodular lobe."

The details of the projection of the cerebellar cortex upon the cerebellar nuclei and the projection of these nuclei upon those of the brain stem and thalamus have not been completely worked out. However, the broad outlines are known. The fastigial nucleus, located in the midline, is apparently the oldest nuclear mass, though it does contain a small-celled component of more recent phylogenetic origin. Consistent with its being the oldest of the cerebellar nuclei, it receives fibers from the Purkinje cells of the paleocerebellum. The fastigial nucleus, in turn, projects mainly onto the nuclear and

reticular substances of the medulla, known to be concerned with postural reflexes. The next most lateral nucleus, nucleus globosus, also receives fibers from the paleocerebellum, but it projects to the nuclear and reticular substances of the midbrain, especially the older, large-celled portions of the red nucleus. The emboliform nucleus lies between the globosus and dentate nuclei and is also intermediate with respect to afferent input, since it receives fibers from both the neocerebellum and the paleocerebellum but not from the flocculonodular lobe. The efferent projections of the emboliform nucleus are like those of the globose nucleus. The most lateral nucleus, nucleus dentatus, receives its main afferent input from the neocerebellum and projects to the lateroventral nucleus of the thalamus both directly and after a synaptic interruption in the phylogenetically recent, small-celled portion of the red nucleus. From the lateroventral nucleus, fibers pass to the motor areas of the cerebral cortex. The dentate nucleus receives some fibers from the paleocerebellum, but, since it is divided into a small- and a large-celled component, it is quite possible that it consists of phylogenetically old and new portions, with the older portion receiving the paleocerebellar connections.

The functions of the cerebellum are at present interpreted in the light of a tripartite division presented in Fig. 19, and of the phylogenetic change in the relative importance of these three divisions. Evidence drawn from lower vertebrates cannot be translated directly to man. However, there is sufficient data for plotting the cerebellar functions throughout the subprimate and primate series. When this is done, man is seen to carry further the phylogenetic development noted in passing from the dog or cat to the monkey. The symptomatology following cerebellar injury also varies considerably with the time lapsing after operation, especially in the cat and dog. Any set of observations of cerebellar symptoms must, therefore, be located on a system of three

variables: (1) the area destroyed, (2) the species, and (3) the time elapsing after operation.

the limbs are not marked by tremor or hypotonicity. In the initial state the monkey documents his unsteadiness by clinging

FIG. 19. Highly schematic diagram of the mammalian cerebellum, showing the cerebellopetal connections and the lobulation and terminology of the cerebellum, according to Larsell and Dow. The shaded area at the left represents a cut through the middle of the vermis to show the depth of the fissures. The diagram shows the cerebellar cortex stretched out laterally, so that the fold between vermis and hemispheres is obliterated. Note that the lobulation, based on comparative anatomical studies, delimits, with some overlapping, fields of cerebellopetal connections. (Dow, 1942.)

Flocculonodular Lobe

One of the immediate results of the Larsell-Dow analysis of the phylogenetic development of the cerebellum was the prediction that ablation of the flocculonodular lobe would produce disturbances of equilibrium. Dow confirmed this deduction by showing that isolated removal of the nodulus and flocculus causes unsteadiness of stance and gait, and swaying and oscillations of the head and trunk, even though movements of

firmly to the cage to gain support. Woolsey and Bard have recently shown that flocculonodular ablation will protect an animal from motion sickness.

The flocculonodular syndrome is quite faithfully produced in man, especially young children, by a tumor (medullablastoma) that destroys the posterior midline structures. There are few signs of cerebellar damage so long as the patient is lying down, but it becomes manifest by unsteadiness, etc., when

he is placed upon his feet. It is apparent that in both monkey and man the sphere of activities affected by flocculonodular damage reflects the connections of this area with the vestibular nerve.

Anterior Lobe

The anterior lobe and the adjacent lobulus simplex are electrically excitable and are apparently topographically organized as follows: lobulus simplex—neck, masticatory, and facial movements; culmen—fore-limb movements; and centralis and lingula—hind-limb and tail movements (Woolsey, 1947). There is also mediolateral organization, with the muscles of the axis or proximal segments of the limbs most influenced from points near the midline. Hampson's (1949) results indicate that the projections from the face, arm, and leg areas of the postcentral gyrus to the cerebellum have the same pattern of localization, and that the spinocerebellar projections are probably similarly arranged.

As would be expected from neuroanatomical considerations, the effects of stimulating the anterior lobe are exerted upon the postural motor mechanisms of the brain stem. For instance, Sherrington, in his original analysis of decerebrate rigidity, showed that it could be inhibited from the anterior lobe. Actually the effects are compounded of both inhibition and facilitation. Which is obtained depends on strength and frequency of stimulation; and rebound contractions are not uncommon. Stimulation of the anterior lobe also affects pyramidal tract activities. The point of interaction between stimulations of the cerebellum and of the motor cortex appears to be in the brain stem, not in the cerebral cortex. It is not unlikely that facilitatory and inhibitory effects are exerted through two different efferent cerebellar outflows which end in the facilitatory and inhibitory areas of the brain stem. There is some evidence that the inhibitory influence may be exerted by way of the fastigiobulbar

tract and the bulboreticular inhibitory area (Snider, Magoun, and McCulloch, 1947).

There is also evidence of a second electrically excitable area within the overlap between the posterior part of the neocerebellum and the paleocerebellum. Movements of the face, limbs, and tail are obtained from stimulation of the paramedian lobule and pyramis, and movements of the head and eyes from stimulation of the folium and tuber vermis. The paramedian lobule possesses spinal afferent connections and shows electrical excitability from stimulation of somatic receptors (Snider and Stowell, 1944) or the somatosensory cerebral cortex (Hampson, 1949). This area is topographically organized and projects into the bulboreticular area by way of the fastigiobulbar tract (Snider, Magoun, and McCulloch, 1947).

It will be recalled that the anterior lobe is mainly under the influence of proprioceptive and vestibular impulses through its spinocerebellar and vestibulocerebellar connections. It is related to the control of proprioceptive reflexes and of certain labyrinthine influences playing upon them. Ablation of the anterior lobe, as first emphasized by Bremer and later by Connor and German (1941), induces "an abnormal responsiveness in the antigravity muscles to all postural influences, whether local, segmental or general static in nature." There ensues a strong opisthotonos (retraction of head and concave bowing of the back), increased positive supporting reactions, and hyperactive and spreading deep reflexes. The labyrinthine tonic reflexes also appear to be directly released since they are manifest in deafferented limbs. In the dog, the overactive antigravity reflexes of the forelimbs may cause the animal to topple over backwards in attempting to walk. This relation of the anterior cerebellum to the postural reflexes is especially marked in the pigeon, and it is striking in the cat and dog; however, it is little in evidence in the monkey and chimpanzee and has not been identified in man. But in the monkey such lesions do intensify

the spasticity, etc., induced by lesions of areas 4 and 6 (Soriano and Fulton). It is quite probable that, throughout phylogeny, this system has undergone a retrogression that is correlated with the greater control of postural reflexes by the cerebral cortex in the higher primates. Postural reflexes are released by motor area lesions to a much greater degree in monkeys than in cats, suggesting that such controls have passed from the cerebellum to the cerebral cortex.

In addition to being concerned with postural brain stem mechanisms, it is not improbable that the paleocerebellum is responsible for the coordination of the activities of the brain stem, such as walking. Thus the paleocerebellum may regulate both the postural and phasic activities of the brain stem and perhaps brings them under restraint during voluntary activity. This would mean that the paleocerebellum bears the same relation to phasic brain stem mechanisms that the neocerebellum does to corticospinal processes.

Neocerebellum

In the higher primates injury or ablation of the cerebellum is largely manifested in the sphere of voluntary activity, though there are striking changes in reflexes as well. Most of the disturbances of motion can be ascribed to injury of the neocerebellum which in man far overshadows the paleocerebellum and archicerebellum in size and functional importance.

In man, and to a lesser degree in the chimpanzee and the monkey, the cerebellar cortex, especially the neocerebellar cortex, is a part of the neural apparatus that effects coordinated voluntary movement. The cardinal signs of cerebellar disorder are (1) hypotonia, (2) disorders in the direction, rate, range, and force of movement, and (3) tremor.

Hypotonia is manifested on a reflex level by the characteristic "pendular knee jerk." The leg, on returning to its original position, is not stopped "dead beat" by proprioceptive reflexes but swings forth and back

like an inert body. If a limb is manipulated, it offers little resistance; if shaken, it flaps about loosely.

The influence of the cerebellum on muscle tone may be exercised through one of two known anatomical pathways. First, the cerebellum discharges via its nuclei upon brain stem mechanisms for posture. Second, the neocerebellum discharges by way of the thalamus to the motor areas, increasing their electrical activity (Walker, 1938). This might result in augmenting the continuous or tonic discharge of the corticospinal tract described by Adrian and Moruzzi (1939) and increase a facilitatory background of spinal internuncial neurons. On phylogenetic grounds the second would appear to be the more important mechanism in the higher primates.

Disturbances of the direction, rate, range, and force of movements are manifested in a variety of ways (Holmes, 1922). Eye-hand coordinations may overshoot, undershoot, or deviate laterally (errors of direction). Movements may be initiated with delay and executed slowly, or they may be executed with abnormal speed (errors of rate). Negative disturbances of force (asthenia) are manifested by a weakness and ready fatigability and are revealed by inability to maintain a sustained voluntary effort such as holding the arms outstretched. Figure 20 illustrates some of these disturbances.

Tremor consists of gross oscillations of the limb, obvious during movement (intention tremor) and especially obvious at the end of a movement (terminal tremor). In reaching towards an object, the hand follows a zigzag course, and the amplitude of the tremor increases as the object is approached (Fig. 21). Tremor almost certainly represents cortical motor activity unmodulated by the cerebellum (see below).

Paradoxically, when rapid oscillatory movements are intended, e.g. handshaking, great difficulty is encountered (adiadochokinesis). Another disturbance of voluntary movement is *asynergia* or bad timing of the components of a movement. In clenching

the hand, the muscles at the back of the forearm normally contract and prevent the wrist from being palmar flexed along with the fingers. The wrist extensor may come in too early or too late in cerebellar patients.

FIG. 20. Myograms of voluntary contractions from the normal (A) and affected (B) arms in a case of unilateral cerebellar lesion. At the vertical line labeled "1" the order to contract was given, and at "2" the order to relax. Note in the lower myogram the long latency, the slowly rising and weak contraction, and the pronounced delay in relaxation. (After Holmes, 1922.)

So-called *decomposition of movement* causes movements to resemble the military "manual of arms." Thus, when a patient lying in bed with arms held upwards is asked to touch his nose with a finger, the arm may be

fundamental activity of the cerebellum. This would be consistent with the lack of cyto-architectural specialization in the cerebellar cortex. Fulton (1943), for example, suggests that a combination of overshooting and undershooting may result in an oscillating tremor. A slight, fortuitous deviation of a movement is not so quickly checked by the defective cerebellum as it would be in a normal patient. Once checked, it is overcorrected (hypermetria), resulting in an opposite deviation which is, in turn, checked only after a lag and then overcorrected, thus leading to ever-increasing oscillations as the movement progresses.

Inability to perform rapid, voluntary oscillatory movements is perhaps a similar difficulty in bringing a movement to an end and initiating the opposite one. In an effort to find a unitary explanation of cerebellar symptomatology, Ectors (1942) and Bailey (1944) have suggested a "braking action." This braking action may also be the primary fault in the paleocerebellar and flocculonodular syndromes, though mani-

FIG. 21. A diagram showing tremulous movement in a cerebellar patient, as revealed in the nose-to-finger test. The hand of the patient is shown as it reaches the examiner's finger, pictured at the left. The figure is modified from a photograph of a patient obtained by Dr. R. S. Lyman by attaching a light to the patient's finger. Note that the tremor is more marked towards the end than in the middle or beginning of the maneuver. (After Pullen, 1944.)

first lowered to the side and then translocated to the nose, a two-stage maneuver.

Unitary Theory of Cerebellar Function

It is tempting to ascribe the protean symptomatology of cerebellar disease to some common mechanism that represents the

manifested in a different category of motor activity. Thus, falling may represent a failure of the vestibular mechanisms to check one of the many small movements that make up body sway. The inhibition of postural reflexes by anterior lobe stimulation is suggestive of a braking action.

Cerebellocerebral Relation

The cerebral and cerebellar cortices are reciprocally interconnected; i.e. fiber systems pass from cerebral cortex to cerebellar cortex and from cerebellar cortex to cerebral cortex. The two components of the systems accomplishing this are as follows:

From the coincidence of origin and terminus in both the cerebellar and cerebral cortex, it is assumed that the two systems form a closed circuit. This singular arrangement must heavily influence any hypothesis of neocerebellar function. That the circuit is closed does not imply that it operates in a vacuum. Corticopontine fibers arise also in the parietal, the occipital, and probably the temporal lobes of the cerebral cortex. Furthermore the histology of the cerebellar cortex suggests ready transmission of impulses to the neocerebellum from the paleocerebellar region, and some projection of this region to the cerebral cortex is not ruled out. The various links in this circuit have been demonstrated physiologically as well as anatomically. Thus Dow (1942*b*), in applying single shock stimuli to the cerebral cortex, evoked potentials in the cerebellar cortex. The pontine nuclei have been similarly stimulated. In both cases the evoked activity was confined to the neocerebellum and closely adjoining areas. The reverse connection was demonstrated by Walker (1938). Stimulation of the cerebellar cortex increased the electrical activity in the motor areas of cats. Rossi in earlier experiments (1912) had demonstrated a lowering of the threshold to electrical stimulation of the cortical motor areas upon stimulation of the cerebellar cortex. An aspect of these experiments often overlooked is that the changes in cortical activity were in the direction of

increased activity, a point inconvenient to current theories of neocerebellar function which emphasize a braking action of the cerebellum.

Further evidence that the cerebellum interacts with the cerebral cortex in the control of movements comes from hemidecerebellation followed by lesions of the cerebral cortex. The movements remaining to the cat after this sequence, decerebellation-decortication, are by no means normal, but they are free from tremor (Fulton, Liddell, and Rioch), and comparable results obtain for the monkey. In the monkey lesions in area 4 reduce tremor, which reappears when voluntary activity returns. Lesions in area 6 have a mixed effect. Added to lesions in area 4, they further restrict voluntary movement and tremor. However, a primary lesion in area 6 may exaggerate tremor (Aring and Fulton). This probably represents the loss of a controlling influence of the extrapyramidal projections of area 6 upon voluntary movement.

Feedback Circuits and the Control of Movement

So little is known of the mechanism by which the cerebellum regulates voluntary movements that speculation is permissible. Account must be taken of two principal facts—that the cerebellum receives impulses from both (1) the cerebral cortex where voluntary movements originate, and (2) the muscles that execute these movements.

Cortically initiated movements are apparently not *performed* in the sense that a spatial and temporal pattern of impulses requisite for the movement is automatically and blindly “reeled off.” This would be analogous to a military headquarters issuing detailed orders for a complicated military maneuver without the possibility of modifying them on the basis of intelligence reports of progress or of difficulties encountered. A report back to the cortical motor areas can be made by way of the posterior columns,

the medial lemniscus, and the thalamus, or by way of the spinocerebellar tracts, the cerebellum, and the thalamus. Thus there are two closed loops by which voluntary activity can be modulated: one is a long loop which includes the muscle; the other is a shorter loop between the cerebral cortex and the cerebellum into which information from the muscles may or may not be fed.

Since Charles Bell discovered the "circle of nerves" * in 1826, it has been appreciated that proprioceptive impulses from muscles are a factor in the control of voluntary and even of reflex activity. On the one hand, the cerebellum receives a heavy (though not exclusively) proprioceptive input, and, on the other, it is involved in the control of movements. Because of these two facts, one view of cerebellar function places the control of movement on a proprioceptive basis. This view has been denied by some; moreover, its proponents have been unable to envisage the precise manner in which proprioceptive information is utilized in the control of movement. Considerations arising outside the field of neurology, to be discussed below, are currently arousing interest in this connection.

The development of the science and mathematics of control (servomechanisms), and of the related field of communications, provides analogies that promise further steps in the analysis of cerebellar control of movements (Brown and Campbell, 1948; Frank et al, 1948; McCulloch, 1947; Wiener, 1948).

* "In standing, walking, and running, every effort of the voluntary power, which gives motion to the body, is directed by a sense of the condition of the muscles, and without this sense we could not regulate their actions." (Bell, 1826, p. 167.)

"Between the brain and the muscles, there is a circle of nerves; one nerve conveys the influence from the brain to the muscle; and another gives the sense of the condition of the muscle to the brain. If this circle be broken by the division of the motive nerve, motion ceases; if it be broken by the division of the other nerve there is no longer a sense of the condition of the muscle, and therefore no regulation of it actively." (Bell, 1826, p. 170.)

It is an interesting coincidence that since 1935 the neurophysiologists have established the existence of numerous circular pathways within the nervous system, and that the science of control has learned the properties of closed-loop control, or feedbacks, in ampli-

FIG. 22. A simple positioning follow-up system. $M-P$, a string attached to a weight J , passes through a movable pulley D and two fixed pulleys E and C . B is a servomotor. Moving pulley D shifts R and applies a potential that rotates the motor. ECD is thus an error-detecting device responsive to a change in position of either M or J . Being a continuous, as opposed to an on-off, system, the weight J follows the changing position of M . The amount of displacement of D during this translocation reflects the steady-state error. If a two-way switch is substituted for R , the system is still automatic but discontinuous. If the error-reporting device is replaced by a hand switch in the motor circuit, the device is an open-circuit control. (Lauer, Lesnick, and Matson, 1947.)

fiers and servomechanisms (see also Chapter 35).

It is convenient to distinguish as servomechanisms those regulators that employ a closed-loop control, as opposed to regulators employing an open-ended control. The components and characteristics of servomechanisms vary considerably, but the common feature in all but the simplest varieties is that they react continuously to the discrepancy (error) between the desired condition ordered from the command element, or input, and the state of the thing controlled. The servomechanism system is given this property by a closed-loop construction or feedback. The components generally found

in such a system, an example of which is given in Fig. 23, are as follows:

1. A command or input station, often remote from the controlled member. Note that this is not the power input for the system.

Figure 22, showing a simple position control system, illustrates some of the principles of servomechanisms that are sensitive to magnitude of error, though not to rate of error change. Figure 23 shows an idealized

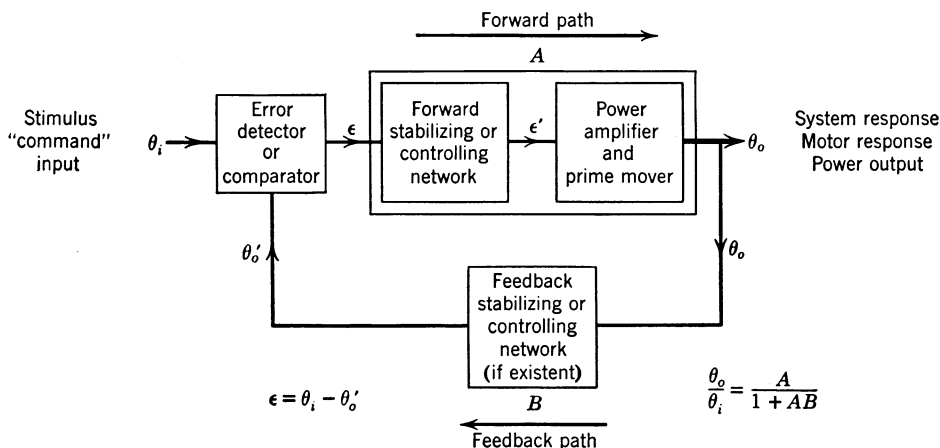

FIG. 23. A feedback system showing the basic elements of a servo system and certain analogies with biological systems as depicted by Frank (1948). A and B are the amplification in the forward and feedback paths, respectively. θ_i = input, θ_o = output. ϵ is the difference between the command and the perceived response and can be called the "error" in a system in which the activity ends when the goal is reached.

1. $\epsilon A = \theta_o$, i.e. the error amplified by A determines the output, and $\epsilon = \theta_o/A$.
2. $\epsilon = \theta_i - \theta_o B$, i.e. the error signal is the input less the θ_o as amplified in the feedback circuit.
3. Combining 1 and 2 in an equation and solving gives the formula

$$\frac{\theta_o}{\theta_i} = \frac{A}{1 + AB} \quad \text{and} \quad \epsilon = \theta_i - \theta_o B = \frac{\theta_i}{1 + AB}$$

Inspection of this formula shows that, if AB is large relative to 1, ϵ becomes inversely proportional to AB , the overall gain in the system. The importance of the amount of feedback (AB) is thus apparent. (From Frank, et al., 1948, after Donald Herr.)

2. A controlled output member.
3. An error-measuring device, or comparator, which measures the difference between the input command and output. The input and the feedback circuit lead to the comparator.
4. A device, often contained with the comparator, that orders a correction as some function of the magnitude of the error. Amplification is often needed at this stage.
5. A servomotor which exerts control directly or by regulating the flow of power into a motor. In the latter case this member is often combined with number 3 or eliminated entirely.

servomechanism with electronic components and their hypothetical biological equivalents.

A servomechanism has been described as a continuously error-sensitive follow-up amplifying system, permitting a wide range of the input command remotely located from the element being controlled (Brown and Campbell, 1948).

The analogy between the neural mechanism for voluntary movements and the servomechanism is close, though not complete. The common feature of importance is the closed-loop or feedback arrangement.

The energy released as corticofugal impulses (input)* from a point remotely located from the muscles is infinitesimal, but it controls a large force represented by the muscles (output). The input command from the motor cortex must have a wide range of freedom to order weak or strong, and fast or slow, movements. The motor cortex must also be allowed random

Since the error is continuously assayed, the output is adjusted until the error is reduced to zero. This process, being continuous, contrasts with a simple on-off step regulator. The error-detecting device not only orders the change of output required to reduce the error but does so in such a manner that the rate of error correction is dependent upon the magnitude of the error.

FIG. 24A. Diagram showing transient error between response (dashed line) and command (solid line) during a sudden change in command. The transient oscillatory behavior is illustrated but not labeled. Steady-state error during the period of unchanging command is also indicated.

B. Diagram illustrating transient stability of a system with varying degrees of damping. Curves 2, 3, and 4 are progressively underdamped and show increasing degrees of oscillatory behavior. Curve 1 is overdamped and shows great stability at the expense of a long response time. (Brown and Campbell, 1948.)

variation, since no mechanism is perfect and there is noise arising from spontaneous fluctuations.

The mechanisms of voluntary contractions have in common with servomechanisms the ability to perform movements accurately despite an unexpected load or a deflection of the member moved by external forces. Servo systems accomplish this by means of an error-sensitive device which assays the difference between the command and the output existing at each moment. This implies a "report back" of the condition attained at each moment, a comparison of this with the input, and an order for a change in output based upon the difference or error.

* The input is, in fact, the impulses passing to the motor cortex from sensory areas, and the corticofugal discharge is the output. However, components of servomechanism systems are often controlled by subsidiary feedback circuits.

Servomechanisms accomplish continuous error correction by employing closed-loop or feedback circuits. The feedback element of a closed-loop servo system is so arranged that some of the output energy or, in positioning devices, a position signal passes to a comparator. Because some of the output energy returns to the command side of the system, it is called a "feedback." The feedback is called "negative" because the signal correcting the discrepancy between the command and the output is always such that it reduces the discrepancy.

Servomechanisms are subject to the three kinds of error defined in Fig. 24, i.e. transient errors, steady-state errors, and transient oscillatory behavior. Unless a small error induces a large change in the servomotor controlling the output, the first two are large. The steady-state error will be large

when output friction is involved, and transient errors will be large where inertia is to be overcome. A small output friction and a sensitive error-correcting device reduce these errors but may introduce oscillation upon starting or stopping. A sudden shift in the input signal results in a correcting movement that may overshoot unless damped, and this error itself may even cause the reverse command to be issued with consequent oscillations that gradually die out. One means of preventing oscillation is to have the rate of error correction dependent upon the magnitude of error. Abrupt transients are, of course, involved in starting and stopping rapid voluntary movements.

In thinking of the nervous system in terms of servomechanisms, it is a mistake to seek too close an analogy and especially to identify various neural structures with the components of those particular servomachines developed in industry. Several differences between the nervous system and servomechanisms must be reckoned with. In servomechanisms the transmission of the report back is usually accomplished at high speed, whereas in the nervous system the maximal rate of conduction is slow enough to introduce critical time factors (see above). Another control problem arises from the fact that the muscular force exerted in many voluntary movements is minute in relation to the tremendous force that the muscles can develop in maximal contraction. Also, the speed with which a muscle develops its tension is a matter of milliseconds. As a limiting case suppose that a maximal motor cortex discharge reached the muscles of the arm as a synchronous volley. The result would be a tension of more than a ton developed in 20 milliseconds on the short arm of a lever, which would cause a jerky start of the movement. The arm would have a terrific kinetic energy which would result in overfling unless restrained. These factors suggest that perhaps the main problem confronting the brain is to avoid an abrupt starting and stopping of voluntary movement because of

the dangers of oscillation in any system sufficiently sensitive to control such transients. There is evidence that transient errors are deliberately incurred in the slow development of cortical discharge (Adrian and Moruzzi, 1939) and by the slow and successive activation of the spinal interneuronal pool by pyramidal tract discharge (Lloyd, 1941). In the design of a servo system there is usually a compromise between transient error and oscillatory behavior (Fig. 24). It is as though the nervous system had chosen large transient errors in order to avoid the hazard of oscillation.

The nervous system resembles complex servomechanisms by involving several closed-loop systems. At the spinal level the proprioceptive reflex arcs constitute closed loops which function not only for error reporting but also for damping. Servo systems often include a damping component, sometimes a simple viscous one, to counter oscillatory tendencies. Since viscous damping introduces a steady-state error, oscillations are better avoided by making the comparator react to the rate of change of error.

Feedback circuits control certain reflex as well as voluntary actions. This can be illustrated by considering the crossed extensor reflex, a reflex contraction of an extensor muscle of the limb elicited by repetitive stimulation of the central end of a nerve of the opposite limb. It consists of a slow rising phase, when more and more motor units are being brought into action (recruitment); a plateau of steadily maintained tension; and a long continued after-discharge following cessation of the stimulus. Part of this "inertia and momentum" is inherent in the internuncial system of the reflex arc, but part is contributed by the secondary proprioceptive reflexes, instituted by contraction of the muscles, which are superimposed on the crossed extensor reflex. Thus, if the posterior roots that conduct the impulses from the reacting muscle are sectioned, the reflex myogram changes appearance in three ways. It rises more abruptly, describing a

curve that is convex upwards; it reaches a slightly higher plateau; and the contraction subsides more abruptly. This last effect is ascribed to loss of a stretch reflex normally appended to the contraction, and due to the stretching of the relaxing muscle by the myograph spring. The first and second effects are ascribed to a lack of "autogenous inhibition" from a different proprioceptive ending. The net result of these inhibitory and facilitatory feedback circuits is to make the transition from relaxation to contraction, and the return to relaxation, a smoother process. The crossed extensor reflex in a deafferented muscle is, in a sense, "ataxic."

In passing, it may be noted that the myotatic reflex bears a certain resemblance to servomechanisms of the type designed to position an object. These reflexes, according to Sherrington's analysis, enable an animal to maintain constancy of posture in the face of varying environmental forces that tend to displace the body from that posture. A load thrown on a horse's back is a good example of a sudden change in gravitational force acting on the leg muscle. The slight stretch of the muscles, resulting from the extra weight on the back, elicits a prompt reflex contraction of the muscle stretched, which neatly counteracts the gravitational force of the extra weight. The horse's posture remains virtually unchanged, although the load is now different. The stretch afferent (the muscle spindle) acts as an error-detecting device, continuously measuring the displacement from the normal posture (the error), and ordering a correcting contraction through spinal reflex connections. The stretch afferent is extraordinarily sensitive to slight stretches, and, like sensitive servomechanisms designed to reduce transient and steady-state errors, the stretch reflex arc is prone to oscillations. When, in certain diseases of the extrapyramidal system, the stretch reflex arc is made hypersensitive by abnormal facilitation from the brain, stretch is likely to throw the muscle into the oscillatory contractions and relaxations known as

"clonus." When the spinal reflex arcs receive less than the normal facilitatory impulses from the brain, an oscillatory phenomenon of quite a different significance supervenes. The knee jerk tends to be "flail-like" and pendulous in the spinal animal. The leg rises abruptly (fling), falls like an inert body, and swings about the position of rest like a pendulum damped only by the viscous properties of the relaxed muscles and ligaments. In the decerebrate cat, the knee jerk is typically dead-beat; i.e. the limb is lowered to the resting position without overshooting.

These facts may be summarized by saying that the spinal proprioceptive reflex arcs function in posture as a time-continuous, error-detecting device that positions the body in space by varying the output of the muscles to counter changes in gravitational force. When rendered oversensitive it is subject to the oscillatory errors of oversensitive feedback mechanisms. The spinal proprioceptive reflex arcs, which consist of excitatory and inhibitory feedback circuits, serve the same function as the damping elements in certain servomechanisms. When these circuits are interrupted or underfacilitated, passive oscillatory phenomena supervene (pendular knee jerk). For certain reflexes, and possibly for voluntary movement, they curb momentum in relaxation and prevent a too abrupt initiation of the movement of the limb, thus overcoming inertia slowly.

Cerebellum as a Feedback Mechanism

Potentially the spinocerebellar tracts → cerebellar cortex → dentate nucleus → thalamus → motor cortex make up a system that could correct, modulate, or intensify a movement during its course on the basis of proprioceptive sensations from the executant muscle.

The question arises whether the report back from the muscles during voluntary movement occurs with sufficient rapidity to permit effective control throughout the course of the movement. It is significant

that the spinocerebellar tract is the largest-fibered and the most rapidly conducting (140 meters per second) ascending tract in the spinal cord. Twelve milliseconds would not be too long for spinocortical and cortico-spinal conduction in man. On the other hand, the myoneural junction and a minimum of seven synapses (not counting inter-nuncial systems of the cerebrum and cerebellum) must be crossed in the complete circuit. Taking synaptic delay at 0.5 to 2.0 milliseconds, we must allow 3.0 to 12 milliseconds for this factor. The total time for central conduction is 15 to 24 milliseconds. The average latency of the knee jerk in man gives a rough estimate of the time consumed in the peripheral portion of the circuit, i.e. 4 to 10 milliseconds, with allowance for time lost at the synapse. The total time for the complete circuit is then 19 to 34 milliseconds.

One may pose the question: "At what rate could a single motor unit contract in voluntary contraction and yet have each contraction modulated on the basis of its previous contraction?" To 19 to 34 milliseconds for the circuit from muscle to muscle through the cerebellar and motor cortex would be added the contraction time of perhaps another 20 to 40 milliseconds, since contraction directly or indirectly stimulates the proprioceptive end organs. Taking the larger figure for circuit conduction time, discharges at slightly more than ten per second could be so modulated. Electromyographic studies show discharges at about this rate in voluntary movements of moderate strength. Slowness of voluntary movement is characteristic of cerebellar patients and of normal individuals executing unpracticed movements. In both cases this may be a device to utilize the proprioceptive return to greater advantage.

Input Informed Feedback Circuits

The essential feature of a servomechanism is an error-sensitive device that continuously measures and reacts to the discrepancy between the ordered state and the realized

state. Such feedback circuits are, therefore, output informed. The question arises in respect of the nervous system whether some of the shorter loops that do not include the muscles constitute, not output-informed, but what may be called input-informed, feedbacks, and hence constitute a class apart from servomechanisms. One reason for raising this question is that cerebellar ataxia is different in some aspects from locomotor ataxia in which the fault is clearly the absence of information from the muscles due to posterior root damage. For example, in locomotor ataxia vision can partly compensate for the missing proprioceptive return, whereas cerebellar ataxia is not greatly aggravated when the eyes are closed.

We have seen that the motor cortex, in addition to firing into the spinal motoneuron pools, fires into the neocerebellum by way of the frontopontine and pontocerebellar fibers. From the neocerebellum a stream of impulses returns to the motor areas via the thalamus. Although the neocerebellum is concerned with the control of limb movements, it receives few spinocerebellar fibers, so that it is not *directly* informed of error in movements. If it is so informed, the neural data must be transmitted from the spinocerebellar projection fields, located anteriorly and posteriorly. If experimentation fails to demonstrate this connection, what function could be ascribed to such a massive uninformed fiber system?

It was pointed out above that starting a movement without jerkiness presents a problem. A movement starting abruptly would endow the limb with kinetic energy which would tax the informed negative feedback in controlling the movement. The alternative is to start movements slowly. This could be accomplished by cascading or, in neural terms, avalanche conduction in which dichotomizing neurons synapse with several neurons, the axons of which in turn dichotomize. However, positive feedback circuits that add to or "amplify" the input energy would accomplish the same purpose. Thus a recur-

rent pathway 180 degrees out of phase with the original discharge would double the frequency of discharge in the centrifugal pathway. The possibility that the reciprocal cerebellar cerebral circuits act in this fashion must be considered. The known effects of this circuit are in the direction of increasing excitability or electrical activity of the motor cortex. If this system is a negative feedback, the effect should be to increase or decrease the cortical discharge, depending on the sign of the error. The movements of the cerebellar patient depart from normal in their sluggishness of inception, as well as in sluggishness of termination (Fig. 20). The former may represent impairment of a positive feedback circuit.

The problem faced by the motor cortex in executing a voluntary eye-hand coordination, such as picking up an object, hinges on time considerations. It can be argued that, at the moment an act is launched, a time-tension pattern of muscle contraction is instituted, projecting into the future, with the object being the goal of this reaction. The end of the movement, removed in time, is implicit in the patterning of the discharge. It seems unlikely that the initial stage of the movement is ordered blindly, then the second stage, and so on, with the goal direction appearing only at the last moment.

The nervous system would be handicapped in "planning movements" in this fashion because there are no known methods for storing impulses in a neuron to be discharged after a fixed delay. Significant delay can be obtained by making use of conduction time. Thus the problem of delay has apparently been solved by circular chains of neurons or reverberating circuits: the nerve impulses circulate within such circuits and give off one or more impulses per circuit. The decay characteristics give a temporal patterning of the cortical discharge.

The cerebral-cerebellar circuit may represent not so much an error-correcting device as a part of a mechanism by which an instantaneous order can be extended forward

in time. Such a circuit, though uninformed as to consequences, could, so to speak, "rough-in" a movement and thus reduce the troublesome transients involved in the correction of movement by output-informed feedbacks. Especially could such a circuit be effective in the termination of movement. To terminate a movement without jerkiness requires terminal deceleration. This might be accomplished by a negative feedback proportional to the velocity of the movement; and corticocerebellar circuits may represent such a feedback. Cerebellar tremor may be comparable to the oscillations of an undamped servomechanism system in which the feedback is removed or is responsive only to the extent of movement, not to its rate. It is perhaps significant that cerebellar intention tremor is also a terminal tremor.

On the other hand, if simple analogies are sought, the cerebellum could be likened to the comparator of a servomechanism. It may receive from the cerebral cortex some representation of the command and from the muscles a representation of the resulting movement. These, compared, may result in a signal that is transmitted to the motor cortex, altering its signal to the muscles so as to diminish the error. In this capacity the cerebellum is acting as a feedback to stabilize one unit of the whole system of neural reaction. However, the cerebellum receives impulses from the distance receptors, and from the cortical areas for vision and audition. These pass to the neocerebellum, which is especially concerned with voluntary movement. Such an arrangement may mean that the cerebellum can compare the true input, the auditory or visual representation of the goal, and the proprioceptive indication of the limb's position.

Finally, one may question the value of likening neural systems to servo systems. Such analogies, devoid of mathematical treatment, are essentially allegorical, somewhat akin to Freudian psychology. Whether a mathematical treatment will lead to predictions capable of experimental verification re-

mains to be seen. Otherwise, we have added little since 1826 to Bell's "circle of nerves."

Homeostasis

EDWARD W. DEMPSEY

Harvard Medical School

Viewed empirically, the physiological reactions of mammalian organisms present an array of contradictory and paradoxical phenomena. The heart rate and cardiac output may increase while the blood flow in a given region increases, decreases, or remains static. An accelerated respiratory rate may accompany muscular activity (exercise) or inactivity (panting). The glucose concentration of the blood may rise during depletion of the glycogen stores of the body, or, conversely, while the carbohydrate reserves are being augmented. Taken without reference to the total needs of the individual, these reactions can but bewilder the systematist. It is understandable, therefore, that a generalization rationalizing these and many other observations would be received gratefully by physiological investigators. Such a generalization was formulated by Claude Bernard (1859) and extensively documented by Walter B. Cannon (1932). Bernard was greatly impressed by the regulatory mechanisms that maintain the concentration of glucose in the blood at a nearly constant level. In a flash of intuitive insight he perceived this to be one example of a general law of constancy of the internal environment. Cannon, aware of many more examples in which a constant state is maintained and having investigated some of the regulatory mechanisms, applied a special name, homeostasis, to designate these steady states.

A few examples will make clear the nature of the steady states. The internal body tem-

perature of mammals remains fixed, although the temperature of the external environment may fluctuate widely. Consequently the thermolabile reactions of cells are protected from external changes. Animals are therefore released from the limitations otherwise imposed by winter's cold and summer's heat. The acidity of the blood remains remarkably constant. A slight shift toward acidity would result in coma and death; a shift toward greater alkalinity would produce convulsions. The sugar concentration of the blood, already mentioned, is nicely regulated by storage and release of glycogen in the liver. If the regulatory mechanism is overwhelmed by excess sugar, it is wasted by excretion through the kidneys. If the concentration were allowed to fall to a low level, abnormal behavior, convulsions, and coma would ensue.

The vertebrate animals of today are the products of millions of years of evolution along widely divergent paths, and yet in many respects their internal environments are remarkably similar. The temperature at which life as we know it is possible permits but slight variation. The bloods of the various animals are closely similar in their ionic compositions, pH, and glucose concentrations. These facts suggest that the conditions under which life is possible are very restricted indeed and have not changed substantially since life first began. Consequently the evolution of different forms of life has necessarily involved the development of mechanisms for maintaining within the animal an

internal environment with the properties required for the continued life of its cells (Baldwin, 1940). The essential truth is contained in Claude Bernard's dictum, "La fixité du milieu intérieur est la condition de la vie libre."

So important for the welfare of the organism are these steady states that many diverse mechanisms have been utilized for their maintenance. The pH of the blood is partly regulated by the presence of buffer systems. Thus the circulating fluid contains chemical substances in an equilibrium between ionized and nonionized forms. Adding acid or alkali to such a system shifts the equilibrium so that the free acidity remains constant, because the added substance is rendered inert in an undissociated form. This is an example of a purely physicochemical system adapted to homeostatic control. However, such mechanisms are effective only within definite limits; if too much acid or alkali is added, the equilibrium breaks down. In the mammalian organism such a contingency is guarded against by physiological mechanisms which excrete the excess through the kidneys or lungs. Too much acid, too much salt, or too much sugar are not allowed to accumulate but are eliminated from the blood by the storage or excretory organs.

The mechanisms cited above are simple and autonomous ones which can function somewhat independently of the activities of other organs and systems. The liver, even after removal from the body, can take up glucose from the surrounding medium and store it as glycogen. Nevertheless, these automatic activities may be adjusted in rate to conform with other procedures occurring elsewhere in the body. For correlating the various processes, two special regulatory systems have evolved: the autonomic nervous system and the endocrine glands. The mechanisms that maintain the steady state can therefore be classified into a hierarchy of three levels: (1) physicochemical buffer systems, (2) automatic physiological excretory and storage systems which supply and sup-

port the chemical processes, and (3) coordinating endocrine and neural systems through which the component steady states are integrated.

Two other aspects of the steady state need be considered. When stability is threatened even mildly, delicate indicators give the alarm and activate the appropriate corrective agencies, so that oscillations to either side of the homeostatic norm are slight. The effector organs react as if they were directed toward nullifying a disturbing condition. The second factor concerns the emergency nature of many of the adaptive changes. When bodily security or survival is seriously threatened, the internal fluid matrix is altered. If noxious stimuli occur, such as bacteria, toxic drugs, or physical damage, the organism responds by altering the proportions of the protective white blood corpuscles, by augmenting the protective antibodies, and by elevating the body temperature. If perceptible foes arouse fear or rage, a number of internal readjustments unify and integrate the activities of the body for its maximal physical effort—flight or combat: blood sugar is increased, the circulation to special regions is greatly augmented, respiration is accelerated, extra red blood cells are mobilized to carry the extra oxygen, and adrenalin is produced to reinforce the adaptive nerve impulses. These reactions profoundly disturb the internal environment, but they disturb it in such a way as to render the organism temporarily more effective in a contest that may end in life or death. The ultimate total stability of the organism is therefore defended even at the cost of temporary disturbance to the welfare of its component parts.

Although the endocrine and nervous systems undoubtedly play some part in maintaining the homeostatic norm, their functions are most strikingly revealed in emergency situations. The nervous reflexes which accelerate the heart and constrict the vascular bed operate more forcefully during strong emotional states than in placid situations.

The hormones which increase the metabolic rate and facilitate the utilization of sugar are secreted in larger quantity upon exposure to cold. The deficiency resulting from impairment or destruction of these systems is more pronounced in some situations than in others. In many instances it is possible to adjust the environment so that deficits of the regulatory systems are not noticeable. Nevertheless such impairment renders the organism at least potentially deficient in the myriad adjustments normally available to it.

THE ENDOCRINE GLANDS

A number of glandular structures, plentifully supplied with blood vessels but lacking ducts, secrete their products directly into the blood stream. Hence these organs are collectively called the ductless or endocrine glands. Their secretions are chemical substances called hormones, which are elaborated in one place and transported through the blood vascular system to another location at which they exert their action.

Strictly defined, there are many substances qualifying as hormones which are usually omitted from endocrinological discussions. Thus glucose is produced from the liver's glycogen stores and carried by the blood to other parts of the body. Similarly secretin and cholecystokinin are formed in the intestine and cause, respectively, pancreatic secretion and contraction of the gall bladder. However, the subject matter of endocrinology is usually restricted arbitrarily to the hormonal aspects of the gonads, the adrenal glands, the pancreatic islets, and the parathyroid, thyroid, and pituitary glands.

Hormones may be grouped into three categories, each characterized by the type of regulation exhibited. The first category comprises the hormones of the parathyroid glands, the pancreatic islands of Langerhans and, as we shall see later, probably the glomerulosa zone of the adrenal cortex. These glands continue to function adequately after denervation or hypophysectomy. They

appear to be regulated in some direct way by the processes they control. Thus parathormone, when injected into an animal, causes its serum calcium to rise, and, conversely, loss of calcium such as occurs in renal diseases entails hypertrophy and overactivity of the parathyroid glands. Similarly the injection of insulin lowers the blood sugar, whereas hyperglycemia stimulates such an excessive production of insulin that, if long continued, exhaustion and death of the islet cells may occur.

The second category contains the hormones of the posterior pituitary body and the adrenal medulla. These glands develop from neural tissue and maintain throughout life extensive functional connections with the autonomic nervous system. The endocrine and neural factors are so closely related that we can profitably consider them in a later section devoted to the autonomic nervous system.

The third category of hormones comprises a group of endocrine factors centering around the anterior lobe of the pituitary gland. The pituitary has sometimes been called the "master" gland because it produces a number of factors (thyrotropin, adrenotropin, and gonadotropin) necessary for maintaining the structure and function of the thyroid, adrenal, and sex glands. In turn the hormones produced by these so-called target organs react upon the pituitary and control its production of the tropic hormones. This group of endocrine factors thus constitutes a self-regulating system.

The hormones of the first category apparently respond in a "dead-beat" fashion to their respective stimuli. That is to say, the rate of secretion is accelerated or depressed directly by the fluctuations of the end process. On the other hand, the type of regulation involved in the second and third categories is indirect. Stimulation of the adrenal medulla is accomplished only by activity in the intermediary nervous system, and alterations in the rate of secretion of thyroid hormone imply similar fluctuations in the activ-

ity of the anterior pituitary gland. With this indirect type of regulation manifold stimuli may compete for or interact in the intermediary center that discharges as the final common path to the secretory gland. In consequence of this intermediation the adrenal medulla may respond in rage, in hypotension, or in hypoglycemia, and, in seasonal animals, light or temperature may serve as the exciting agent for stimulation of the gonads. Moreover inhibition may occur in such systems, as is exemplified by the cessation of gonadotropic activity in malnutrition. The "dead-beat" character of the first category adjusts the secretory process directly to the end process, whereas the second and third categories permit the integration of stimuli so that the end process may be adjusted to a point appropriate for the activity of the whole organism.

For demonstrating hormonal effects, formalized procedures somewhat akin to Koch's postulates have been evolved. These may be described in the following manner. Removal of the organ suspected of producing a hormone must lead to a detectable deficit in the animal. This deficit, once recognized, must be remedied by replacing the secretion of the organ into the operated animal. The procedures utilized in this replacement therapy may vary widely, from transplanting the organ to a different region (thereby presumably eliminating neural effects) to the injection of the active principle prepared by extracting the organ. Once an effective replacement therapy has been found, the hormonal function of the organ may be regarded as proved. Further investigation is then directed toward the isolation, chemical identification, and synthesis of the active principle, and toward an elucidation of the physiological mechanisms that regulate the rate of secretion of the newly demonstrated hormone. These procedures, varied according to the needs of the particular situation, have been applied to all the hormones considered in the following sections.

The Testis

The testis, or male gonad, is a double organ containing tubules in which spermatozoa are generated, and intertubular or interstitial cells that elaborate the steroid substances constituting the male sex hormone. Castration, or removal of the testes, provokes in adults a prompt regression of the ducts and glands associated with the reproductive system. If castration precedes puberty, these structures never attain their adult size, and, in addition, various other events normally heralding maturity, such as change in timbre of the voice, growth of beard, and attainment of adult muscular proportions, do not occur. These defects in castrated animals and man can be repaired by the administration of an androgenic hormone from the testes, now chemically identified and named testosterone.

In addition to regulating the structures and functions mentioned above, testosterone exerts other effects upon the male animal. It regulates growth to some degree, causing a more rapid formation of protoplasm than occurs in its absence. Skeletal growth also is affected by the male hormone. The epiphyses of long bones remain open after castration and close rapidly after the administration of massive doses of testosterone. Thus testosterone will stimulate eunuchoid individuals to grow for a time, but the final stature will be limited by closure of the epiphyses, and, if the hormone is given in too large amounts at an early age, the final stature may be stunted. Androgenic hormone has also been implicated in the control of some of the skin glands and appendages. Aristotle recorded that eunuchs do not grow bald. It is now established that baldness results from an interplay of genetic and endocrine factors and that testosterone is a precipitating factor (Hamilton, 1942).

Various behavioral phenomena are related to the male sex hormone. Although copulatory ability is not destroyed completely by castration, it seems clear that sex drive and

aggressiveness are partly regulated by the amount of circulating male hormone. These masculine attributes are precociously developed in boys who have secreting tumors of the testis. Similarly melancholia, frequently encountered late in life and associated with involution of the reproductive system, is alleviated by testosterone therapy. Indeed one of the major effects of androgens may be the feeling of well-being they induce. It is noteworthy in this connection that patients with interstitial cell tumors secreting fabulous amounts of hormone are usually detected by accident and have no complaint referable to their abnormal hormone conditions.

The testis is regulated by hormones arising in the anterior lobe of the pituitary gland. Hypophysectomy (removal of the pituitary gland) causes the testis to shrink. Furthermore the secondary sex characters and organs also atrophy unless testosterone or some other androgenic hormone is administered. Moore and Price (1932) described a reciprocal relation between the hormones of the testis and the pituitary gland. Injection of androgens into normal animals causes atrophy of the testis, but this atrophy can be prevented by simultaneous administration of pituitary extracts. There is thus a mutual balance between the testis and the pituitary gland. Pituitary extracts stimulate the testis, causing it to secrete testosterone, which in turn inhibits the further production of pituitary hormone.

This scheme of the endocrine interrelation of the testis and the pituitary gland is important historically because it provided a model for other interrelations. However, control of the testis is now known to be more complex. At least two pituitary hormones influence the testis. One stimulates the interstitial tissue to produce androgenic hormone, whereas the other causes activation of spermatogenesis.

The testis is constantly active in some species such as the rat and man, whereas in others it undergoes a seasonal cycle. Thus the ferret, the ground squirrel, and the deer

have active spermatogenesis and enlarged accessory organs of reproduction only during the seasonal period of breeding. In these species the pituitary is responsive to some external influence, becoming activated at the appropriate time. The exciting stimulus seems to be light in the case of the ferret (Bissonnette, 1933), and heat in the ground squirrel; it has not been determined with certainty in deer.

The Ovary

Like the testis the ovary has the double function of producing female gametes and of secreting hormones that regulate the secondary sex apparatus such as the uterus, the vagina, and the mammary glands. However, whereas the testis produces only one known hormone, the ovary secretes at least two. Ovariectomy in adults causes prompt regression of the secondary sex structures; in young animals, these structures never attain their mature condition. Restoration of size and function can be partially accomplished by substances extracted from the Graafian follicle. There are many individual substances that exert this reparative effect upon the sex organs of ovariectomized rats; collectively they are called estrogens. Several such compounds have been isolated from ovaries, and some doubt exists as to whether the natural female sex hormone is a single substance or a group of steroids. These naturally occurring estrogens have been synthesized in chemical laboratories, and, in addition, several other compounds are known which are powerfully estrogenic but which do not exist normally in the mammalian body.

Administration of estrogen causes growth and proliferation of the uterus, the vagina, and other accessory sex organs, but its restorative effect is at best only partial. For the complete repair of the deficiencies induced by ovariectomy, a second ovarian hormone, progesterone, must also be administered. This second principle is produced by the corpus luteum and is peculiarly effective

in producing the conditions in the genital apparatus characteristic of pregnancy. Indeed progesterone seems essential for pregnancy, since without it the normal segmentation of the egg and its subsequent implantation do not occur. Furthermore it is believed but not certainly established that deficiencies in progesterone arising after implantation cause abortion. The uncertainty on this point stems from the fact that the placenta produces progesterone, at least in some species, with the result that the ovary may be removed without interrupting the established pregnancy or destroying all sources of progesterone.

The principal events of the reproductive cycle can be adequately explained in terms of the ovarian hormones. In most animals the ovarian follicle containing the egg grows for a period during which the uterus, the vagina, and the mammary gland proliferate. The degree of stimulation of these organs corresponds closely to those obtained by the injection of estrogenic hormones into ovariectomized animals. At the end of this period the ovarian follicle ruptures, the egg is released into the uterine tubes, and the collapsed follicle becomes organized into a solid corpus luteum. This corpus luteum persists for a period during which the secondary sex apparatus undergoes further development similar to that induced experimentally by injections of estrogen and progesterone. The cycle is ordinarily divided, therefore, into two periods—a follicular phase corresponding to estrogenic stimulation, and a luteal phase characterized by the additional activity of progesterone. These phases can be greatly modified in different animals. In the rat, the mouse, and the hamster, the luteal phase is normally so short as to be practically nonexistent; a follicular phase and ovulation are succeeded without pause by another follicular phase. However, copulation induces the corpus luteum to persist so that a luteal phase is then interposed. In the rabbit the follicular phase occurs spontaneously, but ovulation does not

occur until stimulated by copulation. Once ovulation has been induced, the luteal phase follows spontaneously. The luteal phase is a period during which the uterus is prepared for implantation of the fertilized egg. If pregnancy ensues, the luteal phase is prolonged until the end of gestation; if not, a shorter pseudopregnant phase is succeeded by another follicular phase, and the cycle repeats itself. These basic phases of the cycle occur in all mammals. In the higher primates, including man, the stimulated uterine endometrium desquamates and bleeds in the menstrual process at the end of the luteal phase. In the lower mammals the endometrium atrophies at this time, but overt bleeding does not occur (cf. Allen, Danforth, and Doisy, 1939).

The reproductive cycle, basically controlled by the ovary, is subject to some influence by exterior factors. Exposure to continuous light induces a curious modification of the rat's cycle; follicles grow normally, but ovulation does not occur. Thus a condition similar to that normally occurring in the rabbit can be produced. Also, as in the rabbit, ovulation in such continuous-estrous rats can be induced by copulation (Dempsey and Searles, 1943). Other environmental effects are manifest in the seasonal reproductive rhythms of many wild animals. The ferret normally remains anestrus until spring, but it can be stimulated to estrus earlier if exposed to light. The ground squirrel also is inactive reproductively during the winter, but in this species the stimulating external factor appears to be the warmer temperature of spring.

The ovarian hormones profoundly modify female sex behavior. In rodents estrual activity does not occur after ovariectomy. Mating behavior can be induced in many species by massive dosages of estrogen, but the estrus so invoked is not entirely normal, nor is the treatment invariably successful. A course of treatment involving small amounts of estrogen followed by progesterone is much more efficacious in rodents such as the rat

and guinea pig, leading, in all the animals treated, to estrus indistinguishable from that of normal animals. In the higher primates, including man, sexual behavior is more complex and is not abolished by deprivation of the sex hormones. However, even in man the nervous system is not entirely unaffected by hormones, as is attested by the fact that involuntal melancholia frequently is associated with the menopause and is alleviated by the administration of estrogens.

The Adrenal Cortex

The outer portion of the adrenal gland, like the gonads, develops from the embryonic genital ridge and secretes hormones that are steroidal in nature. For many years little was known concerning these hormones other than that they were essential for life, since adrenalectomized animals invariably succumbed. With the development of potent extracts of the adrenal cortex, great progress has been made in understanding the functions of these glands. However, the topic is far from exhausted and represents one of the most active fields in endocrinology today.

As mentioned above, adrenalectomy is invariably fatal. Different species vary in the rapidity with which death ensues. The operation is rapidly fatal in the guinea pig, but the rat and dog survive for considerable periods. Gradually they lose appetite, become listless and weak, the circulation becomes sluggish, and the animal eventually succumbs. These symptoms seem to reflect profound changes that overtake the metabolism of two groups of substances, electrolytes and carbohydrates. The adrenalectomized animal is unable to conserve sodium; this element is lost in great quantity through the kidney, taking with it chloride and water, with the result that the animal becomes excessively dehydrated and has thick, viscous blood, the potassium concentration of which is abnormally high. The disturbed sodium-potassium balance accounts for the extreme lassitude and lack of irritability, and the hemal concentration accounts for the final

circulatory failure. These deficiencies can be cured rapidly and dramatically by administering an extract of the gland—a dog in complete collapse will recover and evince an interest in food, water, and his surroundings within minutes following an injection of a potent extract. Moreover, to indicate that these deficiencies are caused primarily by a loss of sodium chloride, the life of adrenalectomized dogs and rats can be prolonged almost indefinitely by feeding them large quantities of salt. This added salt substitutes for that lost, and, although the ability of the kidney to conserve sodium is not restored, the concentration of the element in the tissue fluids is maintained above disastrous levels.

In addition to the effect on electrolyte balance, adrenalectomy also disturbs the metabolic machinery that regulates carbohydrates. After adrenalectomy the blood sugar falls and the glycogen stores in liver and muscle are depleted. The ability of the animal to convert protein to carbohydrate is impaired. This conversion, called gluconeogenesis, may be restored to normal or supernormal values by injections of adrenal cortical extract. However, the effect is separate from the electrolyte phenomenon, for the carbohydrate metabolism is not repaired in animals fed excess salt. Moreover it will be shown below that two different hormones from the adrenal cortex control these two phenomena.

Clinical observations provide evidence of the adrenal origin of a third group of factors, the male and female sex hormones. The so-called 17-ketosteroid substances can be isolated from the urine of both men and women. After gonadectomy, the quantity of excreted 17-ketosteroids declines, but only by about one-third. Moreover, after destruction of the adrenal cortex, as in Addison's disease, the 17-ketosteroids are reduced more severely than by gonadectomy. The current interpretation, therefore, is that about one-third of the urinary 17-ketosteroids is gonadal in origin and that the remainder arises in the adrenal cortex. This interpretation fits well

with the facts that adrenal hyperplasia in women is frequently attended by masculinizing symptoms and by increased excretion of urinary ketosteroids, and that the sexual potency of men is depressed more severely by destruction of the adrenal than by castration. Similarly there are rare instances in which adrenal tumors in men have been associated with symptoms of feminization and with increased urinary excretion of estrogens.

The steroids that can be isolated from the adrenal cortex have received exhaustive chemical study. More than a score of separate compounds have been extracted and purified, and their formulas determined. Many of these have no known biological activity. The remainder fall into three general groups. The members of the first group contain oxygen attached to the eleventh carbon atom of the steroid nucleus. These compounds are therefore called 11-oxygenated steroids. The type compound of this group is named corticosterone (or 11-hydroxycorticosterone). The substances of this group regulate carbohydrate metabolism. The second group consists of several substances that lack an oxygen atom at the eleventh carbon; the type compound is therefore called desoxycorticosterone. These are the substances that influence sodium retention. The third group consists of steroids, the individual members of which have biological activity identical with those of the androgenic and estrogenic hormones of the testis and ovary.

The first two factors, the salt-conserving and the carbohydrate-regulating, apparently are elaborated in separate regions of the adrenal gland and are secreted in response to physiologically distinct stimuli. Recent work has suggested that the desoxycorticosterone-like compounds are manufactured in the outermost layer of the adrenal cortex, the glomerulosa, and that the corticosterone-like or carbohydrate-regulating factors occur in an intermediate region, the fasciculata. Moreover hypophysectomy destroys the ability of the adrenal gland to manufacture the

sugar-regulating principles but does not abolish the salt-conserving power of the kidney. Conversely injections of pituitary adrenotrophic hormone greatly stimulate the production of the sugar-regulating factor but do not markedly alter the electrolyte balance. It appears from these facts that the fasciculata, which secretes corticosterone, does so only under the stimulus of the pituitary gland, whereas the glomerulosa secretes desoxycorticosterone but is regulated by non-pituitary factors. The nature of these non-pituitary mechanisms regulating the secretion of desoxycorticosterone can only be conjectured at present. It seems likely that the adrenal glomerulosa responds to changes in the electrolytic balance of the body fluids, but the details of this mechanism are unknown. Little or nothing is known about the site of origin or the physiological regulation of the androgenic and estrogenic steroids of the adrenal cortex.

More is known about the control of the sugar-regulating factors. When animals are subjected to noxious stimuli of many different kinds, the adrenal cortex hypertrophies, and the lipids of the zona fasciculata undergo changes. Exposure to cold, traumatic injury, the administration of toxic drugs, and many other stimuli are equally effective. Such stimuli act through the anterior pituitary gland, because the adrenal changes do not occur in hypophysectomized animals. The details of the homeostatic mechanism that activates the adrenal have not been satisfactorily worked out, but, since adrenal stimulation occurs in animals in which all known nervous pathways to the pituitary have been severed, it seems likely that the noxious stimulus is transmitted to the pituitary by a humoral mechanism. A similar activation of the adrenal cortex occurs in dietary deficiencies of various vitamins, particularly in some of the B group.

The adrenal stimulation invoked in these several conditions has far-reaching physiological consequences. Glycogenesis is accelerated, thus providing a readily available

supply of energy. Marked and rapid changes occur in the lymphatic tissues; the lymphocytes normally contained in the blood, the lymph nodes, and the thymus gland are rapidly destroyed, and their contents are poured into the blood stream. It has recently been shown that the cytoplasm of lymphocytes contains globulins identical with those bearing the immune bodies in the blood plasma. Consequently this lysis of lymphocytes increases the concentration of the blood globulins and provides large amounts of free antibodies. The homeostatic purpose of this reaction is obviously directed against the antigenic materials that may accompany or follow noxious situations.

The Pancreas (Islands of Langerhans)

The story of the discovery of insulin is now one of the classics of the modern era of medicine. After removal of the pancreas the blood sugar rises in concentration and glucose appears in the urine in a fashion characteristic of the human disease, diabetes mellitus. This effect on carbohydrate metabolism is independent of the digestive functions of the pancreas, because ligation of the pancreatic duct, which prevents the pancreatic secretions from reaching the digestive tract, does not affect the blood sugar concentration. On the other hand, extracts of the islet tissue of the pancreas contain a principle, named insulin, which rapidly lowers the blood sugar in diabetes, whether the disease is induced experimentally in animals or occurs adventitiously in man.

Deprivation of insulin does not seem to interfere with the formation of sugar from dietary sources. That is to say, gluconeogenesis, which is impaired after adrenalectomy, proceeds without hindrance after pancreatectomy. On the other hand, some of the pathways by which sugar is ordinarily metabolized are blocked in diabetes. Normally an excess of sugar is removed from the blood and stored in the liver. This does not occur in diabetes: the blood sugar rises because it cannot be reduced by the normal

storage mechanism. However, some of the mechanisms utilizing sugar proceed apace after pancreatectomy. The brain continues to metabolize carbohydrate, and so do other organs. Despite these unaffected avenues, there is evidence that the overall utilization of carbohydrate suffers from an embarrassment of riches because combustion is incomplete, ending in acetone and other products rather than proceeding all the way to carbon dioxide and water.

The biochemical stages and intermediary products of carbohydrate metabolism have been studied intensively since 1930. The combustion of hexose sugars is now thought to proceed stepwise, each step being regulated by an enzymatic mechanism. Among these steps a process by which the sugar or intermediary product reacts with phosphoric acid under the influence of a phosphorylating enzyme is now regarded as an important mechanism for the ultimate liberation of free energy in the metabolic process. Hexokinase, one of the phosphorylating enzymes, causes hexose sugar and phosphoric acid to react, forming a hexose phosphate. This enzyme is inhibited by an anterior pituitary extract and reactivated by insulin, according to Price, Cori, and Colowick (1945). The net effect of insulin deprivation, therefore, is to block phosphorylation of glucose and to prevent any metabolism, such as glycogenesis, in which this process is a necessary antecedent. These considerations accord well with the failure of glycogen storage in diabetes. If verifiable, these results are a milestone in endocrinology, for they represent the first instance in which an enzymatic process has been found to be regulated by hormones.

Recently an experimental observation has opened an avenue into the problem of the mode of formation of insulin. Injections of alloxan cause a transient hypoglycemia, followed by a permanent hyperglycemia and glycosuria characteristic of diabetes. In animals in which diabetes has been so induced, some of the cells of the islands of Langerhans become necrotic and disappear. It appears,

therefore, that alloxan has a marked and selective toxicity for the cells that manufacture insulin. Further work is necessary, but it is reasonable to assume that the selectivity of alloxan's action upon these cells has some relation to the metabolic machinery for elaborating the hormone. It may be possible to study the cellular processes involved in insulin synthesis.

The Parathyroid Glands

Parathyroidectomy causes a state of hyperirritability characterized by spasms of contraction of the skeletal muscles, or tetany. Concomitantly, the blood calcium concentration is decreased. Since calcium is required *in vitro* for normal contractility, the tetany of parathyroidectomy has an adequate explanation. This tetany may be alleviated or prevented by measures designed to raise the concentration of circulating calcium, e.g. by injection of calcium lactate, by administration of vitamin D, or by a replacement therapy utilizing an extract of the parathyroid gland. The active principle in such extracts has been named parathormone. The glands seem independent of the anterior pituitary, since no remarkable changes occur after either hypophysectomy or pituitary replacement therapy. The only clue as to the control of the glands comes from situations involving serious loss of calcium from the body. Thus, in pregnancy and lactation, when calcium is rapidly withdrawn from the maternal circulation, the parathyroid glands hypertrophy. Similarly diets deficient in vitamin D cause parathyroid enlargement, because in rickets calcium is not absorbed properly through the intestine, and consequently the blood level of this ion is low. A similarly depressed blood calcium occurs in some kinds of kidney disease, caused in this instance by an excessive excretion of calcium. In such diseases, sometimes called renal rickets, the parathyroid enlarges. It appears, therefore, that the parathyroid is regulated by a homeostatic

mechanism, but the details of this process are obscure.

The Thyroid Gland

The basic facts of thyroid physiology were derived from clinical observations before physiological methods for animal experiments were available. In 1874 Gull described a clinical syndrome consisting of loss of hair, thickening and dryness of the skin, and loss of physical and mental vigor. He associated these symptoms with atrophy of the thyroid gland. In 1882 the Reverdin brothers observed that these symptoms followed a total thyroidectomy undertaken for the cure of goiter, and in 1883 this was repeated and confirmed by Theodore Kocher. During the years 1891 to 1893 a number of clinicians showed that thyroid substance, whether fresh, dried, cooked, or extracted, was remarkably effective in curing the symptoms of Gull's disease. It was not until 1895 that Magnus-Levy's calorimeter was applied to the study of the thyroid. Following his demonstration that in Gull's disease the heat production was depressed by as much as 40 per cent, the instrument was used to study thyroidectomized animals. It was found that a decrease in metabolic rate was characteristic of thyroid deprivation and that administration of thyroid substance raised the metabolic rate to normal or above. These observations provided a method for detecting and understanding another clinical syndrome, hyperthyroidism or Graves' disease (cf. Marine, 1935).

The effectiveness of thyroid substance in alleviating hypothyroidism prompted an intensive search for the active principle. Baumann showed that iodine in organic combination was a normal constituent of the gland, and Ostwald identified this element in the globulin fraction of the thyroid colloid. Subsequently Kendall isolated a crystalline substance, thyroxine, which exhibited the pharmacologic effects of dried thyroid, and in 1926 Harrington announced its structural formula. Thyroxine may be synthesized by

iodination and oxidation of tyrosine. In the thyroid it apparently exists as part of a larger globulin molecule, and in the blood stream it is associated with one of the fractions of the plasma proteins. For these reasons thyroxine is now regarded as the active prosthetic part of the larger protein molecule comprising the natural hormone.

The mechanism regulating the rate of secretion of the thyroid hormone has received a considerable amount of attention, since it is evident that regulatory factors are disturbed in the principal thyroid diseases, hypo- and hyperthyroidism. After hypophysectomy the thyroid atrophies and the cells appear histologically to be inactive; conversely after injection of pituitary extracts the gland enlarges and the tissue becomes active. Thyrotropin, a specific fraction from the pituitary, exhibits this stimulating effect upon the thyroid. Thyroid atrophy can also be produced by the administration of large quantities of thyroid hormone, which produces an experimental state of hyperthyroidism. From these facts it can be stated that thyroid activity is poised at a point determined by the balance between opposing forces. Pituitary thyrotropin stimulates the thyroid gland, and the thyroid hormone inhibits the further production of thyrotropin. The normal rate of secretion represents the point at which these opposing actions balance.

For a long time there has been a body of clinical impressions that this balance point might be shifted by various ecological forces. Hyperthyroidism tends to occur in excitable individuals and frequently occurs soon after an emotional crisis. The geographical distribution of hyperthyroidism strongly suggests an influence of climate, since it is a rare disease in the tropics, is more frequent in the cooler northern latitudes, and is especially prevalent in areas that have great variations in temperature. Europeans and Americans who emigrate into tropical countries frequently become lethargic and experience a mild depression of the basal

metabolic rate. A speculative interpretation of these facts is that the thyroid gland becomes inactive. It has also been suggested that breeds of animals may differ in the rate of activity of the thyroid gland—the Boston terrier, for example, is regarded as a hyperthyroid breed, whereas in the St. Bernard the thyroid seems inactive.

Some of these speculative impressions have been put to physiological test. Employing a method designed to determine the rate of secretion of the thyroid hormone, Dempsey and Astwood (1943) found that rats maintained in cold temperatures secreted about twice as much hormone as did those kept at normal room temperatures. Correspondingly, maintenance in hot rooms more than halved the rate of secretion. Using a similar technique, Mixner, Reinecke, and Turner (1944) found the rate of secretion much higher in the breeds of chickens used for meat production than in the lighter strains bred for a high rate of egg production.

The discovery of the so-called "antithyroid" compounds has opened a new era in thyroid physiology. Richter and Clisby (1941) noted that thiourea caused hypertrophy of the thyroid gland. Soon thereafter MacKenzie and MacKenzie (1943) and Astwood et al. (1943) published their now classical reports in which were established the following facts: (1) several substances related to thiourea, including sulfaguanidine and thiouracil, induced rapid and extreme hyperplasia of the thyroid gland; (2) the administration of these compounds caused a decreased metabolic rate, despite the hyperactive appearance of the gland; (3) the antithyroid drugs did not interfere with the calorogenic effect of thyroid hormone when administered experimentally; (4) thyroid hormone administered together with the antithyroid drug prevented or abolished the hyperplasia of the thyroid; and (5) the drugs did not cause thyroid hyperplasia in hypophysectomized animals. From these facts it can be concluded that the antithyroid drugs prevent the synthesis of thy-

roid hormone in the gland and thus cause a pharmacological thyroidectomy. This conclusion was subsequently verified by demonstrating that the iodine content of the thyroid fell almost to the vanishing point during antithyroid medication. Further evidence comes also from the clinical demonstration that thiouracil and other antithyroid drugs lower the metabolic rate in man. The high rates characteristic of hyperthyroidism may be reduced to normal by appropriate dosage, or normal values may be reduced to myxedematous levels.

The discovery that synthesis of thyroid hormone can be blocked led to an intensive search for the mode of action of the antithyroid compounds. That the blocked synthetic mechanism somehow involves the metabolism of iodine seems evident from the fact that the iodine stores of the gland are depleted by administering the drugs. Further evidence comes from experiments in which radioactive iodine is used as a tracer substance. Normally the thyroid gland takes up nearly all of a tracer dose of iodine and rapidly converts it into an organically bound compound. After thiouracil, however, any iodine taken up by the thyroid remains there as inorganic iodide. It would seem, therefore, that the antithyroid compounds prevent the iodination of organic compounds.

A word is necessary at this point about the uptake and storage of inorganic iodide. The thyroid gland can accumulate iodide so that its concentration within the gland is many times that of the blood plasma. This function is analogous to the well-known distribution of potassium, which is much more highly concentrated inside cells than in the extracellular fluids. This concentration of inorganic iodide in an "iodide compartment" is not abolished by antithyroid drugs; indeed, the iodide compartment seems to be enlarged during the hyperplastic increase in size of the thyroid brought about by thiouracil. On the other hand, the ability of the thyroid to concentrate iodide can be abolished by other means. The thiocyanate ion

abolishes the iodide compartment and destroys the thyroid's ability to maintain a concentration higher than that in the blood stream. Thus the uptake of iodine into the thyroid gland is accomplished by two mechanisms. The first concentrates the available iodide ion and is destroyed by thiocyanate. The second converts the inorganic iodide to an organically bound compound and is destroyed by thiouracil and other antithyroid compounds (cf. Astwood, 1945).

The question next arises as to how the antithyroid drugs prevent the iodination of organic compounds. It was pointed out earlier that thyroxine, the active prosthetic part of the thyroid hormone, is a derivative of the amino acid tyrosine. Proteins containing tyrosine residues are easily iodinated merely by adding iodine in alkaline solution. Consequently, if the iodide normally taken into the thyroid were reduced, the iodine so formed would iodinate the tyrosine radicles of the thyroid proteins. Of the possible mechanisms to bring about this reduction of iodide, the enzyme peroxidase is a prominent contender. Peroxidase is known to catalyze the reduction of iodide to iodine, and peroxidase is inhibited by antithyroid drugs (Sumner and Somers, 1947). Furthermore peroxidase has been demonstrated histochemically in the thyroid cells (Dempsey, 1944; De Robertis and Grasso, 1946). At the present writing, therefore, the most likely mode of action of the antithyroid drugs is that they inhibit peroxidase or some similar enzyme that catalyzes the iodination reaction in the thyroid gland.

The Anterior Pituitary Gland

The anterior pituitary gland produces several principles which act upon the so-called "target glands" discussed above. A close relation between the pituitary body and these other endocrine glands has been suspected for many years by clinicians and pathologists, since tumors and other lesions of the anterior pituitary gland are followed by disturbances of the gonads and of the

thyroid and adrenal glands. However, accurate and detailed knowledge of the pituitary relations dates from 1930 when Smith devised a procedure for surgically removing the pituitary body in a small experimental animal, the rat.

Hypophysectomy in growing animals causes a sudden and complete cessation of growth. The animal does not gain further weight, nor does its skeleton enlarge. If the operation is performed before puberty, the gonads remain infantile in size, and, since the accessory sex structures do not enlarge, the endocrine functions of the gonads also are impaired. If adult animals are hypophysectomized, the gonads and secondary sex apparatus promptly atrophy to a condition closely resembling that before puberty. Lactation, if occurring, stops immediately after the operation. The thyroid shrinks in size, the follicular cells become flattened, and the basal metabolic rate falls. The adrenal cortex atrophies, particularly in the zona fasciculata. The carbohydrate regulation of hypophysectomized animals is impaired to approximately the same degree as after adrenalectomy, but the electrolyte balance is relatively unimpaired.

The deficiencies in hypophysectomized animals are repaired by replacement therapy. Smith and Engle (1927) showed that subcutaneous implantation of pituitary material restored the size and function of the target glands. Following this classical study, an enormous amount of work has been devoted to isolating and purifying the hormones from the anterior pituitary gland. At the present writing at least six fractions have been isolated from the gland. These are the growth hormone, the thyrotropic hormone, and two gonadotropic hormones, comprising the follicle-stimulating hormone and the luteinizing hormone. The latter is sometimes called the interstitial-cell stimulating hormone because of its effect on the testis (cf. van Dyke et al., 1943). The last two of these six fractions are the lactogenic hormone and adrenotropin.

Several criteria of purity have been applied to these fractions. All have been shown to be biologically pure; that is to say, when injected into hypophysectomized test animals they stimulate the appropriate end response and do not affect detectably the other end effects. For example, growth hormone causes an increase in weight of hypophysectomized rats, but it does not affect the thyroid, adrenal, gonad, or mammary glands. Three physicochemical criteria of purity have also been applied to the protein hormones of the pituitary gland. These are the rate of sedimentation in the ultracentrifuge, the rate of migration in the electrophoretic field, and the solubility properties. Five of the six fractions mentioned above have been prepared in a chemically pure form as tested by one or all of these procedures; one, the follicle-stimulating hormone, satisfies the biological criterion but has not yet been purified chemically.

The physiological regulation of the pituitary hormones is complex. The injection of adrenal cortical extract causes the adrenal cortex to shrink, and this atrophy may be prevented by simultaneously administering pituitary adrenotropin. Apparently, therefore, adrenotropin stimulates the production of adrenal cortical hormone, which in turn inhibits further adrenotropin secretion, and the two hormones constitute a balanced, self-regulating system. A similar balance characterizes thyrotropin and the thyroid hormone. Likewise estrogen injections cause atresia of growing ovarian follicles, progesterone inhibits the production of luteinizing hormone, and testosterone causes testicular atrophy. These facts indicate a series of mechanisms whereby the pituitary secretions are regulated at values just adequate to provide the normal amount of activity on the part of the gonads and of the thyroid and adrenal glands. Such regulation is unknown, however, for the growth and lactogenic hormones. Moreover the situation is further complicated by the effects of varied environ-

mental situations, a topic discussed further in the following section on endocrine balance.

Endocrine Balance

The data in the preceding sections have been presented for the most part in terms of the simple end-organ responses to the various hormones. A multiplicity of such responses has been described, together with a few words discussing the physiological mechanisms regulating the active concentrations of the various factors. The question arises as to whether each of these endocrine factors is a physiologically independent unit capable of variations without affecting the activity of the other factors, or whether some or all exhibit physiological linkages such that the varying of one item leads to a corresponding readjustment of others until the entire constellation achieves a new quantitative interrelation.

At this point a related topic should be introduced. For many years endocrinologists have debated the question of the "master" hormone of the pituitary gland. Cytologically, the pituitary contains two principal types of secreting cells, the acidophiles and basophiles. It has been suggested, therefore, that only two hormones, one from each type of cell, should be elaborated by the gland. This point of view has received some support from clinical observations, since in acromegaly, a type of pituitary disease involving the acidophiles, symptoms are present that involve the growth and thyrotropic hormones, whereas in Cushing's disease, a type of disorder associated with adenomas of the basophiles, there is another symptom complex involving chiefly adrenotropin. Nevertheless the two types are not clearly divided, because sexual failures presumably caused by gonadotropin deficiencies are common in both.

The principal evidence refuting the argument for the "master" hormone of the pituitary has been the demonstration that the individual pituitary fractions can be obtained in chemically pure form. Neverthe-

less such chemical data do not conclusively prove the point, because, conceivably, a large molecule with several prosthetic parts could be disintegrated and separated into several active fractions by chemical treatment. However, Dempsey and Searles (1943), using environmental stimuli as a means of altering the rate of secretion of the various pituitary factors, showed that luteinizing hormone, adrenotropin, and thyrotropin could vary independently, each from the others. The discovery that thiouracil, by suppressing the inhibition normally exerted by thyroid hormone, caused a great increase in the production of thyrotropin also allows observations on the physiological independence of hormones. Since in rats the reproductive cycle, pregnancy, and lactation continue normally after antithyroid treatment, it seems unlikely that the gonadotropic hormones or lactogen are seriously affected. Furthermore the adrenal may be atrophic, normal, or hypertrophic in rats treated with thiouracil, depending upon the concurrent stimuli to which the animals are exposed. These experiments indicate that the pituitary can secrete several qualitatively different factors at quantitatively independent rates.

Although considerable autonomy is possible for the individual factors, the above considerations do not imply the absence of linked readjustments of multiple endocrine factors. In preceding sections the responses to environmental and nutritional stimuli, such as light, cold, heat, and vitamin deficiencies, have been noted. As an example, after exposure to cold the adrenal cortex enlarges and the thyroid becomes more active. These hyperactive glands are still subject to their normal regulatory mechanisms, for injection of adrenal cortical extract or thyroid hormone reduces the responses of the respective glands. Similar reasoning applies to the effect of heat on the thyroid gland. In this case the new setting is achieved at a point corresponding to lessened activity. It

appears, therefore, that environmental stimuli set the regulatory mechanisms of one or several of the factors at new points, corresponding individually to increased or decreased activity of the individual glands.

From the point of view of homeostasis these responses to exteroceptive stimuli represent changes in endocrine balance directed toward nullifying the external forces. Thus thyroid and adrenal activity induced by cold results in an increased metabolic rate and increased utilization of carbohydrate. This augmented metabolism provides more heat and allows the animal's body temperature to be held constant despite the cold. These environmentally induced fluctuations in endocrine activity indicate that endocrine balance is not a static, specific endocrine interrelation but that it is a flexible, dynamic state, changing and shifting constantly according to the particular constellation of stimuli operative at any instant.

For a fuller understanding of the homeostatic adjustments of the endocrine glands, there is great need of information about the concentration of the various hormones in the blood stream. It seems clear that some environmental stimuli cause increased secretion and that other stimuli suppress the production of hormones. It is not clear, however, whether the increased or decreased rate of secretion corresponds to an elevated or depressed concentration of hormones in the blood stream. Conceivably an increased secretion would be necessary to hold a constant blood concentration if the hormone were fixed and inactivated by the end organ. It is also conceivable that the metabolic process regulated by the hormone might respond to an altered concentration without the hormone's being used up in the process. In the latter type of system the secretory rate might well be proportional to the blood concentration. New and sensitive analytical methods need to be developed to answer these questions about the nature of the homeostatic mechanisms.

THE AUTONOMIC NERVOUS SYSTEM

That the motor activities of the nervous system might be divided into a voluntary and an involuntary part was appreciated many years ago by Bichat (1801), who also used as alternate terms the "animal" and "vegetative" divisions of the nervous system. During the nineteenth century came gradual clarification of the anatomical relations of what now is described as the paravertebral chain of ganglia and their connections. Toward the end of the century it was appreciated that the thoracolumbar outflow from the spinal cord was gathered into a great system of ganglia and fibers supplying smooth and cardiac muscle and glands. Langley recognized that this system formed one part of the involuntary or autonomic system and designated it the sympathetic. He also recognized a second part, which he called the parasympathetic, as composed of a craniobulbar and a sacral division. His usage has been widely adopted. (For a schematic diagram of the autonomic system, see Chapter 14.)

Langley defined the autonomic nervous system as the "nerve cells and nerve fibers, by means of which efferent impulses pass to tissues other than multi-nuclear striated muscle." This definition restricts the autonomic to a peripheral motor system, no reference being made to its ramifications in the brain and spinal cord nor to the afferent connections of these ramifications. This restriction seems untenable today, since stimulation and ablation experiments have shown that autonomic regulations are carried on within the central nervous system at all levels, including the cerebral cortex, itself. Moreover the central ramifications of the somatic and autonomic functions are inextricably intermingled, both anatomically and physiologically. It seems necessary, therefore, to extend the definition to include the central ramifications and their afferent connections as well (Fulton, 1938).

With these definitions in mind it is possible to consider the autonomic system in the following ways. The efferent fibers extend to and regulate the activities of smooth and cardiac muscle and glands. The activities of these elements, which make up components of major physiological systems of the body, are coordinated in synaptic regions lying either in peripheral ganglia or in the central nervous system. The autonomic system may be activated or inhibited through its afferent supply from receptor organs (e.g. from painful stimuli) or from the higher centers of the brain (e.g. during rage). Since the efferent fibers establish connections with individual or local effector organs, and since many of these effector organs respond collectively in constellations of activity, the problem arises as to the kind and degree of integration exhibited in the various regions of the system.

The Sympathetic System

The sympathetic division of the autonomic system seems admirably designed to discharge as a unit. Stimulation of any of the rami communicantes, which constitute the spinal outflow, results in activity widely distributed in the system. In other words it appears that the preganglionic fibers of the rami synapse extensively at the paravertebral ganglia so that many of the postganglionic fibers are activated by a relatively small number of preganglionic afferents. The physiological consequences of this arrangement are that activity does not remain localized within the sympathetic system but spreads to all parts of it. In consequence, activity in the sympathetic system results simultaneously in dilatation of the pupil, increase in heart rate and rise in blood pressure, rerouting of the circulating blood by dilatation of the vessels in striated muscle and constriction of those in the skin and elsewhere, inhibition of peristaltic movements in the gastrointestinal tract, and so forth.

Inspection of this list of effects of sympathetic activity immediately brings to mind the fact that adrenalin, the hormone secreted by the adrenal medulla, exerts similar actions. Furthermore the adrenal medulla receives sympathetic fibers and is activated by sympathetic stimulation. Consequently the effector organs of the sympathetic system may be acted upon either by the nerve impulses delivered by the sympathetic fibers, or by circulating adrenalin, or by both. In other words the adaptive nerve impulses are reinforced by adrenalin.

Not only are the sympathetic activities reinforced by the secretion of adrenalin, but the effector impulses of many of the sympathetic fibers are mediated by the local production of an adrenalinlike compound. Upon stimulation of a sympathetic nerve this adrenergic substance is produced by the nerve's terminal ramifications and diffuses into the effector organ where it exerts its stimulating or inhibiting effect. Thus a chemical stage is interposed between the nerve impulse and the effector action, and the activity induced by nervous stimulation is said to be mediated by the chemical agent. Such agents are collectively known as neurohumors. Sympathetic activity, therefore, is mediated by an adrenalinlike chemical compound produced locally at the nerve endings or secreted by the adrenal medulla and carried to the effector organ by the circulation. Most of the sympathetic postganglionic fibers are adrenergic; a few, notably those supplying the sweat glands, produce acetylcholine as their neurohumor and are therefore cholinergic. The preganglionic fibers also secrete acetylcholine at their synapses in the ganglia.

The constellation of effects called forth by sympathetic stimulation or by adrenalin injection also brings to mind another correlation. The physiological effects of such stimulation are similar to those brought about during strong emotional states such as fear or rage (see Chapter 14). This similarity was recognized by Cannon, who demon-

strated the essential identity between the physiological responses of strong emotional states and those of sympathetic stimulation. It appears that the autonomic nervous system is the mechanism by which many of the bodily manifestations of emotion are effected. Cannon regarded these physiological effects as preparatory for flight or combat and described them collectively as emergency functions.

The Parasympathetic System

The parasympathetic division of the autonomic nervous system is sharply contrasted with the sympathetic division in a number of ways. The parasympathetic outflow is restricted to the cranial and sacral regions of the neuraxis, whereas the sympathetic outflow is located in the thoracic and lumbar segments. The peripheral ganglia are located near the end organ so that the preganglionic fibers are long and the postganglionic fibers are short. The opposite arrangement characterizes the sympathetic system. Moreover the extensive interconnections of the paravertebral ganglia have no counterpart in the parasympathetic division, so that activation of one parasympathetic end organ does not necessitate simultaneous activation of others, as is the case with sympathetic activity.

In general, parasympathetic fibers reach the same end organs that are innervated by the sympathetic. Thus with few exceptions the involuntary muscle and glands of the body have a double innervation. The effects of activity of these two nerve supplies are opposite in direction, so that the organs are described as receiving reciprocal innervations. For example, stimulation of the sympathetic nerves accelerates the heart, whereas stimulation of the vagus (parasympathetic) slows it. Similarly the intestine is stimulated by the parasympathetic and inhibited by the sympathetic. Many other examples are known in which two divisions of the autonomic system act in opposite directions.

The reciprocal control of the involuntary activities introduces a new factor into the homeostatic mechanisms. This factor concerns the rapidity and accuracy with which the homeostatic adjustments follow disturbing stimuli. A mechanical analogy springs to mind to illustrate the nature of this mechanism. A stone resting on the ground is immobile, yet it may easily be moved by an applied force. If this stone is now anchored between two fixed posts by springs that are stretched equally in opposite directions, the stone will still be motionless; but it will now require a stronger force to move it, and it will return to its original place when the force is removed. Similarly autonomic activities are disturbed less drastically and recover to their original level more quickly when innervated by the "push-pull" reciprocal mechanism than when receiving a single nerve supply or none at all.

Another aspect of the reciprocal innervation displayed by the autonomic system is that some measure of local autonomy is achieved. The sympathetic effects are collectively mobilized as a unit, whereas the parasympathetic functions may be activated selectively. A means is thereby provided to permit local readjustments. For example, strong emotion increases sympathetic tone and therefore leads to all the sympathetic responses—increased blood pressure and heart rate, piloerection, sweating, inhibition of peristalsis, dilation of the iris, etc. Nevertheless, if a strong light is shown to an enraged man, the previously dilated pupil will constrict because of the parasympathetic light reflex. The selective nature of the parasympathetic elements, when coupled reciprocally with the sympathetic activities, permits a certain amount of individual correction and readjustment of the various components of autonomic responses.

The discrete nature of the parasympathetic activities is further exemplified by the nature of the principal neurohumor of this system. Acetylcholine is produced at the endings of both the pre- and postganglionic

parasympathetic neurons. This agent is rapidly destroyed in the blood and tissues by an enzyme, cholinesterase. In consequence the neurohumor is destroyed before reaching points distant from its origin and cannot normally reinforce nervous activity at distant regions, as can adrenalin.

The relation of the posterior lobe of the pituitary gland to the autonomic nervous system requires special consideration. Embryologically the posterior lobe is derived from neural tissue. It remains attached to the brain by the pituitary stalk throughout life. A considerable number of nerve fibers arise in the supraoptic, periventricular and other hypothalamic nuclei and course through the stalk to end in the posterior lobe of the pituitary gland. The neural supply to the gland comes, therefore, from an autonomic center. There is an increasing tendency to classify this hypothalamico-hypophyseal system as part of the parasympathetic system and to regard it as part of the cranial outflow. Regardless of this question, substances are formed in the posterior lobe that inhibit the production of urine (antidiuretic substance), cause uterine contraction (oxytocic principle), and raise the blood pressure (vasopressor principle). Since these fractions act upon smooth muscle and the kidney tubules, they appear to be autonomic neurohumors analogous to adrenalin and acetylcholine.

The physiological mechanisms involved in the maintenance of water balance by the antidiuretic hormone of the pituitary gland have been investigated extensively by Fisher, Ingram, and Ranson (1938). Destruction of the hypothalamic nuclei, of the nerve tract anywhere along its course, or of the posterior lobe of the hypophysis causes a condition known as diabetes insipidus, characterized by the production of excessive amounts of dilute urine. This condition may be corrected by extracts of the posterior lobe. Furthermore destruction of the pituitary stalk leads to a profound loss of antidiuretic substance from the neural lobe of

the hypophysis. These observations are in accord with Verney's hypothesis which states that the excretion of water is regulated by a mechanism that is partly neural and partly endocrine. The neural portion resides in the hypothalamus and is activated by excessive concentration of some element of the blood, and the endocrine factor arises in the posterior pituitary gland and acts upon the kidney tubules to increase the reabsorption of water from the glomerular filtrate.

Little is known concerning the physiological regulation of the other neural lobe principles. Some observations indicate that parturition is difficult or abnormal after destruction of the hypothalamico-hypophyseal system, but the data are fragmentary and insufficient for final conclusions.

Central Representation of the Autonomic System

The autonomic outflow from the spinal cord arises in a column of nuclei lying intermediate in position between the anterior and posterior horns. Rostrally, in the brain stem, this column continues forward as the gray substance surrounding the central canal and ventricles to end finally in an enlargement, the hypothalamus. Degeneration and ablation experiments show that an extensive system of short neurons interconnect to form pathways up and down this column. Thus, although no long ascending or descending fiber tracts serve the autonomic system, its activities are mediated by multiple relays of elements. The location of this autonomic column has been determined largely from neuroanatomical studies, but significant information has also been obtained from autopsies of patients who exhibited autonomic disturbances and from physiological observations during localized stimulation of the brain stem (cf. Chapter 14).

Although the hypothalamus has been extensively studied for many years, its small size, anatomical location, and relation to the pituitary gland on the one hand, and to the higher neural centers on the other,

have rendered understanding difficult. Although considerable progress has been achieved, many uncertainties and mysteries still surround the subject, and only a partial account of hypothalamic physiology can yet be attempted.

Stimulation and ablation experiments have been undertaken systematically in the cat's hypothalamus by Ranson and his collaborators (Ranson and Magoun, 1939). By means of the stereotaxic instrument designed by Clarke and Horsley, it has been possible to place small electrodes into predetermined regions of the hypothalamus. Through these electrodes electrical stimuli can be applied and the results therefrom noted. Small electrolytic lesions may also be produced in particular regions. Such experiments have drawbacks, arising from the fact that anesthetics that depress hypothalamic responsiveness must be used, and that fibers passing through or near the hypothalamus may be inadvertently stimulated. Nevertheless, when compared with the results of other kinds of observations, useful information has been obtained. It has been possible to subdivide the hypothalamus on the basis of responses to its stimulation and ablation.

The posterior and lateral hypothalamic nuclei appear to form a homogenous system that, when stimulated, evokes activity in the sympathetic system. The heart rate is accelerated, the pupils are dilated, gastrointestinal movements are inhibited, and piloerection occurs. These responses occur in chronically decorticate cats and presumably are not caused by inadvertent stimulation of descending cortical tracts, which degenerate after operation. Moreover the gastrointestinal effects still occur in vagotomized animals and must therefore be mediated by the sympathetic nerves. Ablation of these areas by electrolytic lesions leads to the opposite results; relaxation of the nictitating membrane, enophthalmos, and ptosis have been observed. Lesions in the neighborhood of the mammillary bodies frequently cause

excessive somnolence and lethargy, a condition similar to that observed in encephalitis lethargica in which degeneration of the nuclei along the floor of the third ventricle has been found.

Stimulation of the tuberal nuclei (those in the middle portion of the hypothalamus adjacent to the pituitary stalk) evokes responses quite different from those described above. In general the reactions are parasympathetic in type. The heart rate is slowed, and conduction time in the heart is increased. Intra-gastric pressure, intestinal peristalsis, and contraction of the bladder are increased. The gastrointestinal effects are abolished by section of the vagus, and the bladder effects are destroyed by sectioning the caudal parasympathetic nerves (cf. Fulton, 1938).

Heat regulation in warm-blooded animals has been shown to require an intact hypothalamus. After decerebration a virtually poikilothermic preparation results. On the other hand, the decorticate cat maintains its body temperature at fairly constant levels. Small lesions, located in the various hypothalamic regions, have further clarified the problem. After destruction of the posterior hypothalamus animals are unable to activate their heat-conserving mechanisms and their body temperature falls. It is noteworthy that the heat-conserving mechanisms such as piloerection, increase in heart rate, and vasoconstriction are produced by stimulating the posterior hypothalamus. On the other hand, the heat-dissipating mechanisms appear to be located in the anterior hypothalamus. Cats with anterior hypothalamic lesions are unable to hold down their body temperature when exposed to heat, but the capacity to regulate against cold is unimpaired. It appears, therefore, that separate mechanisms, one integrating the heat-conserving actions, and the other regulating the heat-dissipating functions, reside in the posterior and anterior hypothalamic regions, respectively.

The foregoing discussion indicates that both sympathetic and parasympathetic activities are integrated into patterns in the hypothalamus. Since the various autonomic responses characteristically occur in strong emotional states, it would appear that the hypothalamus must also be involved in the regulation of the bodily processes accompanying these emotions. That this is so is attested by a wealth of experimental and clinical facts (cf. Chapter 14). Decorticate animals (cf. Bard, 1934) exhibit the bodily changes associated with fear and rage in integrated patterns practically indistinguishable from those displayed by normal individuals. In order to avoid controversy over the question of the animal's perception of these conditions, they have been called pseudoaffective states. At any rate the integration of the motor patterns of emotions—rage, fear, and sex—are unimpaired if the hypothalamus is intact, but they are disorganized after its destruction. Component reflexes of the emotional pattern may still be evoked after destruction of the hypothalamus, but the full-blown constellation does not appear. Similar conclusions may be drawn from clinical information. Destruction of parts or the whole of the hypothalamus, although not destroying the responsiveness of the unit end effects, leads to a deterioration of the total emotional pattern.

The hypothalamus not only integrates the activities of the autonomic nervous system but also regulates various metabolic activities. Since the anterior pituitary gland is in close proximity to the hypothalamus, and since the endocrine organs also have important metabolic functions, the separation and identification of the pituitary from the hypothalamic effects has proved difficult, and our understanding of these phenomena is still far from perfect. Nevertheless it appears that carbohydrate metabolism is somehow influenced by hypothalamic centers. Hyperglycemia can be induced by direct stimulation of the hypothalamus, and

ablation of the anterior hypothalamus causes hypoglycemia (Barris and Ingram, 1936). After such lesions animals are abnormally sensitive to insulin; with lesions elsewhere in the hypothalamus no such insulin sensitivity develops. It has also been reported that destruction of the tuberal region of the hypothalamus reduces the severity of pancreatic diabetes in a fashion similar to that occurring after hypophysectomy. This evidence indicates that carbohydrate reserves are mobilized by the posterior hypothalamus and the sympathetic-adrenal system and that insulin tolerance is somehow modified by the anterior hypothalamus.

The hypothalamus has also been implicated in fat metabolism. Although it was originally thought that cachexia was a primary result of hypophysectomy, it now appears that both animals and man can remain in states of good nourishment after destruction of the hypophysis, provided the caloric intake remains adequate. In other words so-called pituitary cachexia is now regarded primarily as a failure of appetite rather than as a metabolic deficiency. Similarly it was originally thought that pituitary abnormalities led to obesity, but the experiments of P. E. Smith and of Hetherington and Ranson (1942) have shown that obesity results from damage to the tuber cinereum and that obesity can occur in the complete absence of the pituitary gland. Although extensive search has been made, no metabolic abnormalities have been found in obesity, and it again appears that the primary difficulty is a matter of appetite, coupled perhaps with predisposing constitutional factors. Since hyperphagia can be produced routinely by lesions in the tuberal nuclei of rats, and since obesity is a common finding in all kinds of expanding tumors lying above the sella turcica in man, it seems likely that the hypothalamus presides over appetite and regulates the food intake according to the energy requirements. Disturbances of this mechanism lead to failure of appetite on the

one hand and abnormally increased appetite on the other.

The metabolic functions of the hypothalamus almost surely have endocrine repercussions, since the hypophysis and its satellite glands also influence the pathways through which foodstuffs are metabolized. In addition, there is more than a suspicion that the external factors such as light and heat which modify endocrine activity are at least transmitted through the hypothalamus. Brooks (1938) reported that ovulation in rabbits, normally occurring after copulation, was abolished by transection of the pituitary stalk. However, in other species, including the rat, the guinea pig, the monkey, and man, ovulation proceeds without hindrance after transection of the stalk. Similarly the thyroid hypertrophy following exposure to cold does not occur in stalk-transected rats (Uotila, 1939), although responses to exteroceptive stimuli, enlargement of the adrenal cortex, and the ovarian response to continuous light, are unaffected by the operation (Dempsey and Searles, 1943). It has been suggested that a neurohumor links the hypothalamus to the pituitary, but the experimental facts are so meager that this is entirely speculative. In any event the mechanism through which exteroceptive stimuli are transmitted to the anterior pituitary gland is one of the important unsolved problems of neuroendocrine physiology.

Although the hypothalamus has sometimes been called the head ganglion of the autonomic nervous system, this is true only in the sense that the hypothalamus is the lowest center capable of a considerable amount of autonomic integration. Indeed the hypothalamus is extensively connected with forebrain structures, and perhaps its principal function is to integrate the autonomic activities with the somatic ones. The medial forebrain bundle is an extensive tract carrying impulses to and from the hypothalamus and the olfactory centers. The frontal cortex and the hypothalamus are interconnected both by the fronto-septo-

hypothalamic tract and by interconnections through the medial thalamic nuclei. Similarly the anterior thalamic nuclei are way stations between the hypothalamus and the cingular gyrus of the cortex. These connections provide ample opportunity for cortical activity to modify autonomic responses, and vice versa. Experimentally stimulation and ablation of cortical areas have been shown to modify sympathetic reflexes (Morison and Rioch, 1937). These considerations indicate that ramifications of the autonomic nervous system extend to the very highest neural levels and provide an ample physiological and anatomical basis for the well-known influences of the higher mental functions upon autonomic responses.

Homeostatic Aspects of Somatic Behavior

The concept of homeostasis originally was applied to the automatic activities comprising the internal housekeeping affairs of the body. Once enunciated, however, the concept has gradually expanded until it now cannot be restricted to any single mechanism or activity. Rather the physiological steady states, by whatever means they are regulated, may properly be regarded as examples of homeostasis. In other words Bernard's formulation of the physiological maintenance of the *milieu interne*, originally conceived as applying to the regulation of blood sugar, has gradually evolved to include many other examples and the specific mechanisms by which the individual phenomena are controlled. Thus a generation ago the principal examples of homeostatic adjustments concerned the activities of the autonomic nervous system. The detailed knowledge of the workings of the endocrine system were later shown to constitute another comparable system. By a similar expansion of the concept many kinds of somatic activity may be recognized to have homeostatic aspects, since the end result of the activity contributes to the maintenance of steady states of the internal environment.

Perhaps the clearest example of the interweaving of somatic and automatic responses is to be found in respiration. The concentration of oxygen and of carbon dioxide in the blood are important examples of homeostasis. When carbon dioxide accumulates, respiration is quickened until normal values are again attained. Yet respiratory movements are made by somatic muscles, and the respiratory muscles may be contracted or relaxed at will.

Another example involves the restlessness and general motor activity accompanying hunger. When hungry an animal becomes active and searches for food. After feeding, the restlessness and interest in food cease. Stated in homeostatic terms, hunger calls forth a behavior pattern that leads to abatement of the hunger. The behavior pattern, therefore, counteracts the depletion of the food reserves and maintains their constancy.

A similar formula applies to many other behavioral patterns. Thirst, like hunger, calls forth motor searching activity. Postural hypotension can be alleviated by tensing the muscles of the legs and abdomen, a fact known to all soldiers compelled to stand at rigid attention. The impulse to seek shade and reduce activity to a minimum on hot summer days is irresistible to all animals, including man. Conversely, shivering and voluntary activity are well-known responses to cold. Many other examples could be cited, but enough has been said to indicate that reflexes, actions, and behavior patterns involving somatic musculature are frequently involved in activity, the purpose of which is to maintain or restore the *status quo ante* of the internal environment.

Evolutionary Aspects of Homeostasis

The principle of homeostasis has been developed as a generalization covering all activities serving to maintain constant the physiological milieu of animals. Since this constancy of the internal environment is necessary for life, it is clear that homeostasis has considerable evolutionary signifi-

cance. Indeed the phylogenetic ascent may be regarded as an increasingly successful effort by animals to free themselves from the limitations of their environments. The ancestral habitats were ones in which reasonably constant conditions favorable to life were maintained. Thus temperature regulation was unnecessary for the life of tropical oceans, since wide fluctuations in the water temperature did not occur. Similarly mechanisms for regulating water and electrolytes were not essential in the dwellers of the Archean seas where the ionic concentration of salts were remarkably like those of the blood sera. In order to free themselves from the confines of their marine habitat, they had to devise mechanisms for maintaining the fluid concentrations of the body. Once this was done, the marine forms invaded fresh water and, as the mechanisms became more perfect and lungs for gaseous exchanges put in their appearance, they marched out upon the land. Conquest of the terrestrial environment was limited to diurnal or seasonal forays until temperature regulation was established, because until then the external variation was so great that a body temperature compatible with life could not be maintained. With the development of heat-conserving mechanisms, cold environments could be withstood, and migration into the temperate and arctic zones became possible; similarly, heat-dissipating mechanisms permitted the conquest of tropical regions.

From the foregoing account it seems that homeostatic regulation did not spring up full-fledged at its first appearance, but that a few simple devices were gradually succeeded by many complex mechanisms, the increasing effectiveness of which accounted for evolutionary advances. Moreover, in the course of evolutionary progress animals have adopted diverse sorts of processes to homeostatic control. Mention has already been made of the use of physicochemical buffer systems and excretory and storage mechanisms, and of the integration of these functions by the endocrine and autonomic nerv-

ous systems. Muscles have been adapted to the control of the blood vascular system and to heat regulation. The skin subserves heat regulation and protection against desiccation in addition to its other manifold functions. The skeletal supporting tissues may be regarded as devices to suspend the soft parenchyma so as to facilitate the circulation of blood and lymph. In short the principal functions of the major tissues and organs are supplemented by homeostatic functions to which the principal activities have been adapted.

Not only are diverse processes adapted to homeostatic functions, but homeostatic problems admit multiple solutions. Temperature regulation may be taken as an illustrative example. Increased metabolism may be caused by thyroid hormone and its attendant increase in metabolic rate, by adrenalin and its consequent mobilization of sugar, or by increased activity, either of a voluntary or an involuntary variety. Moreover some arctic animals protect themselves against cold by growing an extensive insulating pelt; others, notably the aquatic mammals, achieve the same result with a thick fatty pad of blubber. Evasive action may be taken against the enemy, cold. The migratory birds flee the approach of cold, and the hibernating mammals find protected places where they lapse into a poorly understood state of suspended animation by which they conserve their energies for combating a future, less rigorous climate. Lastly, the higher mammals, including man, exhibit increasing ingenuity for finding or building protective devices that mitigate the rigors of the climatic excesses. Man's activity in this direction involves highly intellectualized functions and will be examined more carefully in a later section.

It is not surprising, then, that the central nervous system is no exception to the general rule that all tissues contribute according to kind to the maintenance of the internal milieu. The examples involving nervous activity cited in the foregoing sections have

involved chiefly automatic or semiautomatic activity of a reflex character. However, voluntary activity, instinctive reactions, and even intellectual behavior of a high order cannot be excluded from consideration. Indeed the homeostatic aspects of the higher neural activities are so diversified and so important that they will be considered in separate sections.

Homeostatic Aspects of the Instincts

In a thoughtful article Kubie (1948) has pointed out that the concept of instinct has led a stormy life. Since it stands at the border between the realms of the body and the mind, it has aroused many prejudices and has been regarded as all-powerful by some and as powerless by others. The concept has been restricted to patterns of behavior inherited *in toto* and unmodifiable by growth, development, or experience. On the other hand, it has sometimes been used so broadly as to include every possible form of behavior and even integrations so complex as to be almost superbiological.

By avoiding extremist definitions and assuming that instincts are based upon a biochemical milieu, an inherited but modifiable nervous system, and a complex psychic superstructure of phantasies and phobias, Kubie suggested a classification of the instincts. The primary or vital instincts comprise the behavior related to the intake of raw material and the elimination of waste. Thus the behavioral aspects of respiration, hunger, thirst, urination, and defecation come under this heading. The homeostatic relations of these are obvious. Each produces a change in the biochemical machine that is the body; each sets up a stimulus which is transmitted through the nervous system and which evokes behavior designed to nullify the biochemical change comprising the stimulus. The secondary instincts are the sexual or procreative ones. In them the biochemical basis is at best obscure. They are related to the preservation of the species rather than to the preservation of the indi-

vidual. Nevertheless they evoke behavior that, temporarily at least, displaces other homeostatic processes. Thus the spawning migration of salmon and eels takes precedence over every other activity including those preserving life itself. The tertiary instincts are designated as executive by Kubie; they consist of the elaborate patterns of behavior through which the primary instincts are executed. Examples of such behavior patterns are those that involve the respiratory muscles in breathing, the execution of the muscular activities of eating, and the characteristic poses and muscular coordinations of excretion. These neuromuscular synergies are directly related to the primary instincts and through them to the underlying biochemical disequilibrium. However, unlike the primary instincts they are played upon by psychological forces which determine the effectiveness with which the primary and secondary instinctual needs are served.

Homeostatic Aspects of the Intellectual Functions

Many intellectual activities are directed toward aiding homeostatic functions. Clothing and housing, for example, are directly related to the heat-regulating systems. Heavy clothing permits man to withstand temperatures that otherwise would overwhelm his capacity for conserving heat. Tropical clothing, on the other hand, not only aids in heat dissipation but also protects against the excessive tropical sunlight. Similarly houses are designed to mitigate the natural environments in many ways; roofs and walls insulate against heat loss in winter and provide shade in summer; heating devices nullify cold external temperatures, and air conditioning neutralizes excessive heat. In other words man's solution to the problem of external climates, so severe as to overpower his physiological mechanisms for heat regulation, is to construct an artificial intermediate environment in which his homeo-

static capacity is adequate. Thus, just as the appearance of salt-conserving mechanisms allowed marine animals to invade fresh water, so has the ability to manufacture clothing and to build houses permitted man to live in climates otherwise inimical to his existence. The intellectual process by which this problem was solved must therefore be regarded as a homeostatic mechanism.

Man's use of his intellect to solve the problem of heat regulation is by no means a unique example of this evolutionary new homeostatic mechanism. Devices for regulating pressure, coupled with other mechanical inventions, have freed man from the limitations of gravity. Pressure cabins in airplanes permit life at altitudes otherwise incompatible with life, and similar devices worked in reverse allow man to exist in submarines at depths otherwise fatal. Irrigation and water-supply projects may be regarded as adjuncts to the homeostatic controls for water balance, since in their absence reclaimed desert regions would not support life, and the population density of cities would prove too great for the natural resources. Sanitary measures and public health procedures—indeed, all of preventive and therapeutic medicine—are designed to aid the bodily defenses against invasion by pathological agents. Just as appetite is a psvysiological device for balancing the intake of food against the capacities of the body to metabolize and store it, so is the agricultural industry and the transportation, processing, packaging, storage, and distribution of its products designed to make available food when the bodily needs require it. Thus, regardless of its primary function, the intellect subserves homeostasis in almost every field of human endeavor.

The adaption of the intellectual functions introduces a new factor into homeostasis, in that they are capable of regulating the internal environment not only of one but of many individuals. This quality is peculiar

to the intellect alone, among all other homeostatic mechanisms. If two individuals are exposed unprotected to cold, the one with the most efficient temperature regulation will survive longer. Given access to suitable materials, however, the one with adequate intellect will contrive a shelter which can protect both. Thus the fruits of the greatest intellects can be made available widely to the lesser ones. It is possible, therefore, for a moron who is incapable of conceiving or building a house to be protected by a house conceived and built by another individual. Homeostasis, by adapting the intellectual functions to its use, has transcended the bounds of the individual and has become operative in interpersonal relationships. In other words homeostasis is a generalization applicable in the field of sociology as well as in physiology.

The suggestion that homeostatic principles govern sociological as well as physiological forces implies that parallel or analogous mechanisms should be demonstrable in both fields. We have seen that homeostasis maintains the constancy of the physiological internal environment, that "telltale" mechanisms respond to forces tending to disturb this equilibrium and activate other mechanisms directed toward nullifying the disturbances, and that the successful operation of these homeostatic forces is necessary if life is to persist. We have also seen that states of extreme emergency cause essential organs and functions to be favored at the expense of others. These statements apply equally well to social organizations. Cannon (1941) has pointed out the analogies between the body physiologic and the body politic and has presented numerous examples of the similarities between the two. Commercial storage of perishable foods by sterilization or freezing has practically made obsolete the former seasonal glut or dearth in the markets. Great strides have been made in industry toward abolishing seasonal unemployment. Agricultural and commodity

credit policies that permit the withholding of surpluses in fat years for sale in lean periods were inaugurated by Joseph in Egypt, and within recent years there has been increasing governmental recognition of the importance of uniform distribution for both producers and consumers. "Telltale" devices in social organization are so frequent as to require no more than mention. The press and radio are well adapted to discover trouble and to call for the corrective measures. Fire-alarm systems, meteorological stations, and periodic routine inspections also fulfill these functions. In the normal course of events the recognition of danger signals calls forth the appropriate protective device—pestilence reported by press or radio calls forth public health measures; the fire alarm mobilizes fire engines and teams; excessive rainfall reported through the weather bureau causes flood control procedures to go into operation in the water sheds. The failure of the physiological homeostatic mechanisms leads to disease or death of the individual, and the failure of the social homeostatic mechanisms leads to depression, pestilence, or war. Moreover, during national emergencies activities are given priorities in direct ratio to their utility for prosecuting the war or combating the pestilence.

It is perhaps not surprising, in view of the recent evolutionary emergence of the mind as a homeostatic instrument, that in some respects its functions should be less efficient than the older physiological ones. That the social homeostatic mechanisms are only partially effective is indicated by the facts that booms alternate with depressions, hunger with abundance, periods of overtime work with forced idleness, and war with peace. Adequate defense against attack by disease is often neglected, and maximum efficiency is demanded with little regard for the welfare of the units of the functioning groups. In such respects the body physiologic has

evolved methods of operation better than those thus far prevailing in the body politic.

The idea of a constant internal environment and of physiological mechanisms designed to preserve it has often been paraphrased by the statement that homeostasis preserves the physiological *status quo*. This is true only in the very limited sense that the *status quo* is the only condition compatible with life, and to preserve it is a necessary condition if the individual is to be released from the limitations of his external status. Thus the homeostatic ideal is not an external environment of placid serenity but an instrument for regulating the internal environment so perfectly that external fluctuations are a matter of indifference. Similarly, in social terms homeostasis is a guiding principle directing the evolution of a social organization that will sail on an even keel in the face of buffetings by disruptive forces.

Mechanisms of Neural Maturation

R. W. SPERRY

University of Chicago

The development of behavior is directly dependent upon an orderly assembling of the neurons of the nervous system into appropriate patterns of interconnections. Although neural maturation involves certain other factors, such as the adjustment of excitation thresholds, the present chapter is concerned almost entirely with what appears to constitute its principal and most problematic feature, namely, the developmental organization of those elaborate and intricate patterns of neuronal linkages necessary to adaptive function. Knowledge of this phase of neurogenesis is at present still little beyond the theoretical stage, and it extends only to relatively simple aspects of the integrative structure, such as the connections between center and periphery and the central synaptic associations of the more direct reflex circuits. However, study of the developmental organization of these elementary integrative relations may be expected to yield general principles of maturation applicable as well to the more complex behavior patterns.

When the problem is reduced for the purpose of analysis into its most simplified form, it may be stated as follows: *how do the outgrowing axons and dendrites of the developing nerve cells manage to form and to maintain proper end-organ terminations in the*

periphery and proper synaptic associations within the centers? The problem requires particular regard to the differential specificity with which the neuronal connections are established. It demands answers, for example, to such questions as the following: How do motoneurons innervating a flexor muscle acquire central reflex relations different from those acquired by neighboring motoneurons innervating an extensor muscle? How are optic fibers from different retinal areas able to establish their synaptic relations in the visual centers so that the retinal field becomes projected onto the brain in an orderly manner, permitting objects in space to be seen discretely and localized accurately? Why, again, should the sensory fibers of the horizontal semicircular canal of the labyrinth, on growing into the medulla, form reflex associations different from those formed by accompanying sensory fibers entering the same vestibular centers by the same route, but associated peripherally with the vertical canals? How are the secondary central neurons, which link the different types of sensory fibers with the various motor systems, enabled to form their intracentral associations in the particular patterns necessary for adaptive reflex function? In the course of growth, sensori-neuro-motor associations are somehow laid down in a consistent, orderly manner. How are such patterns organized in development? What is the nature of the regulative processes involved?

The preparation of this chapter was aided by a grant from the Dr. Wallace C. and Clara A. Abbott Memorial Fund of the University of Chicago. Figures 1, 2, 3, 4, 7, and 8 were drawn by E. Bohlman.

"Maturation" versus Learning

A first problem to be considered is the extent to which the neuronal associations are (1) preformed directly by processes of growth and cell differentiation and (2) patterned by functional regulation through experience and training. Where adaptation by function is indicated, we are led into the problems of the physiological basis of conditioned reflexes and learning. On the other hand, where inherent predetermination is indicated, further analysis must deal with the embryological, cytological, and physico-chemical phenomena involved in the growth, migration, and differentiation of nerve cells, and in the formation of contact relations with other neurons and with their respective end organs.

The maturation-learning problem has long been a subject of controversy. In 1931 Holt, among others, was arguing that none of the patterning of synaptic connections between sensory, central, and motor neurons is inherently predetermined. He maintained that developmental forces leave the nervous system an unorganized, equipotential network capable of nothing but diffuse, random reaction. Out of initially random movements, neural organization is gradually achieved, according to this view, through the supposed neurobiotactic outgrowth of dendrites toward axons excited in the course of activity. The most primitive reflexes and even the primary synaptic connections of the peripheral nerves, as well as all higher integrative relations, were presumed to be patterned functionally in this manner.

Since the proposal of this extreme hypothesis, however, contradictory data have been accumulating until now the pendulum of opinion is swinging sharply in the opposite direction toward increasing recognition of the forces of inheritance (Hunter, 1947). A survey of the evidence as it now stands leads to the conclusion that the basic patterns of synaptic association throughout the vertebrate nervous system are organized for the most part by intrinsic forces of

development without the aid of learning. This would include most of the integrative structure of the spinal cord and brain stem. At higher levels of the brain, even in the primates, all the intricate interrelations known to neuroanatomy, such as the various projection systems to and from the cerebral and cerebellar cortices and the interconnecting systems between cortical areas—in so far as they are constant within a species—must likewise be included among the relations of the nervous apparatus subject to inherent organization. By process of elimination the interneuronal relations patterned by learning would seem to be relegated to those circuits farthest removed from the direct conduction pathways which, in the mammal, would be confined mainly to the cerebral cortex. Regarding the limits and overlap of the respective influences of learning and maturation, the evidence remains vague and incomplete.

For present purposes it is sufficient to recognize that the basic integrative architecture of the nervous system is organized directly in the growth process itself. Although the building of integrative circuits presents a fascinating embryological problem in its own right, it is considered here primarily with regard to its implications for the structure and function of the adult nervous system. Knowledge of how inherent behavior is installed may give some clues to the neural basis of learned behavior. The nature of central nervous integration and of the structural framework subserving it should become clearer in the light of such information.

GROSS MORPHOGENESIS

The precise patterning of neuronal interconnections constitutes the ultimate and most refined step in the development of the nervous system. A proper final adjustment of the synaptic associations, however, is dependent upon preceding grosser phases of development in which are attained the gen-

eral form, size, and location of the major parts of the nervous system.

The manner in which the embryonic neural tube becomes transformed into the adult brain and spinal cord is depicted in many standard texts. The histological picture has also been described in considerable detail, particularly for the earlier stages of development, including the proliferation, polarization, differentiation, and migration of the neuroblasts, the outgrowth of the axons and dendrites, the appearance and enlargement of the various nuclear fields, the laying down in successive steps of many of the main fiber tracts, and their progressive enlargement and myelination (see papers and references of Barron, Coghill, Herrick, Langworthy, and Windle).

At first the nerve fibers are few in number, span very short distances, and interconnect only a few nuclear masses. In the course of growth many more fibers are added to the original "pathfinder" lines, and the short fibers become lengthened and drawn into circuitous courses. Additional nuclear fields appear, and new connecting links are laid down to form a structure of ever-increasing complexity. There are successive shifts in topographical relations and a nicely geared timing of the developmental events.

Further insight into these phases of development has been added by the methods of experimental embryology, which have begun to unravel some of the regulative forces involved (see reviews of Detwiler, 1936; Harrison, 1935; Herrick, 1925, 1933, 1948; Piatt, 1948; Weiss, 1939, 1941c). It has been found, for example, that fibers of the sensory nerve roots, on entering the brain, tend to be deflected into those nuclear centers that happen, at the time, to be undergoing cellular proliferation. Similarly, outgrowing fibers of the peripheral nerves verge toward rapidly growing peripheral organs. Likewise intracentral fiber tracts tend to form connections with those nuclei undergoing accelerated proliferation at the time of the fibers' outgrowth. As successive

constellations of proliferative foci make their appearance, new patterns of connecting links are established. In all these instances the influence of proliferative centers on the direction of nerve outgrowth appears to depend upon the formation of lines of force in the interstitial medium which converge on the given growth centers and which in turn cause a converging alignment of the ultra-microscopic particles along which the tips of the nerve fibers are mechanically guided (Weiss, 1941c). That specific chemical factors may also be involved is suggested in the studies of Hooker (1930) who rotated a piece of the spinal cord and found a tendency for the fiber bundles to reconnect with their corresponding fascicles in the rotated segment.

The ingrowth of fibers into a given nuclear field tends to stimulate the growth of the invaded center and to enhance the development of its dendritic ramifications. A correlation has been demonstrated between the size of peripheral structures and the quantitative development of their associated spinal ganglia and central nuclei. The ultimate basis of such effects is still in doubt, but the evidence (Barron, 1945; Hamburger, 1946; Levi and Levi, 1942) suggests that these phenomena are correlated entirely with the growth phase of the nerve and end-organ tissues, and not with their functional phase.

The gross architecture of the nervous system, including the locations of nuclear centers and the patterns of fiber tracts, is the result of a manifold interaction of numerous growth factors. Mechanical and spatial relations, and the mechanisms of cell proliferation, migration, and differentiation, along with embryonic induction, are all involved. The whole process depends upon a neat timing of the developmental steps. Clearly this grosser patterning is determined independently of activity, in a manner characteristic of the species. Even individual variations, almost as characteristic of brain structure as of the face (Lashley, 1947), seem to be genetically determined.

REFINED PATTERNING OF INTEGRATIVE CIRCUITS

It is not enough, of course, that fiber tracts terminate in particular nuclei. The fibers of each tract must, in addition, form the proper synapses within each nucleus of termination. For example, the optic tract in the amphibian must not only make its connection with the optic tectum instead of with other regions of the brain, but the separate fibers composing the tract must terminate in a selective, individuated fashion within the optic tectum itself. The sensory fibers of each spinal nerve must likewise form associations appropriate to the modality of their end organs and to the particular ligament, tendon, muscle, joint, or region of skin, periosteum, or fascia, etc., in which the end organs are located. And within most nuclei localized circuits must be formed. These refined aspects of neurogenesis hold most interest from the functional point of view. It is the most difficult feature to analyze, and until lately our only explanatory concepts, such as "neurobiotaxis," "chemotaxis," "electrodynamic fields," etc., have been vague and speculative.

During recent years a series of experiments dealing with the establishment of synaptic associations in the amphibian central nervous system has given rise to a more definite "chemoaffinity" theory. This scheme attempts to account for the development of neural patterns in terms of cell differentiation and embryonic "induction" processes closely akin to those known to be involved in other organ systems. This aspect of neurogenesis has thereby been brought into line with better-understood phases of development, the main difference being that in the nervous system the final product is far more specific in design and more highly differentiated.

Because it is often easier to study the secondary growth of neuronal connections than to work with the initial embryonic growth, much of the available data is de-

rived from experiments on nerve regeneration. All evidence indicates that the patterning in regeneration is regulated by essentially the same forces as in development.

End-Organ Connections

In the periphery, where the specific termination of neurons is open to observation, the problem of linkages is more accessible to experimental analysis than it is when central connections are involved. It is not usually maintained, even in theory, that learning influences the formation of end-organ connections. Indeed the peripheral relations are generally laid down well before the onset of reflex function. The fact that a precise patterning can be achieved in the periphery without the aid of learning lends credence to the idea that associations within the centers may likewise be adjusted by the forces of growth alone.

Electrical, mechanical, and chemical influences have each been thought at various times to play the predominant role in guiding nerve fibers to their destinations. Except for a slight directive effect of strong currents under special conditions of tissue culture (Marsh and Beams, 1946), the electrical theories have found little experimental support. On the other hand, the universal importance of mechanical factors has been clearly demonstrated. It was noted by Harrison (1914) that nerve fibers grow only in contact with a supporting surface, never in a homogeneous fluid medium. The later studies of Harrison (1935) and particularly of Weiss (1941c) have further emphasized the profound influence of the mechanical substrate on the guidance of growing nerve fibers. Even the ultramicroscopic particles of the interstitial fluid and the most delicate of interfacial films, as well as all larger structures, serve to deflect and to channel the fine filamentous pseudopodia of the advancing fiber tips.

Many aspects of the growth and termination of nerve fibers, however, cannot be accounted for purely in terms of contact

guidance. This is particularly true of the patterning of refined synaptic connections in the centers. From here on it will be taken for granted that mechanical factors are ubiquitous in nervous development and our attention will be concentrated on certain additional factors of more selective action which seem to be largely chemical in nature.

From observations of nerve development and regeneration it has been inferred (Cajal, 1928, 1929; Harrison, 1910; Tello, 1923; and others) that the different end organs must possess some kind of selective chemical affinity for the various types of outgrowing nerve fibers. In the development of the tongue, for example, the fibers of nerve XII establish connections selectively with the striated muscle cells; those of VII and IX connect with the cells of the taste endings; those of V form touch, pain, and thermal endings; and those of the autonomic system connect with the smooth muscle cells of the blood vessels. This selective termination seems to call for differential responses on the part of the outgrowing nerve fibers to specific chemical properties of the end organs. It need not be assumed that the advancing fiber tips are attracted from any great distance by chemicals diffusing from their prospective terminations. Presumably the interstitial pathways to terminal tissues are chemically conditioned by the types of cells surrounding them, and different nerve fiber types are prone to grow preferentially along certain of these diversely flavored pathways. This is suggested in the predisposition of sensory and motor fibers to form separate distal branches in the developing limb bud. (Hamburger, 1929; Taylor, 1944).

Piatt (1942) contributed further evidence that the role played by peripheral nerve fibers in attaining their goal is not so passive and mechanically controlled as had previously been thought. Limbs reared on parabiotic salamander twins to an advanced stage of development in complete absence of innervation were grafted in place of the cor-

responding limb on animals otherwise normal. The resultant nerve pattern formed by the invasion of the host nerves into the developed "aneurogenic" limbs proved to be remarkably normal. Many features of the process, such as the penetration of cartilage masses by the nerves, the tunneling of the ulnar nerve through the belly of the ulnocarpal muscle instead of coursing around it, and the entrance of nerves into their muscles at the customary motor points, suggests a significant influence of chemical factors. The course of some of the cranial nerves is even more difficult to account for unless we assume chemical influences.

Once the fibers have reached their general region of termination, local chemical effects supposedly come into play to determine the specific type of end-organ cells with which the fibers will make connection (Cajal, 1929). In regenerating nerves in the tadpole tail, Speidel (1946) found that aberrant lateral-line fibers show a marked tendency to arrive at and innervate displaced lateral-line organ tissue, whereas no such tendency is ever displayed by spinal nerve sprouts nearby. Nerve regeneration studies, in general, reveal considerable latitude in the extent to which nerve fibers can be forced to form atypical terminations. On the other hand, some examples of strict incompatibility have been observed such as the inability of adrenergic fibers to form functional connections with cholinergic endings, and vice versa (Langley and Anderson, 1904), and the inability of sensory fibers to form transmissive junctions with muscle fibers (Langley and Anderson, 1904; Weiss and Edds, 1945).

Sometimes, instead of growing to their appropriate end organs, the nerve fibers may themselves induce the formation of the appropriate endings from indifferent tissue. In the catfish, for example, the taste buds as well as lateral-line organs are induced to develop at the tips of invading nerve fibers (Bailey, 1937; Olivo, 1928; Olmsted, 1931). On the other hand, the nerve fibers of the

general cutaneous system pervade the integument in the same regions, but these do not induce formation either of taste buds or of lateral-line organs (cf. also Speidel, 1948). Thus, within a given area of the skin, fibers from the gustatory nerve induce gustatory endings, fibers from the lateral-line nerve induce lateral-line endings (these two types of receptors being quite different histologically), but fibers from the general cutaneous nerves terminate freely without inducing any specialized endings.

The type of end organ that is formed may also be conditioned by the type of tissue into which the nerve grows (Bailey, 1937; Dijkstra, 1933). Still another type of terminal relation, discussed more fully below, has been found (Weiss, 1936) where the outgrowing nerves terminate indifferently on their end organs, after which the end organs induce biochemical specificity in the nerve fibers.

The early idea that peripheral nerve fibers differ from each other in their chemical make-up (Cajal, 1928; Hering, 1913; Langley, 1898) has thus been confirmed in studies of peripheral innervation. Neuron specificity influences end-organ connections in different ways in different regions. Nevertheless it is only one factor operating in conjunction with many others. Since connections in the periphery must be made with reference to the central connections, it is difficult to deal with the one apart from the other. Accordingly more detailed discussion of neuron specificity is postponed until it can be taken up in relation to central patterning.

Synapses of Sympathetic Ganglia

A relatively simple type of synaptic relation exists within the sympathetic ganglia of the autonomic system located outside the neuraxis. Preganglionic fibers emerge from the spinal cord via the ventral roots and make synaptic terminations upon the neurons of the sympathetic ganglia. These neurons in turn send their axons to visceral end organs. The neurons within a single gan-

glion may innervate a variety of end organs which function separately and which therefore require separate control from the centers. If the preganglionic fibers were to establish their synapses in a haphazard manner within a ganglion, excitation from the centers could lead only to massive, undifferentiated response. Excluding the possibility of specific nerve energies (see p. 272), selective activation must depend upon orderly synapsis within the ganglia, which, like the end-organ linkages, can hardly be ascribed to learning.

The early studies of Langley (1898, 1900) on nerve regeneration in the sympathetic system of the cat suggest that the synaptic patterning is determined by biochemical differences among the classes of neurons involved. The superior cervical ganglion in the cat innervates the smooth muscles of the auricular blood vessels, the nictitating membrane, the eyelids, the iris, the facial hairs, and the salivary glands. The preganglionic fibers reach the ganglion through the main sympathetic trunk, which they join after emerging from the spinal cord through different thoracic nerves from T1 to T7. Preganglionic fibers associated with different classes of ganglionic neurons tend to exit from the cord at different segmental levels.

Following severance of the sympathetic trunk, the preganglionic fibers regenerate to reestablish connections within the superior cervical ganglion. Despite the mix-up and disarrangement of the original fiber pattern in the nerve scar, inevitable under the conditions of the experiments, Langley found a remarkable tendency for the preganglionic fibers to restore their original type of linkages among the various classes of ganglionic neurons. After regeneration separate stimulation of the preganglionic fibers of the different thoracic nerves, T1-T7, evoked their typical selective action in the periphery. Langley stated that he could see no feasible means, except chemiotaxis, by which the preganglionic fibers could pick and choose

the particular ganglionic neurons with which they become associated. Hypoglossal fibers will also regenerate readily into the superior cervical ganglion and arborize profusely among the cell bodies, but unlike the pre-ganglionic fibers they fail to form the proper synaptic structures necessary for impulse transmission (Hillarp, 1946).

As pointed out by Langley, chemical specificity of neurons may in many instances have only a preferential rather than an all-or-none effect on termination. In regenera-

The functional relations between retina and brain centers must be patterned with orderly precision for visual perception. Each retinal locus must possess its unique "spatial sign." Anatomically it has been shown that the retinal quadrants have an orderly projection upon the brain centers throughout the vertebrate series from fish to man (Stroer, 1939). The problem therefore is to account for the selectivity with which the ingrowing optic fibers form their central associations.

FIG. 1. Surgical rotation and inversion of the eye. It is possible to invert the eye completely by rotating it through 180 degrees, or the eye can be inverted on any one axis by transplanting it to the contralateral orbit. A: Normal orientation. B: 180-degree rotation. C: Dorsoventral inversion. D: Nasotemporal inversion.

tion, for example, a given neuron may terminate more readily on the class of cells with which it was originally connected, but when the fibers cannot reach their favored terminals atypical connections may be formed. It is well substantiated that nerves can be forced by surgical measures, such as nerve crossing, to form atypical linkages under a wide variety of conditions. The readiness with which different types of neurons form terminal endings on other cells appears to vary from complete indifference to highly exclusive selectivity.

Central Synapses of the Retina

Much of the experimental work on the patterning of central synapses has been performed on amphibians, partly because of the oft-cited advantages of this group for embryological study and partly because the amphibian central nervous system in larval stages, and even in the adult, retains a capacity for regeneration far greater than that of higher vertebrates. In amphibians, furthermore, adjustment by learning is not so much a complicating factor.

It was shown by Matthey (1926*a, b, c*) that the optic nerve of the grafted adult urodele eye is capable of reestablishing functional connections in the brain. It was already known that most of the retina of such eyes disintegrates and is then regenerated from the surviving ciliary margin. In his microscopic examinations Matthey also observed an atypical meandering and intermixing of fibers in the regenerated optic nerves. Nevertheless his descriptions of the recovered visual reactions indicated accurate spatial localization and movement perception. Similar findings were later reported from Stone's laboratory (Stone and Ussher, 1927; Beers, 1929; Stone and Cole, 1943). Inclusion, among these earlier reports, of good visual recoveries following 90- and 180-degree rotation of the eye and following atypical connection of the optic fibers with the wrong brain center suggested that some sort of functional adaptation might be involved. Further analysis, as outlined below, however, contradicts this possibility in favor of organizational forces, strictly developmental in character.

It is possible in amphibians to rotate the eyeball on its optic axis through 180 degrees, leaving the optic nerve intact. The eye

(Sperry, 1942*a*, 1943*b*). For example, the optokinetic reactions to movement of the visual field around the dorsoventral and

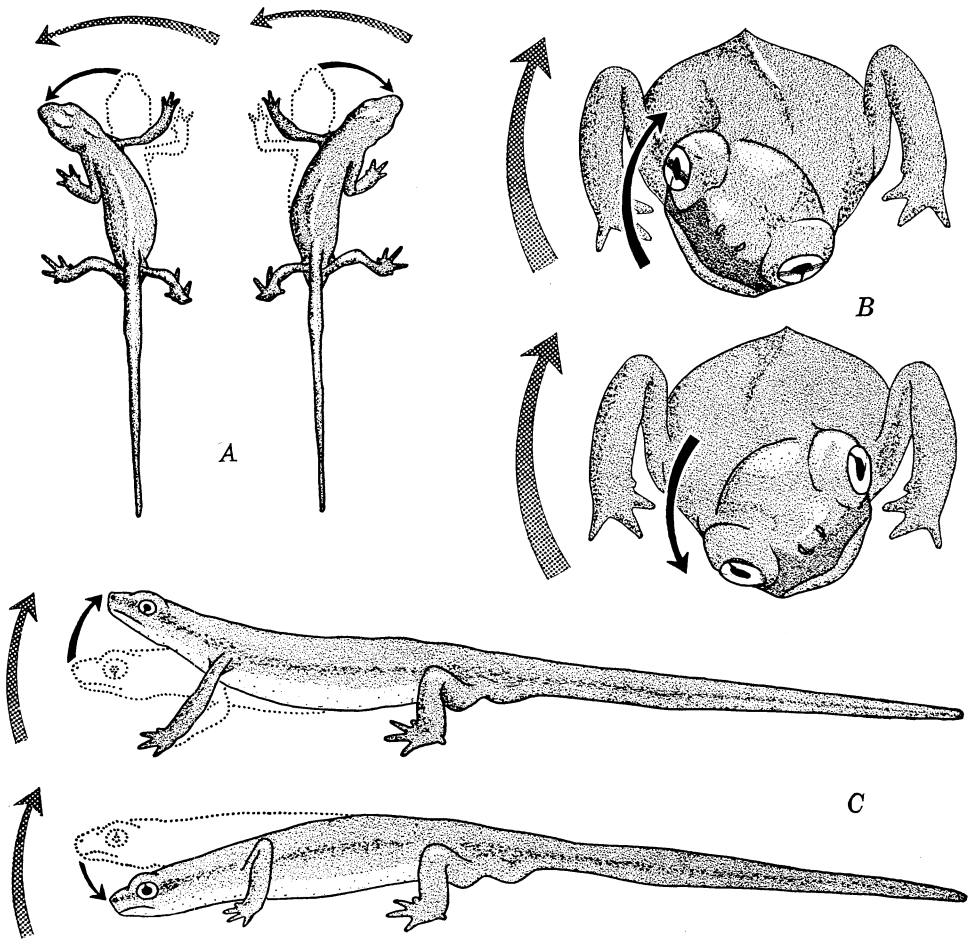

FIG. 2. Reversal of optokinetic responses following surgical rearrangement of retino-central relations. The normal pursuit phase of the response is shown, along with the reversed pursuit reactions for the three primary planes, as caused by (1) 180-degree rotation of eyes, (2) dorsoventral inversion, (3) nasotemporal inversion, and (4) cross union of the optic nerves. Large arrows indicate the actual direction of movement of the visual field. Reversal in *A* caused by 1, 3, and 4; in *B* by 1, 2 and 4; and in *C* by 2 and 3. More complicated correlations are obtained by 90-degree rotation and by combinations of eye rotation, inversion, and optic-nerve cross union.

heals in this new position, with the dorsal quadrant of the retina placed ventrally in the orbit and with the temporal quadrant turned to the nasal side (see Fig. 1*B*). The visual responses then become reversed

rostrocaudal axes of the body are made in the direction opposite from normal, as illustrated in Fig. 2. The predatory reactions involving approach, pursuit, and striking at small moving objects are directed toward

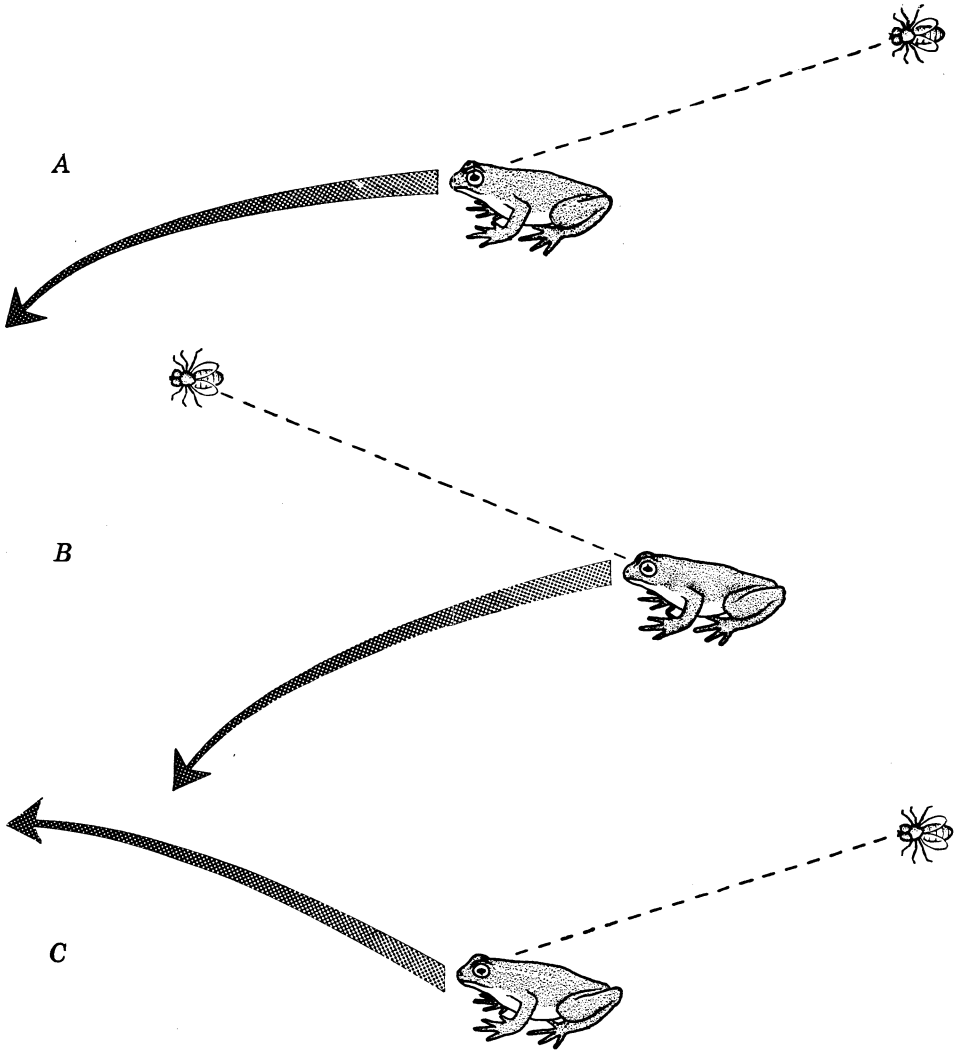

FIG. 3. Sample types of error in spatial localization of small objects following rotation and inversion of the eye. *A*: With eye rotated 180 degrees, frog strikes at a point in the visual field diametrically opposite that at which the lure is actually located. *B*: After dorsoventral inversion of the eye, frog strikes correctly with reference to the nasotemporal dimensions of the visual field, but inversely with reference to the dorsoventral dimensions. *C*: After nasotemporal inversion of the eye, frog strikes correctly with reference to the dorsoventral dimensions of the visual field, but inversely with reference to the naso-temporal dimensions.

corresponding points in the opposite sector of the visual field from that in which the bait is located (Fig. 3A). The animals also exhibit persistent circus movements. The maladaptive responses persist indefinitely without correction. This refractoriness to reeducation suggests, in itself, that the structure mediating these reactions is not organized by the learning process.

Surgical rotation of the eye can be combined with severance of the optic nerve (Sperry, 1942a, 1943c, 1944). This results in blindness for a period of approximately 4 weeks, during which time the fibers regenerate from the retinal stump and eventually reestablish central synaptic connections in the brain. Histological examination has shown that the optic axons, in the course of regeneration, commonly become intertwined with one another in the scar region, with a thorough disarrangement of the original fiber pattern (see Fig. 5A and B). Nevertheless the formation of synaptic relations in the centers does not follow a confused or random pattern. Instead an orderly restoration of the original functional relations between retinal fields and brain centers is achieved. This is evident in the recovery of systematically reversed visuomotor reactions directly correlated with the rotated position of the retina. Inasmuch as recovery leads to maladaptive reactions, which persist without correction, the patterning of the synaptic relations can hardly be ascribed to functional adaptation.

If the blood supply to the retina is sufficiently impaired in this operation, the retina degenerates and in the urodeles a new retina is regenerated. In the course of about 2½ months, new optic axons grow centrally from the ganglion cell layer of the regenerated retina (Fig. 5D). These new optic fibers form central reflex relations within the optic lobe in the same orderly way as do those of cases in which the original axons regenerate directly from the point of severance.

The amphibian eye can also be transplanted to the orbit on the opposite side of

the head with only one of the primary retinal axes inverted instead of both, as diagrammed in Fig. 1C and D. In an eye transplanted to the contralateral orbit, the optic fibers of the original retina (or of the newly regenerated retina if the original retina degenerates) establish central synaptic connections in the same systematic manner as described in the previous experiments (Sperry, 1945a). Following recovery of vision by the transplanted eye, the animals behave as if the visual field were inverted in one dimension, corresponding to the actual inversion of the retina. Responses are properly directed with reference to the axis of the eye correctly oriented, but they are reversed with reference to the inverted axis (see Fig. 3B and C). When the eye is inverted on intermediate axes or rotated through intermediate angles, the visuomotor coordinations become misdirected accordingly. Similar results have been obtained with salamander embryos prior to the initial ingrowth of the optic axons (Stone, 1944).

The optic nerves can be cut and cross-united to the nerve stumps of the opposite eye in such a way that, after nerve regeneration, the retina becomes projected onto the opposite side of the brain from that with which it is normally connected (see Fig. 4). The consequent visual responses indicate that the part of the visual field viewed through either eye appears to the animal as if it were being seen through the contralateral eye (Sperry, 1945a). There is reversal of optokinetic reactions around the dorsoventral and rostrocaudal axes of the body, forced circus movements on these same axes, and errors of spatial localization with reference to the left-right aspect of the visual field. These visuomotor responses remain uncorrected by experience.

Following each of these surgical rearrangements, the neuronal connections are laid down in the same prefixed manner. The optic axons may be growing into the brain for the first time in embryonic development, they may arise from newly proliferated neuroblasts in a regenerated retina in the adult,

or they may be old fibers regenerating directly after transection. Regardless of whether the retina is upright or upside down or whether the optic tracts are connected to the proper optic lobe or to the opposite lobe, the central reflex associations formed by the ingrowing optic fibers are established in the same systematic pattern. These functional relations are formed in a predeter-

minations with the same areas of the optic lobe with which they were originally connected.

These experiments all indicate that fibers arising from a given locus of the retina are predestined to form their central synapses with neurons located in a specific locus. Each retinal point has its corresponding point in the optic lobe. The formation of

FIG. 4. Contralateral transfer of retinal projection on the brain. *A*: By excising the optic chiasma and cross-uniting the four optic nerve stumps as diagrammed, the central projection of the two retinas can be interchanged. *B*: After optic-nerve regeneration the animals respond as if everything viewed through either eye were being seen through the opposite eye. For example, when a lure is presented at *X* or at *Y*, the animal strikes at *X'* or at *Y'*, respectively (see also Fig. 2).

mined fashion without regard for the adaptiveness of the functional effect. Extension of the experiments to teleost fishes (Sperry, 1948*b*, 1949) has yielded similar results.

A lesion made in a given quadrant of the optic lobe of the midbrain of a normal frog produces a "blind" area in the corresponding quadrant of the visual field (Sperry, 1944). The animal then makes no response when the lure is presented in the "blind" area. This fact, bolstered by the anatomical studies of Stroer, indicates that the retina normally has an orderly projection upon the optic lobe. If, in addition, the eye has been surgically rotated, the "blind" area shifts correspondingly. The regenerated optic fibers, despite their mix-up in the scar region, apparently manage to restore functional con-

nections is governed strictly by anatomical relations, not by the adequacy of the functional effects.

Although the mechanisms involved in the establishment of these central reflex relations remain somewhat obscure, several inferences may be drawn from the evidence now available. The general direction of growth of the optic tract as a whole might be due largely to mechanical guidance. On the other hand, it is clear that the arrangement of terminations within the optic lobe itself could hardly be explained in this way. The frayed and disoriented condition of the nerve stumps, the erratic and tortuously intertwined course of the optic axons through the nerve scar, the absence of preconstructed pathways both in the embryo and in animals with newly

regenerated retinas, all indicate that mechanical guidance could not possibly be responsible for the patterning of synaptic relations. Nor does the assumption of a precise timing

mechanical alignment in the substrate of the optic pathway is lacking.

It is obviously necessary that optic fibers arising from different retinal loci be distin-

FIG. 5. Optic nerve regeneration (from Sperry, 1943c, 1945a). Despite extreme intermixing of the regenerating fibers in the scar region and despite rotation or inversion of the opposing nerve stumps as diagrammed in *A*, the fibers reestablish their functional associations in the brain in an orderly manner. The photomicrographs show the interwoven, nonparallel course of the regenerated optic fibers in animals that had shown orderly functional recovery. *B*: Optic-nerve regeneration scar in a newt. *C*: Regenerated optic chiasma in a frog, following contralateral transplantation of the eye. *D*: Regenerated optic nerve of a newt, following retinal degeneration and regeneration.

of axon outgrowth help the situation. All the fibers start their outgrowth at approximately the same time from the cut surface of the nerve stump, and the required me-

guished from one another in the centers. Were the optic axons all alike in character, there would be no basis—with mechanical guidance, timing, and functional adaptation

all ruled out—for a selective arrangement of synaptic relations. Consequently there must be some kind of qualitative specificity among the ingrowing axons determined by the loci of the retinal field from which they arise. Not only the optic axons but also the secondary neurons of the optic lobe with which they connect must each have a distinctive character. If the secondary central neurons were all alike, there would again be no way of attaining order.

The qualitative specificity must parallel the topography of the retinal field. This means a true "field" distribution of qualitative properties among the retinal ganglion cells from which the optic fibers originate and among the tectal neurons on which they terminate. It means, furthermore, that the retina must be differentiated with respect to at least two axes of the eyeball in order that each locus may have biochemical properties different from those of all other loci.

How and when differentiation is established in the retina and optic lobe are questions proper to embryology and cytochemistry. Of more direct interest to us is how this neuronal differentiation affects the patterning of synaptic associations. The simplest assumption is that this patterning is governed by biochemical affinities and incompatibilities between the central neurons and the ingrowing optic axons.

As the optic fibers invade the optic lobes, they have opportunity to make many contacts among the dense population of nerve cell bodies, dendrites, axons, blood capillaries, glial cells, and other optic fibers that have preceded them into the area. Of these many contacts only a few result in the formation of synaptic endings. The fiber tips grow around and past glial cells, capillaries, axons, and the majority of dendrites and nerve cell bodies they happen to encounter. But, when they reach the appropriate part of the optic lobe, they meet neurons whose physicochemical nature is right for the formation of synaptic end feet. It is likely that a single optic axon terminates on a large number of sec-

ondary neurons whose dendrites may spread over a considerable portion of the optic tectum but whose cell bodies occupy only a small area. The cells in the center of such an area would receive the greatest number of terminals from that particular axon. The terminations of neighboring cells would presumably overlap considerably, but the projection of each retinal locus would still be centered about a unique focal point in the field of tectal neurons. The relative degree of overlap has apparently decreased along with a decrease in the spread of the axonal and dendritic arborizations during evolutionary development.

Similar developmental phenomena could account for the orderly projection of the retinal field upon the striate cortex in mammals, although further complications arise from the overlap of the visual fields and the partial crossing of fibers at the chiasma. The close termination of optic fibers from congruent points of the two retinas is a difficult feature to explain. In this regard it is noteworthy that the geniculate cells on which the fibers from the two eyes terminate, tend to migrate into separate layers.

Central Synapses of the Vestibular Nerve

From the nature of vestibular reflexes it is evident that the fibers that supply the crista of one one semicircular canal must have different reflex relations in the hind-brain from the fibers supplying the crista of either of the other canals. Similarly the fibers to each of the approximately seven separate end organs of the amphibian labyrinth must have their own special linkages. There exists a certain overlap, undoubtedly, in the central relations of the fibers of some of these separate end organs. At the same time, however, fibers supplying different parts of a single end organ, such as those to the utricular macula, must have differential central associations to match their functional diversity.

Complete bilateral severance of the VIII cranial nerve root along with the root fibers

of VII was performed in the adult frog, *Hyla squirella* (Sperry, 1945b). The root fibers were able to regenerate centripetally

experimental cases but not in control cases in which regeneration was prevented. Regeneration restored the various reflex re-

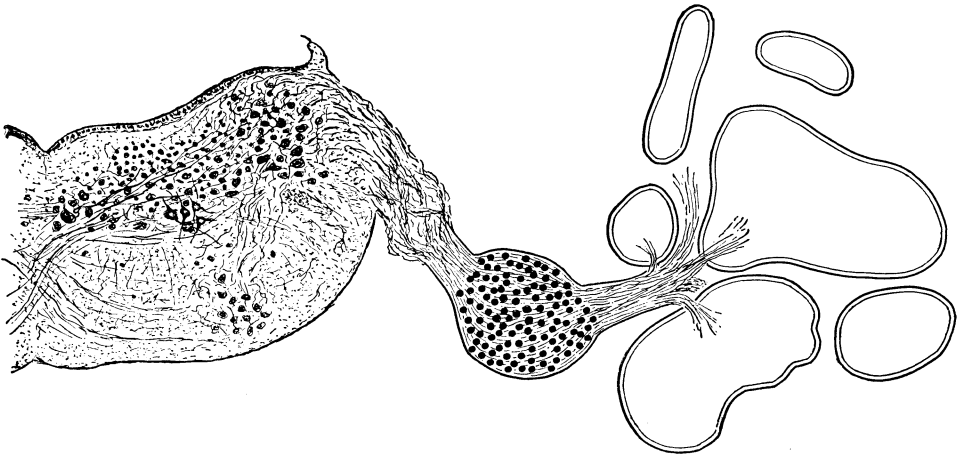

FIG. 6. Diagrammatic section through regenerated vestibular nerve root at its entrance into the medulla. Fibers connected to the various sensory endings in the semicircular canals, the utriculus, the sacculus, and the lagena become intertangled at the point of nerve section, but they nevertheless reestablish central reflex relations in a systematic pattern.

FIG. 7. Vestibular reflexes. Different patterns of labyrinthine stimulation produced by rotating and tilting animals in the three primary planes of the body elicit specific reflex responses and postures which, along with other vestibular responses, furnish good criteria of the orderliness of functional recovery following regeneration of the vestibular nerve root.

into their nuclei in the medulla, as indicated by recovery of function and by histological examination (see Fig. 6). The profound disturbance of equilibration caused by section of the vestibular nerves was repaired in the

responses to angular acceleration and tilting of the animals in the three primary planes of the body (Fig. 7). Evidently the different neuron types among the heterogeneous collection of divided sensory root fibers were

able to reestablish functional relations with the secondary central cells in a discriminative manner. Judging from the number of different kinds of sensory end organs supplied by nerves VII and VIII, one would estimate that at least eleven distinct classes of fibers regenerated from the point of transection with ample opportunity for a chaotic

less. The normal development of the vestibulo-ocular reflexes in blinded animals, including amphibians (Sperry, 1946), pigeons (Mowrer, 1936), chickens (Kuo, 1932), and rabbits (Nasiell, 1924), is further evidence that learning is not important in patterning the synaptic associations of the vestibular nerve.

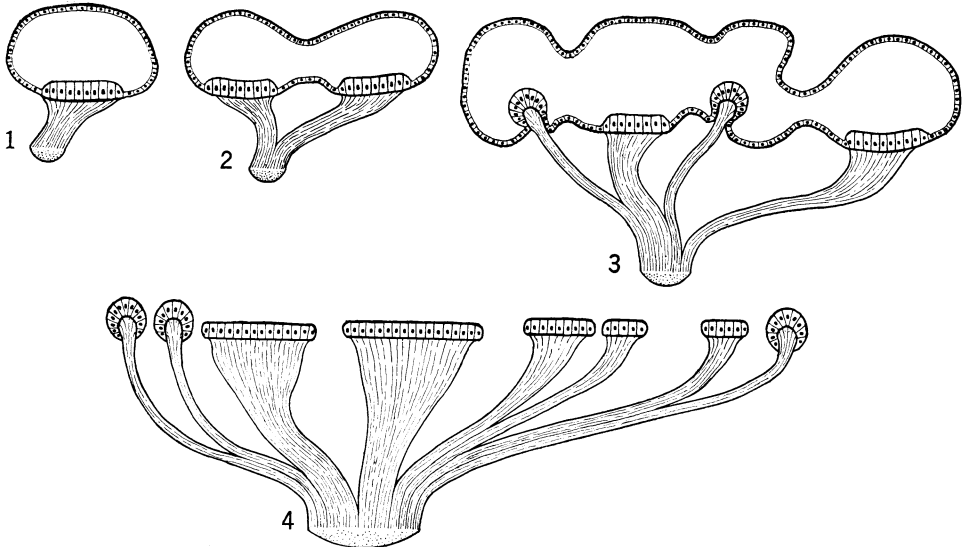

FIG. 8. Differentiation of the vestibular sense organs (schematic, after de Burlet, 1929). As the simple otic vesicle enlarges and transforms into the complicated adult labyrinth, the single patch of sensory epithelium, with nerve fibers attached, becomes subdivided into many parts which undergo independent differentiation to form the various adult sense organs.

interspersions into abnormal pathways, and with very little chance for particular fiber types to be directed to their proper central terminations by mechanical factors alone. Nevertheless reflex relations were restored in an orderly fashion.

There was no indication of learning during the period of recovery. Nor were the recovered reactions impaired by decerebration. Regeneration of the VIII root in tadpoles was also found to restore the compensatory vestibulo-ocular reflexes, even though the optic nerves in these animals had been previously excised so that the formation of proper reflex relations was functionally use-

The strict correlation between the behavior of the vestibular fibers and their peripheral connections suggests a causal relation. From descriptions of the development of the vestibular apparatus and its nerve supply (Harrison, 1936; de Burlet, 1929), it appears that here, as in the visual system, the end organs probably lead the way in the matter of differentiation and induce specificity in their associated nerve fibers. Early in development the vestibular fibers are all connected to a single patch of sensory epithelium. From this single patch of cells are pinched off approximately seven separate parts that become the various end organs of

the labyrinth (see Fig. 8). Presumably, as the parts undergo differentiation, they induce a parallel differentiation in the neurons connected to them.

Unlike the situation in the retina, the sensory cell bodies and dendrites are not embedded within the end-organ tissue. It must be supposed, therefore, that specification is imposed on the neurons through their terminal connections. Specification of this kind is well authenticated in the case of the nerves to the limb muscles (Weiss, 1941*d*). The chemical or physical basis of the "induction" effects of one tissue upon the differentiation of neighboring tissue has long been a matter of conjecture. It would appear to involve some type of contact or chain-reaction process. For further discussion of the general problem, see Weiss (1947).

In order that the vestibular fibers may form proper synaptic relations among the central neurons, it is necessary that the secondary neurons also be heterogeneous in character. This could be achieved through self-differentiation or possibly, in part, through induction effects from axon connections with the motor system. It is a general rule of early development (Coghill, 1929, 1930*b*; Herrick, 1939; Windle, 1944, etc.) that the association neurons join with the motor neurons before synapses are established with the sensory fibers. Hence it is possible that axon connections with the already differentiated cells of the motor system influence the refined stages of specification among the association cells.

Genesis of Cutaneous Local Sign

Most vertebrates including man are able without visual aid to localize a tactile stimulus applied to the skin anywhere on the body. Even the frog localizes with considerable accuracy. Mild cutaneous stimuli applied at different points about the back, thorax, hip, thigh, knee, shank, and foot will evoke responses well aimed at the points stimulated. The false localization that follows misregeneration of nerves into foreign regions of the

skin shows that the local sign quality depends upon the central relations of the cutaneous fibers. For normal localization the central connections of each fiber must suit the particular peripheral area that the fiber innervates. In a sense the map of the body surface must be reflected in the central circuits.

It has been widely assumed that cutaneous local sign is acquired by experience. Holt (1931) presented a scheme, based on the

FIG. 9. Contralateral translocation of skin flaps. Skin translocation across the midline of the back in frog tadpoles results in contralateral misdirection of localizing reactions after metamorphosis.

theory of neurobiotaxis, by which this "education of the sensory surfaces" might conceivably take place (see pp. 237 and 263). A later study on the cross union of sensory nerves in the rat (Sperry, 1943*a*), however, has furnished strong evidence of an inherent organization in these animals. Inherent organization is also the rule in the development of cutaneous local sign in amphibians.

In the frog the hind-limb localizing reactions survive cord transection, indicating that they are organized mainly at the spinal level. Skin flaps with their original innervation largely intact can be transplanted across the midline of the back (Fig. 9) of the metamorphosing tadpole, prior to any experience with localizing responses. After metamorphosis is complete, the frogs display localizing reactions that are misdirected to the contralateral side. Stimuli applied to the translocated skin elicit wiping reactions on the

opposite side falsely aimed at the original site of the skin flap.

It is also possible by surgery to cross-connect the dorsal roots of the hind-limb nerves to the opposite side of the cord (Fig. 10). When the operations are performed in tadpole stages, the root fibers regenerate to

responses in the urodele amphibians. In frog tadpoles the ophthalmic branch of the trigeminal nerve on one side can be crossed peripherally to the contralateral ophthalmic nerve (Fig. 11). After metamorphosis the wiping responses are misdirected to the wrong side of the head; e.g., stimulation of

FIG. 10. Contralateral cross union of dorsal roots. When the dorsal roots of the hind-limb nerves are crossed in the manner indicated, the regenerating sensory root fibers establish functional relations with the spinal centers of the contralateral limb similar to those that they establish with the ipsilateral limb centers. This selective formation of the central reflex connections cannot be attributed either to mechanical guidance or to functional adjustment.

form reflex relations with the motor centers of the contralateral limb. After metamorphosis cutaneous stimuli applied to the foot result in characteristic reflex reactions of the opposite leg, while the foot stimulated remains motionless (Sperry, 1947*b*). Cutaneous local sign in the spinal hind-limb area can hardly be ascribed, therefore, to functional adjustment.

Stimulation of different points about the head and face within the area innervated by the large trigeminal nerve will elicit specific wiping reactions of the ipsilateral forelimb in frogs and toads and specific withdrawal

the left ophthalmic area elicits wiping reactions of the opposite forelimb aimed at the right ophthalmic area (Sperry and Miner, 1949). When the ophthalmic nerve is crossed into the contralateral mandibular nerve, stimulation of the ophthalmic-innervated mandibular region evokes reactions of the opposite forelimb misdirected not only to the opposite side but toward the ophthalmic instead of the mandibular area (Miner, 1949). The ophthalmic branch of V has also been crossed in efts to the ipsilateral mandibular branch of V, the central root of which was then cut and allowed to regenerate into the

brain (Fig. 12). The regenerating root fibers reestablished orderly relations, but, because of the peripheral nerve cross, the resultant responses were functionally maladaptive. Pricking the underside of the jaw caused the head to be depressed more strongly against the point of the needle (Sperry and Miner, 1949). Thus, in regeneration as well as in

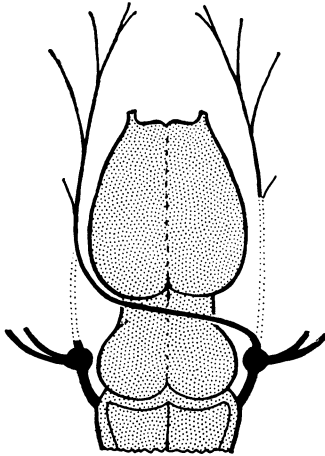

FIG. 11. Contralateral cross union of ophthalmic nerves (from Sperry and Miner, 1949). The left side of head and snout become reinnervated by the crossed right ophthalmic nerve in larval stages. After metamorphosis localizing responses are misdirected to the wrong side of the head.

development, the central circuits became patterned in an orderly manner with reference to certain anatomical relations but without regard for functional adaptiveness.

Good functional recovery of the transected root V following haphazard intertangling of fibers in the scar (Fig. 13) shows that the central patterning is not merely the product of an orderly spacing and timing of fiber ingrowth. Even when the cut root of V is made to regenerate into the brain over the central pathways of nerve VII (Fig. 14) the local sign properties of the trigeminal cutaneous field are correctly restored. It is apparent that in the latter case there is no opportunity for the individual fibers to

follow their old channels to the original central terminals. The dorsal roots of the hind-limb nerves are exceptional in this regard, in that full recovery of functional specificity is not obtained, save in a small percentage of cases. After recovery the foot reactions are less differentiated than normal, with the more refined wiping responses usually lacking. Possibly in this instance the timing of fiber ingrowth may be involved in the adjustment of central linkages.

The conclusion is evident that the sensory neurons supplying different cutaneous areas must differ in character. Fibers from different loci must somehow be distinguishable in the centers. A correlated specificity among the second-order neurons is also indicated.

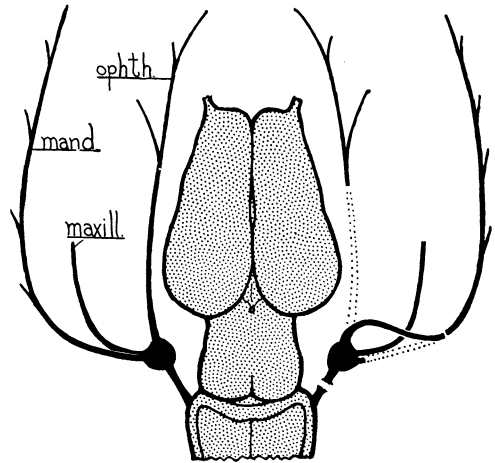

FIG. 12. Cross union of ophthalmic and mandibular nerves with section of root V (from Sperry and Miner, 1949). After recovery, the eft's withdrawal responses to stimulation of the mandible are reversed.

The central neurons must be distinguished in accordance with their various efferent relations. The orderly patterning of central reflex relations then becomes explicable, as in the visual and vestibular systems, on the basis of differential chemoaffinities between the sensory and central neurons.

Furthermore the specificity of the sensory fibers must correspond to the topography of

the cutaneous field, reflecting the spatial interrelations of all cutaneous points. Finally the experiments indicate a highly refined, fieldlike differentiation of the entire integu-

and termination of the sensory fibers, followed later by induction of specificity in the fibers as a consequence of their connections with the cutaneous field.

FIG. 13. Centripetal regeneration of trigeminal nerve root. *A*: Diagrammatic frontal section through the regenerated Vth nerve root at its entrance into the medulla. *B*: Different kinds of avoidance or withdrawal reflexes mediated by regenerated fibers of V are consistently restored in an orderly manner.

ment, itself. Without this it would not be possible to obtain the neat adjustment of central-peripheral linkages.

Conceivably the parallel specification of the sensory neurons and the integument might be achieved by independent self-differentiation. In this case the attainment of proper peripheral connections would call for a selective outgrowth of the sensory fibers, each to its correct cutaneous locus. The required linkages could also be established through a relatively indifferent outgrowth

The evidence at present tends to favor the latter possibility. Fibers of the thoracic nerves can be made to connect atypically with limb instead of thoracic skin by extirpating the sensory ganglia of the limb, or by transplanting limbs into the midthoracic region of the back. The sensory fibers then develop central linkages suited to the particular part of the limb integument in which they happen to terminate (Miner, 1949). A similar specification of sensory fibers mediating the corneal reflex has been inferred from

the results of transplanting extra eyes to atypical locations about the head (Weiss, 1942; Kollros, 1943). Evidence of this specification failed to appear in the ophthalmic to mandibular nerve crosses cited above, but the fiber specificity may already have become irreversibly determined. Even in mid-larval stages in the frog tadpole the ophthalmic and mandibular divisions of nerve V have been found to retain their original cen-

FIG. 14. Cross union of V and VII (from Sperry and Miner, 1949). The trigeminal fibers regenerate into the brain via pathways of VII.

tral associations after connecting with foreign integument (Miner, 1949).

The evidence thus far does not preclude the probability that the sensory ganglia of the various cranial and spinal nerves undergo some degree of differentiation independently of contact with the integument. But the refined specification necessary for localizing different points within a given dermal segment is apparently dependent upon inductive effects imposed upon the nerve fibers by the differentiating skin. An extensive overlap in the terminations of neighboring cutaneous fibers both in the periphery and in the centers must be assumed.

An additional dimension of differentiation among the cutaneous fibers is required for the different modalities of pain, touch, and temperature. Presumably the "local sign" specificity is superimposed upon this more

general modal differentiation. How the modal differentiation is controlled and how the different classes of fibers become distributed in proper proportions to the cutaneous field are problems thus far untouched.

Central Reflex Connections of the Proprioceptive Fibers

The sensory neurons supplying the proprioceptors of the musculature develop specific reflex relations in the centers suited to the particular muscles that the neurons innervate. This is necessary to the regulation of posture and of motor coordination. Functional specificity is manifest in stretch reflexes like the knee jerk or ankle jerk, in which sudden stretching of the muscle calls forth a reflex contraction selectively centered in the same muscle (Lloyd, 1946).

It has been shown (Verzár and Weiss, 1930; Weiss, 1937*a*) that the reflex properties acquired by the proprioceptive fibers of different limb muscles depend upon specification of the fibers by their muscles. When divided fibers of a limb nerve regenerate into the muscles of an extra limb transplanted in the vicinity of the normal limb, their reflex relations become adjusted to suit the particular muscles with which they happen to connect. After recovery passive stretching of different muscles in the extra limb elicits a contraction of the stretched muscles, and also of the homologous muscles of the normal limb. The functional relations thus automatically become adjusted to the pattern of the peripheral connections.

This cannot be ascribed to learning, because the movements of the extra limb serve no purpose. In some cases they are positively detrimental to the animals. The assumption that fibers connect selectively with particular muscles has also been ruled out. The only remaining possibility is that the character of the proprioceptive neurons is determined by inductive effects from the muscles.

In regeneration of the dorsal roots of the hind limb, proprioceptive fibers reestablish

connections along with the exteroceptive cutaneous fibers. The proprioceptive reflex relations are restored in a selective manner. If the dorsal roots of the right leg are crossed into the spinal centers of the left leg, the reactions of the left leg in response to

The central patterning of the proprioceptive reflexes following centripetal regeneration of the root fibers can be readily interpreted in terms of chemoaffinity. We need only assume that the ingrowing fibers from different muscles form synapses with

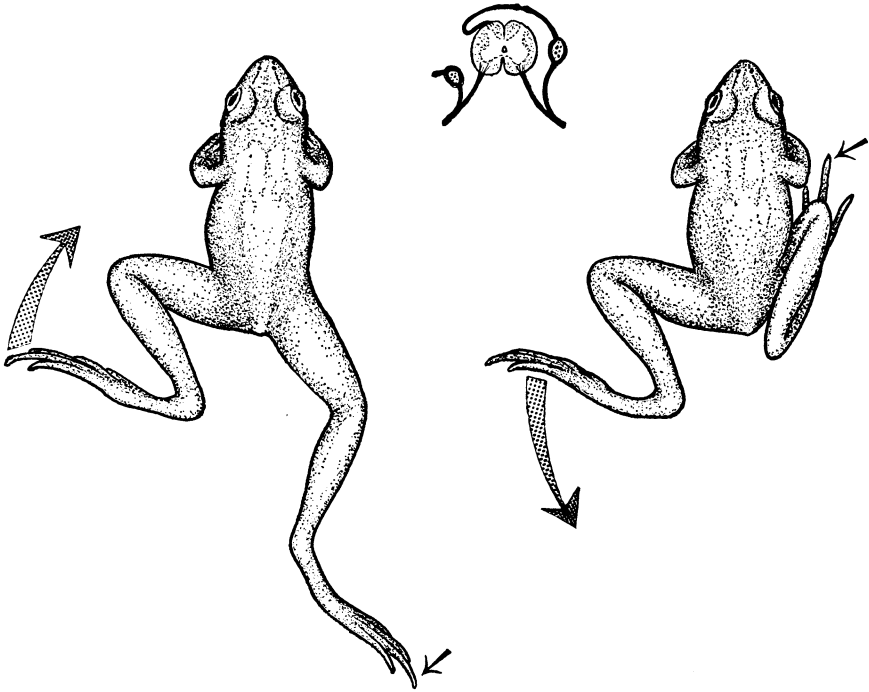

FIG. 15. Systematic reestablishment of proprioception. After crossed regeneration of the dorsal roots, the posture of the right limb comes to condition the type of reflex responses made by the contralateral limb in the way it usually conditions its own responses. Stimulation of the right foot (small arrows) causes flexion or extension of the left leg, respectively, depending on whether the right leg is extended or flexed.

stimuli applied to the right leg are conditioned by the posture of the right leg. For example, as illustrated in Fig. 15, a tactile stimulus to the toes of the right foot may evoke either an extensor kick or, conversely, a flexor withdrawal of the opposite left foot, depending on whether the right leg happens to be flexed or extended. Similar influence of the leg's posture upon its own responses is observed after ipsilateral regeneration of the divided dorsal roots.

different classes of central neurons in a discriminative manner.

The interpretation is not so easy, however, in the earlier limb-transplant experiments of Weiss in which the original central connections were left intact. On the assumption that the central connections remained fixed, the orderly establishment of the myotatic responses after disarrangement of the peripheral connections was taken to mean that specific connections are not basic to central

nervous integration. It was inferred that the central-peripheral selectivity must be based instead upon physiological "resonance" phenomena (see p. 273) and that the muscular specification of the proprioceptive fibers modulates the quality of the impulses the fibers transmit. In order to bring these results into harmony with our present connectionist interpretation it is necessary to postulate that the existing central synapses undergo some kind of trophic breakdown and rearrangement in response to the new peripheral relations.

The foregoing evidence on the development of sensori-central connections reveals a recurring pattern throughout. In the visual, vestibular, cutaneous, and muscular proprioceptive systems, the end-organ tissue apparently undergoes the primary differentiation and then induces local specificity in whatever sensory fibers are in contact with it. The induced fiber specificity then determines in turn the pattern of synaptic associations to be formed in the centers. It seems likely that this same type of "peripheral regulation of central synapsis" may occur also with other tissues such as the cochlea, the tendons, the joints, the ligaments, the facias, the periosteum, etc., the sensory innervation of which possesses local functional specificity. On the foregoing scheme neuronal connections neatly designed for adaptive function can be laid down between the sense organs and the centers by purely developmental forces.

Motor Neuron Associations

The central relations of the primary motor cells must be adjusted to suit their peripheral connections in the musculature. The experiments of Weiss (1922-1937) dealing with the factors controlling selectivity between musculature and nerve centers in amphibians antedate most of the investigations already cited. Much of the more recent work has been stimulated directly by these pioneer investigations and the challenging conclusions to which they led. Their con-

sideration has been delayed to this point because the results on the motor system involve relations and interpretations somewhat more complicated than those dealing with the sensory systems.

It is conceivable that the motor neurons might attain their proper peripheral connections by means of selective axon outgrowth. A given neuron might seek its appropriate muscle. This would require a previous specification of the motor cells into as many different types as there are muscles to be innervated. Actually, however, the outgrowth and termination of the spinal motor axons in amphibians has been reported (Piatt, 1940; Weiss, 1937*b*) to be entirely nonselective, both in regeneration and in development. Under normal conditions some selectivity of axon termination would seem to be assured by the proximodistal order in which the limb segments develop (Saunders, 1947) and by the chronological order in which the neurons differentiate and send forth their axons. Nevertheless considerable freedom remains within any limb segment, and, since proper muscular coordination is achieved even with highly random outgrowth and termination in the periphery, it follows that the central relations must be adjusted secondarily to suit the peripheral innervation. Even when divided motor axons are forced to regenerate into entirely foreign muscles, the timing of the central discharge becomes adapted to the new terminals (Weiss, 1928, 1936, 1941*d*).

This adaptation in the timing of the central discharge is not achieved by the learning process. If limbs are transplanted to dorsal positions such that their movements are of no value to the animal, the central-peripheral adjustments occur in the usual systematic manner. This is true even when the limbs are transplanted to the contralateral side and reversed in such a way that the movement of the limbs tends to push the animal backward when it attempts to go forward and vice versa, as indicated in Fig. 16 (Weiss, 1941*d*). Similar effects are ob-

tained when the limb transplantations are made in prefunctional stages (Brandt, 1925, 1940; Detwiler, 1925; Weiss, 1941*d*), showing that these relations are patterned initially through developmental forces and not through any kind of functional adjustment. Furthermore it has been shown that these motor patterns develop in the same systematic way in the absence of sensory innervation (Weiss, 1937*c*) and that they persist after decerebration and cord transection

turbed. The recovery of typical muscle function with atypical end-organ connections might be accounted for by assuming either (1) that central-peripheral selectivity is independent of specific connections and is achieved instead on a physiological "resonance principle" (Weiss, 1928, 1936, 1941), or (2) that the rearrangement of muscular connections produces a compensating readjustment among the central connections (Sperry, 1941, 1943*c*). Decisive proof re-

FIG. 16. Reversed locomotion after interchange of right and left forelimbs (after Weiss, 1941*d*). After prefunctional reversal of the anteroposterior axes of the forelimbs, the central coordination patterns develop in the usual way, with the result that the transplanted forelimbs oppose the normal action of the hind limbs.

down to levels of the cord just rostral to the limb segments (Weiss, 1936). The possibility that learning or any type of functional adaptation might be responsible has thus been excluded.

The motor neurons must somehow be distinguished from one another in the centers according to the muscles they innervate, because the timing of their central discharge is always adjusted on this basis. Weiss concluded that the motor neurons possess some constitutional (presumably biochemical) specificity induced in them by their muscles. This apparently was the first suggestion that nerves may be specified or "modulated" by their end organs. The corollary follows that each muscle of the limb must have biochemical properties all its own. Indeed it would be difficult to account for the morphogenesis of the limb musculature itself in the absence of such a differentiation.

In these experiments of Weiss it was only the end-organ connections that were dis-

garding these two alternatives is lacking. However, the latter fits in with our general chemoaffinity theory of synaptic patterning and is also favored at present because it does not necessitate any significant revision of our current views of central nervous integration. Accordingly the biochemical specification of the motor neurons may be tentatively considered to influence the type of synaptic linkages the cells will tolerate. It is presumed that the sensory and association neurons form their synapses among the motor cells originally in a selective manner, depending upon the biochemical specificity of the motor neurons. When axons regenerate into foreign muscles, the change in biochemical properties induced by the new muscles is thought to cause a trophic degeneration of the synaptic endfeet upon the motor cells. New synapses are then established according to the revised pattern of chemical affinities (see Fig. 17).

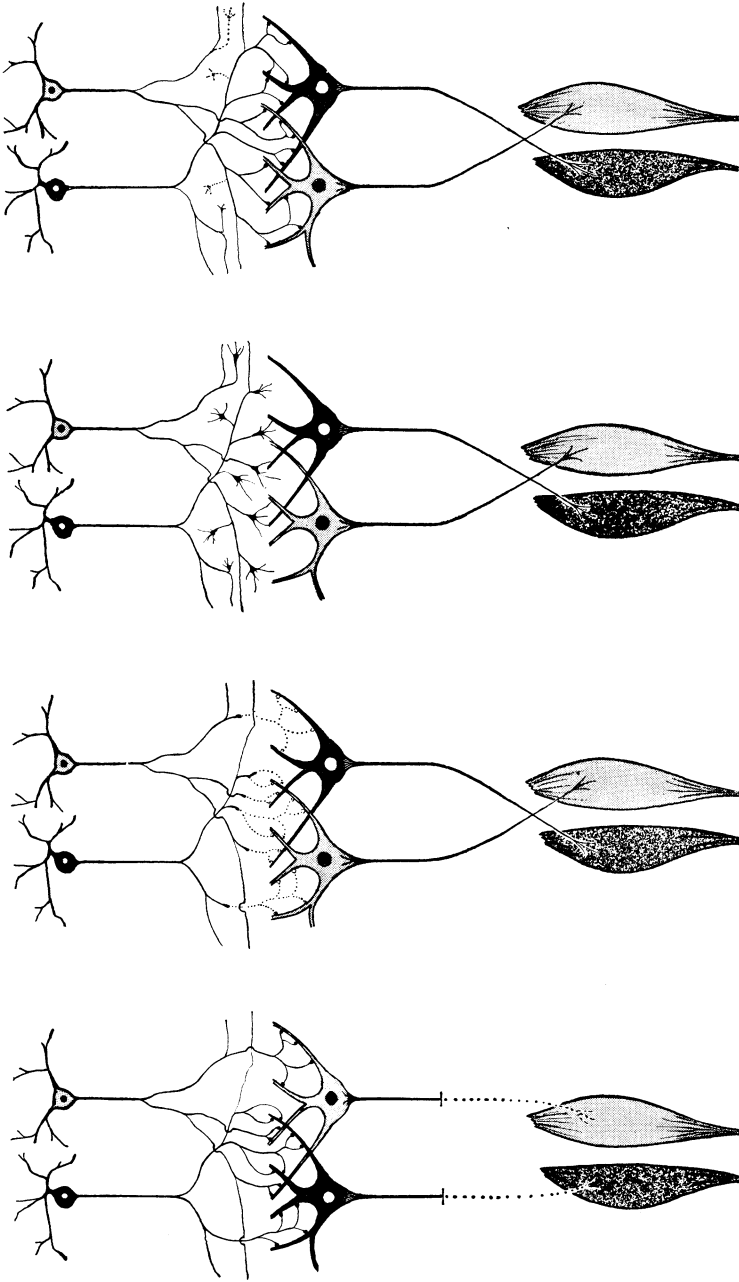

FIG. 17. Schematic representation of a possible connectionist explanation of the orderly recovery of muscle coordination that follows peripheral cross-up of nerve-muscle connections in amphibian larvae. The central synaptic associations are assumed to be established originally on a selective chemoaffinity basis. The specificity of the primary motor neurons is imposed by the musculature, and it changes when the nerves regenerate into foreign muscles, as shown by Weiss. This shift of chemical specificity is presumed to cause a breakdown of the original synaptic endings on the motor cells, followed by reestablishment of a new pattern of synaptic terminals determined by the new interneuronal affinities.

Motor reorganization of this kind occurs readily in the limbs of amphibian larvae. It goes more slowly during and shortly after metamorphosis (Weiss, 1936) and evidently does not occur at all in full-grown anurans. In the phylogenetically more ancient oculomotor system of amphibians the capacity for reorganization seems to be lost at a very early larval stage in both anurans and urodeles. Regeneration of the oculomotor nerve yields undifferentiated mass contraction similar to that obtained in mammals (Sperry, 1947*a*). Also cross innervation of the inferior oblique muscle by the nerve of the superior oblique muscle yields a reversal of wheel movements of the eye. The function of congenital supernumerary fingers in man (Weiss and Ruch, 1936) suggests that, if nerve rearrangements could be performed sufficiently early in mammals, results similar to those obtained in amphibian limbs might be demonstrated. In the rat the relations of the limb motor neurons has been found to be already irreversible at, or shortly after, birth (Sperry, 1941). The newborn opossum has yet to be investigated in this respect. Where adjustment fails to occur, it may be attributed to the fact that either the motor neurons in postembryonic and postlarval stages are no longer subject to respecification, or else that such respecification no longer causes a breakdown in the existing synapses.

Apparently the cranial motor nuclei III, IV, and VI undergo self-specification prior to the formation of peripheral connections, and the outgrowing axons, unlike those in the amphibian spinal system, take special courses to terminate in specific premuscle masses. Evolutionary refinement in the developmental process may verge in the higher vertebrates toward a similar arrangement in the spinal system as well. Motor axons added after establishment of the pioneer connections might follow previously specified fibers to specific muscles. These, however, remain matters for further investigation.

Tectobulbar and Tectospinal Linkages

The foregoing has not ruled out the possibility that the adjustment of synaptic relations deeper within the centers, i.e. among the second- and higher-order neurons, might be subject to a rather different sort of regulation. Independence of the learning factor, at least, is indicated in data mentioned above on the development of visual reflexes following prefunctional rotation of the eyes, development of vestibulo-ocular responses in the absence of the optic nerve, development of limb coordination following prefunctional transplantation of the limb buds, and also in studies on the development of the swimming pattern under anesthesia (Carmichael, 1926; Harrison, 1904; Matthews and Detwiler, 1926). This kind of evidence, however, fails to eliminate the possibility that mechanical relations, along with a scheduled timing of neuron proliferation, differentiation, fiber outgrowth, and related phenomena, might be sufficient in themselves for the development of central organization, with no need for neuronal specification.

That the second-order neurons are, in fact, biochemically differentiated has been inferred already from the manner in which the primary sensory and motor synapses are formed. More direct evidence of the existence of qualitative specification among the association cells, and of its regulative role in the establishment of their synaptic associations, has been found in experiments dealing with regeneration of the secondary neurons of the visual system (Sperry, 1948*a*). From the primary visual centers of the brain into which the optic fibers discharge, second- and higher-order neurons running mainly in the tectobulbar and tectospinal tracts transmit the impulses of vision to the motor systems of the bulb and spinal cord. The efferent synaptic relations that these higher-order neurons maintain with the bulbar and spinal systems must be selectively adjusted to suit the differential afferent relations of the cell bodies and dendrites in thalamus and midbrain. For the

attainment of proper function in development or in regeneration, the efferent synapses have to be established in a discriminative manner. Otherwise distortion and confusion would appear in the visuomotor coordinations.

When the brain of the adult water newt, *Triturus viridescens*, is transected posterior to the optic lobes, somewhat rostral to the

turns during the following weeks. At the end of approximately two months all the lost functions seem to have been restored in good order.

More than a dozen main fiber tracts are recognizable histologically at the level of transection (Herrick, 1936), and each of these has its own intrafascicular fiber differentiation. With conditions favoring an

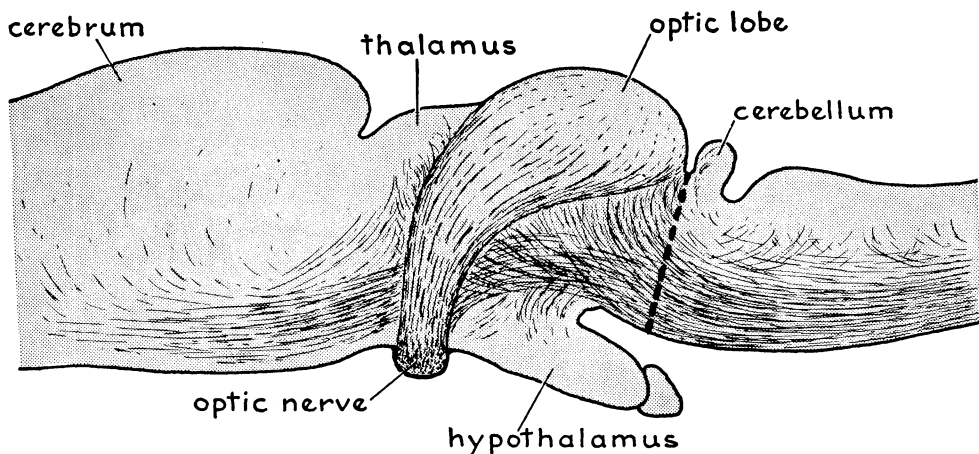

FIG. 18. Level of transection of the secondary central tracts mediating visuomotor coordination (from Sperry, 1948a). After transection of all the ascending and descending tracts that link the higher centers with spinal cord and medulla, regeneration leads to a systematic recovery of visuomotor and other coordinations, even though the eyes meanwhile have been rotated 180 degrees.

entrance of cranial nerve V and close to the level of the trochlear nuclei (Fig. 18), the tectobulbar and tectospinal tracts, plus the many other descending and ascending tracts passing through this level, are interrupted, with consequent functional defects including abolishment of all visual responses. In addition to being blind and anosmic, the animals are weak and deficient in purposeful direction of activity, and they also show abnormalities of posture, equilibrium, and coordination. Animals that manage to survive begin to show functional improvement during the third week. Optokinetic responses begin to reappear at approximately the end of the third week, and the ability to locate accurately small moving objects in space re-

enters during the following weeks. At the end of approximately two months all the lost functions seem to have been restored in good order.

More than a dozen main fiber tracts are recognizable histologically at the level of transection (Herrick, 1936), and each of these has its own intrafascicular fiber differentiation. With conditions favoring an

extreme jumbling and intermixing of fiber types in regeneration, the fact that the functional relations are nevertheless restored in orderly fashion points to the presence of specific regulative agents.

That the orderliness of recovery is not due to functional adaptation was shown by rotating the eyes on the optic axis 180 degrees in some of the animals during the period when the central tracts were regenerating. In such animals the visual responses upon recovery showed a systematic reversal in direction just like that produced by rotation of the eyes in animals otherwise normal.

With other possibilities eliminated we are forced to conclude that these higher-order

neurons, like the primary neurons, differ in character and form their synaptic associations selectively on the basis of constitutional specificities. Functional adaptation was not eliminated as a regulative factor in recovery of functions other than vision, but there is no reason for supposing that the other central fiber tracts that were transected re-established their synaptic associations in a manner entirely different from those subserving vision. Good functional recovery has also been reported to follow regeneration of the transected spinal cord in amphibian larvae (Lorente de Nó, 1921; and others) and in certain teleosts (Hooker, 1932; Tuge and Hanzawa, 1937). Although adaptation through function has not been ruled out in these cases, it appears likely that here also the adaptation mechanisms are developmental, not functional, in character.

Patterning of Complete Reflex Circuits

From the data relating to the separate systems of sensory, motor, and central neurons, it is possible to assemble a tentative working picture of the developmental organization of the entire sensori-neuro-motor pathway of a few reflex circuits. The myotatic reflexes are mediated by a "two-neuron arc" consisting of the proprioceptive and the primary motor neurons (Lloyd, 1946). Evidence regarding the acquisition of specificity and central connections has been presented for both these sets of neurons, and we need add only the temporal order of events. The motor cells first form their peripheral connections and then develop wide-spreading dendrites. The afferent neurons meanwhile attain their end-organ relations and send their central root fibers into the cord to form ascending and descending branches. Later these send off numerous collaterals into the neuropil, some of which contact directly the dendrites and cell bodies of the motor neurons. In forming synapses the afferent fibers of each muscle apparently exhibit a special predilection for those motor

neurons specified by the same muscle, and to a lesser extent for those of the most closely related muscles. This would seem to involve a simple affinity of like for like. Such simplicity in interneuron affinity is exceptional, however, and even in this case the same proprioceptive root fibers probably form connections on a different basis at other levels of the cord. Inhibitory associations also must be formed with antagonist motor neurons. Little can be said about the latter, however, in the absence of more information regarding the neural basis of reciprocal inhibition.

The cutaneous reflexes for withdrawal from irritating objects are more complicated, requiring at least one set of intracentral neurons (Lloyd, 1946). The number of distinct motor patterns employed in the localizing reflexes of the frog hind limb, for example, would require several specific classes of association neurons, each tending to activate a distinct combination of motor neurons. Specification of these association neurons must occur principally by self-differentiation. According to the usual order of development, the various classes of association cells probably form their selective relations with the motor neurons before the sensory connections are established. Neurons connected with different cutaneous regions presumably show a preference for specific types of association cells. The extent of functional variability would indicate that the neuronal affinities are not very strict and permit extensive overlap among the afferent terminations. Additional inhibitory associations must also be established among the inter-nuncial cells so that the ascendancy of one excitation pattern automatically inhibits all others.

The vestibulo-ocular reflexes for compensatory eye movements are mediated by a "three-neuron arc." Specification and synthesis of the sensory and motor neurons have already been discussed, and the existence of specificity among the association neurons located in the vestibular nuclei has been in-

ferred. The latter could be achieved by self-differentiation or, in part, through inductive effects from contact with the already differentiated motor ocular nuclei. In the former case the outgrowing axons from the vestibular nuclei would have to find their appropriate neurons in nuclei III, IV, and VI. Alternatively the association neurons might first establish their efferent relations in a more random fashion, with the final specification being induced by the motor nuclei.

Studies on the optic nerve, the secondary visual tracts, and the primary motor cells cover the main orders of neurons involved in optokinetic and other visual reflexes. Here also the developmental steps involve specification of the motor and sensory fibers under the influence of their end organs, plus a correlated but largely independent specification of the intracentral neurons. Connections are formed in the usual order first with the motor periphery, then between the central and motor cells, and finally the circuits are closed by ingrowth of the optic fibers. Without repetition of details, the evidence indicates that the synaptic junctions are formed in each case in a selective manner on the basis of interneuronal affinities. With regard to these as well as to the foregoing reflexes, only the most direct pathways have been considered. Alternative reflex routes often exist, and, according to Lorente de Nó (1933), the main reflex pathways have superimposed upon them local open and closed circuits. It is not difficult to visualize in a general way the serial organization of such accessory circuits through the subsequent spread of inductive effects after the main lines of differentiation have been laid down.

Not only the structural linkages but also the excitatory thresholds of the nerve cells must be properly adjusted. Little is known about the mechanisms controlling the latter. Apparently the different types of neurons and neuron groups acquire a characteristic resting threshold in the course of their differentiation. Shock phenomena suggest that

the excitatory thresholds must be adjusted in development to the number and type of synaptic endings present. Cutting off some of the afferent connections of a neuron raises its excitatory threshold. In the course of time the neuron then tends to regain its characteristic threshold in new equilibrium with whatever afferent influences remain. Extrinsic trophic as well as nerve-discharge effects from the connecting cells thus seem to be involved, along with intrinsic metabolic processes, in determining the neuron's basal excitatory state.

It is evident that the central organization even of the relatively simple reflex patterns can be discussed as yet only in a simplified and speculative manner. The few inquiries we have thus far made into the complex picture of the organization of central synaptic relations reveal something of the possible nature of the mechanisms involved, but they only begin to suggest the complications of actual detail.

OTHER PATTERNING FACTORS AND CERTAIN THEORETICAL CONCEPTS

Neurobiotaxis

The theory most widely supported as an explanation of the structuring of integrative patterns is Kappers' (1932) law of "neurobiotaxis." Electrical currents are presumed in this theory to play a dominant role in determining neuron relations. It is maintained (1) that the neuron is electrically polarized, (2) that axons grow out from the cell body along the direction of an electric current and dendrites against the current, (3) that the nerve cell bodies tend to migrate along with dendritic growth against the current, (4) that dendrites and axons tend to grow perpendicularly toward and away from a neighboring fiber tract, owing to the electrical field set up around the tract by the passage of impulses, and (5) that the collection of similar fibers into bundles and the selective

linkage of particular neurons are due to the timing of electrical discharges in the developing nervous system. A related hypothesis proposed by Bok (1915) under the term "stimulogenous fibrillation" likewise assumed that outgrowing nerve fibers are directed by electrical irradiation from stimulated fiber tracts and also from sensory surfaces and muscles. The present discussion concerns only those aspects related to fiber outgrowth and synaptic formation.

The cogent criticisms of Weiss (1941c) cast strong doubt on the whole idea that electrical fields can play any major role in patterning the neuronal relations of the developing embryo. There are numerous phenomena in nervous development and regeneration, as, for example, the simultaneous growth of fibers in the same locality in different directions (Speidel, 1933), that are incompatible with the contention that the direction of fiber growth is electrically determined. Even some of the original observations on which the electrical theories were largely based have now been discredited (Hamburger, 1946; Windle, 1933). The report of a weak influence of electric current on nerve growth *in vitro* (Marsh and Beams, 1946) leaves open the possibility that certain aspects of the theory of neurobiotaxis may yet find verification. These, however, seem to have very limited explanatory value with reference to the patterning of functional interconnections.

Kappers himself was well aware that the postulated stimulo-concurrent character of axons and stimulopetal character of dendrites was not sufficient, *per se*, even in theory to account for the selective formation of inter-neuronal connections. To explain selective synapses he had to invoke the additional factor of timing. It is the differential timing of discharges in the developing nervous system that is supposed to cause selective linkage of particular neuron combinations. Connections form between neurons that happen to be excited simultaneously or in

immediate succession. Thus the selective timing of neuron discharge is reasoned in circular fashion to cause the growth of selective structural relations on which is supposed to depend the selective timing of neuron discharge.

Any attempt to apply such a scheme to concrete cases leads to obvious and insurmountable difficulties. In the case of the retino-central connections it would be necessary to suppose that every animal of a species encounters exactly the same temporal and spatial pattern of retinal stimulation in the course of its development. Furthermore the light stimuli in each individual would have to be met in a schedule adjusted to the growth of the central dendrites with a precision utterly beyond the bounds of probability. Finally there is good evidence that the orderly projection of the retina upon the brain centers will develop even in complete darkness (Goodman, 1932; Hebb, 1937).

Recourse at this point to spontaneous retinal discharge is of no help, because the equally precise and systematic timing of the implicit discharges would then have to be accounted for. Assuming either implicit or overt discharges to be formative factors in the foregoing manner, it becomes necessary to suppose further that, once the various neurons have established their connections, they cease to discharge thereafter; otherwise they would continue to attract the growing fiber tips of all neurons developing subsequently, the terminals of which should be formed elsewhere. These and other difficulties discourage any attempt to make the concept of neurobiotaxis a primary formative factor in the ontogenetic patterning of synaptic associations. That something akin to neurobiotaxis may be involved in the learning process of the developed nervous system cannot be denied at this time in the face of our ignorance of the neural basis of learning. The speculative nature of any such contention should, however, be recognized.

Disuse Atrophy and Trophic Interdependence

The outgrowth of an excessive number of nerve fibers in development and in regeneration followed by atrophy and degeneration of those that fail to acquire terminal connections has been described by Cajal (1928, 1929) and others. The destruction of unconnected neurons and fiber branches is much slower in peripheral nerves than in the centers and is said to require months and perhaps years in the adult mammal. In the centers the process may occur within a few days. This phenomenon has been referred to by Cajal as the "law of utilitarian atrophy" or "atrophy of disuse."

That it is the "use" or discharge of the fibers that determines their survival, as might be inferred from the name, appears unlikely. In the first place the impulses of an axon, so far as is known, are conducted over those collaterals that are not terminally connected, as well as over those that are. Furthermore there are a number of instances in which the survival of neurons and end organs is known to depend upon the existence of adequate connections under conditions where the passage of excitations is clearly not the essential factor. For example, the degeneration of taste buds and of other sensory endings after severance of their nerve supply, the retrograde degeneration of motor horn cells in young mammals after destruction of their peripheral connections, and the retrograde degeneration of thalamic neurons after cortical lesions can hardly be attributed to lack of excitation, because ample sources of excitation under these conditions remain undisturbed. The functional relations are reversed in so-called "transneuronal" effects such as degeneration of the lateral geniculate nucleus after section of the optic nerve, degeneration in the red nucleus after section of the brachium conjunctivum, and degeneration of striated muscles after section of their somatic motor nerves. With regard to such phenomena also, however, there is evidence that the primary cause of degeneration is not the lack of excitation.

The responsible factor seems to be some kind of trophic, metabolic, chemical, or physical influence of these connections upon the nerve cells and their end organs. Apparently there is a general tendency for the elements of the sensori-neuro-motor system to become dependent in varying degree upon the linkages that they normally acquire. Accordingly some term such as "trophic degeneration" or "isolation atrophy" would seem more suitable for this class of phenomena.

To some extent the trophic interdependencies of neurons and end organs may be selective in character, as where motor fibers (Arey, 1941) or the sensory fibers of general sensibility fail to maintain taste buds in the tongue of mammals, or to maintain either taste buds or lateral-line organs in the skin of the catfish (Bailey, 1937). In other situations, however, there is considerable leeway in this respect, as where the same sensory fibers in the duck have been shown by skin transplantation to be capable of maintaining either the corpuscles of Gandry or the corpuscles of Herbst (Dijkstra, 1933).

In addition to the various phenomena of retrograde and of transneuronal chromatolysis, atrophy, and degeneration, there are certain other indications that linkages have a profound influence upon the general status of the neuron. The formation of terminal connections appears to act as an impetus to the differentiation of the embryonic neurons (Hamburger and Keefe, 1944). Terminal connections are also important in a selective manner for the attainment of normal fiber diameter (Aitken, Sharman, and Young, 1947; Weiss, Edds, and Cavanaugh, 1945). Acquisition of connections tends to bring about a state of equilibrium in the neuron, with cessation of further growth. Growing fibers are inclined to adhere to and to follow in a preferential manner other fibers that have succeeded in forming connections (Weiss, 1941c) as if there occurred a change in the surface of the connected fibers that distinguishes them from fibers still unconnected. Perhaps most important from the

point of view of the present discussion is the evidence already elaborated that the terminal cells and tissues may induce specification of neurons and thereby influence their central synopsis.

The fact that any fiber branches at all should remain unconnected in the organism deserves comment because, no matter where excess fibers may stray, there are always cells of some sort in the vicinity with which connections might be established as far as mechanical accessibility is concerned. That connections are, nevertheless, not always made indicates in itself a degree of chemical selectivity in neuron termination. The saturation and denervation effects discussed below are closely related phenomena.

It is conceivable that some kind of elimination of excess and maladaptive fiber connections is achieved on an essentially functional rather than on a trophic basis in the learning process in the developed nervous system. Unlike the foregoing growth and trophic phenomena, however, this has no direct observational foundation.

"Individuation versus Integration"

Influenced by certain Gestalt concepts in vogue at the time, Coghill (1929, 1930a) emphasized features of the development of behavior patterns that seemed to illustrate the application of Gestalt principles in this field. From his classical studies on the development of the nervous system and behavior in urodele larvae Coghill inferred that discrete responses always emerge out of larger patterns by a process of individuation. The organization of the larger, "total" behavior patterns he considered to be primary, not a secondary effect arising through integration of partial patterns. In studies of embryonic and fetal behavior much concern has been given ever since to the confirmation or refutation of this idea. Windle (1944) accepts Coghill's conclusions for salamanders but not for mammals, in which he has found discrete reflex responses appear-

ing very early, with no prior mass movement or total pattern stage.

Coghill's conclusions in this regard were drawn primarily from behavioral evidence, although he was able to support the concept by certain anatomical correlations. The latter, however, were based largely on the diffuse outgrowth of the peculiar primary motor system of *Amblystoma*, which can hardly be considered typical of the organization of behavior patterns for higher vertebrates or even for succeeding developmental stages of *Amblystoma*. Precise anatomical correlates are not so easy to observe in higher vertebrates or in the later stages of urodele development, and accordingly most of the evidence from these sources is behavioral. What behavioral observations may mean regarding the nature of the underlying mechanisms is often difficult to infer. Individuation of behavior might conceivably be achieved in a variety of ways, as, for example, by the selective elimination or the addition of fiber collaterals, by the elimination or addition of entire neurons, by the selective reinforcement or the weakening of synapses already present, by the selective adjustment of excitatory thresholds, by the selective sensitization of neurons to each other, etc. On the other hand, the specificity of initial reactions need not necessarily imply absence of individuation from a "total pattern." It could mean merely that neural individuation is completed before the onset of function rather than after. Correlations between behavior and the developmental processes that produce the structure that mediates the behavior must frequently be rather remote.

When we consider the complicated developmental mechanisms involved in the patterning of interneuronal relations, "individuation versus integration" tends to fade as a crucial issue. As far as the evidence goes, there is nothing intrinsic to the nature of the developmental processes that would prevent the initial establishment of specialized, discrete functional relations. Also it is

clear that the development of "total" behavior patterns, particularly in the higher vertebrates, is dependent upon an array of developmental events occurring at all levels of the nervous system as well as in the periphery, many of which are widely separated and regulated quite independently of one another.

Myelination and Function

The addition of myelin to nerve fibers probably has little or no direct influence upon the formation of proper reflex connections. It deserves mention, however, as a conspicuous feature in the development and maturation of the nervous system and as an indicator of the order in which various systems become functional. The central nervous tracts tend to become myelinated in a definite sequence that shows considerable constancy in all mammals and follows roughly the order in which the tracts were developed phylogenetically (Langworthy, 1933). A general correlation between the order of the appearance of stainable myelin and the order in which the nerves become functional has suggested a causal relation. The relation, however, is not simple, and it appears to be reciprocal in nature.

It has been shown by Langworthy that fairly complex activity can be carried out prior to myelination. On the other hand, functions in general show considerable improvement in speed, strength, steadiness, and precision coincident with the laying down of myelin. However, it is not entirely a matter of myelination acting to improve function, because, conversely, the laying down of myelin is stimulated and accelerated by function. At the same time absence of normal function does not prevent or decrease the ultimate degree of myelination (Romanes, 1947). Myelination and the order of its occurrence would seem thus to be an inherently predetermined process capable of proceeding in the absence of function in the usual sense. Function when present, however, stimulates and accelerates myelination,

which in turn appears to act reciprocally to improve function. It cannot be said to what extent the apparent myelination-function interrelation is directly dependent upon these factors, *per se*, and to what extent upon other maturational processes that may be going on simultaneously.

Flux in Neuronal Associations

Studies of the details of nerve termination in the tail of the frog tadpole (Speidel, 1940-41), in the cutaneous plexus of the ear of the rabbit, and in human skin, particularly where it is subject to frequent stretching and abrasion (Weddell and Glees, 1942), support earlier contentions that the peripheral connections are not stable but are in a continuous state of flux with degenerative and regenerative changes commonly taking place among the terminal arborizations.

Speidel suggests that a similar state of flux probably characterizes the synaptic terminals in the centers.

With constant readjustment of this sort taking place, there must exist continuous opportunity for the establishment of atypical connections. In the skin, for example, there should be ample opportunity for temperature fibers to terminate in tactile "spots," and vice versa. There should be even greater chance for the formation of abnormal terminations in the closely packed central nuclei. That the general pattern of neuronal termination does not become severely disarranged by these changes means that there must be persistent influences acting to maintain the proper relations.

It is not just a matter of the regenerating fibers' being guided back along their previous pathways to the former terminals. Speidel (1940-41) states that the regenerated pattern distal to the neurilemma sheaths bears no specific resemblance to the original pattern. Weddell and Glees (1942) describe dichotomy in regenerating fibers indicative of new collaterals, and the sprouting of new collaterals into neighboring denervated areas is well authenticated (Wed-

dell, Guttman, and Gutmann, 1941). Apparently the same type of selective force that determines the original pattern of connections in development continues to be effective in maintaining the general pattern after it is formed. The range of possible terminations of each neuron may be restricted by its constitution and by its affinities for the various cell types within its terminal area. This would permit some variability to occur in the terminations of individual fibers but would keep constant the overall pattern of termination.

Selective Fasciculation

During the outgrowth of fibers from spinal cord grafts into nearby grafted limbs (Weiss, 1941c) those pioneer fibers that first become attached to the limb acquire thereby some property that converts them into a preferential contact pathway for later fibers. Subsequent fibers adhere to earlier fibers that have made terminations in preference to fibers that have not. Axon fibers of supernumerary Mauthner's cells, the giant neuron of the fish brain, exhibit a marked tendency to follow the original Mauthner's fibers (Oppenheimer, 1942). Also, grafted ectopic cranial nerve roots tend to enter the brain at the same level as the corresponding host nerves to which they become adherent (Piatt, 1947). Experimental observations of this sort, plus the fact that nerve fibers of similar type tend normally to collect together in separate fascicles in the neuraxis and to some extent in the peripheral nerves, indicate that outgrowing nerve fibers adhere selectively to other fibers of their own kind, for which Weiss (1941c) has suggested the term "selective fasciculation."

As new fibers are added to the spinal nerves during growth, the outgrowing motor fibers apparently turn into muscular branches at each bifurcation, whereas cutaneous fibers avoid muscular branches and turn into cutaneous pathways (Taylor, 1944). Something must prevent the motor fibers from following cutaneous branches,

and vice versa. Moreover both motor and sensory fibers distribute themselves in proper proportions to their respective peripheries. Something, therefore, must prevent the motor fibers from all turning into the same motor channels, leaving other branches undersized. A tendency for fibers to stick selectively to preceding pioneer fibers of their own kind would conceivably help to account for this proportionate distribution of new fibers.

Saturation and Denervation Effects on Fiber Termination

Under normal conditions nerve endings tend to be limited to a characteristic density, even in situations where it is clear that many more terminations could be established were it merely a matter of space and numbers of available fibers. In muscle, for example, the nerve terminations are distributed in a strictly limited manner to the individual muscle fibers and spindles. One may well ask why some muscle fibers do not get several dozen axon terminals, others half that many, and some none. Similarly in the skin the nerve endings tend to be scattered evenly. The same is true of some of the central nuclei. In the lateral geniculate nucleus, for example, the telodendria of the optic axons are distributed evenly, with a characteristic number of endings on each geniculate cell.

One of the reasons advanced to explain the fact that neurons and end organs do not become smothered with nerve terminals beyond a characteristic limit is that nerve connections cause a reaction in the cells of termination that makes these cells impervious to the advances of additional fibers (Harrison, 1910; Weiss, 1941c). When the saturation point, which varies for different cells and tissues, is reached, conditions become unfavorable for further fiber growth and termination. The situation has been compared to that of the fertilization of eggs in which the penetration of the first spermatozoon causes a reaction in the egg cell, pre-

venting the entrance of more sperm. Some experimental evidence for this has been found in the innervation of muscles and of whole limbs (Fort, 1940; Litwiller, 1938). The fact that some fibers in central tracts terminate abruptly in nearby centers while others push on to much more distant regions might be due in part to the successive saturation of the various areas. The additional possibility must be considered that, in the centers, neurons may reach a saturation point for certain types of synapses while still accepting others.

The opposite phenomenon has also been observed, namely, a stimulative effect of denervated areas on nerve fiber outgrowth (Speidel, 1940-41; Weddell, Guttmann, and Gutmann, 1941). Fort (1940) found that motor nerve fibers grow out faster in denervated muscle than in innervated muscle, and that, the longer the muscle is denervated, the faster the outgrowth within the time limits he investigated. Geohegan and Aidar (1942) report experiments suggesting that partial denervation of the sympathetic ganglia causes the growth within the ganglia of collaterals from the remaining intact fibers to supply the denervated cells. However, in this case it is difficult to be sure how much the effect may be due merely to hypersensitivity of the denervated neurons.

Central Self-Differentiation of Coordination Patterns

The central patterns of coordination develop with considerable independence of connections with the sensory periphery. In the early stages of differentiation the motor system, as a rule, achieves a precocious organization of its own so that spontaneous or central excitations lead to coordinated motor responses before any sensory connections have been established (Coghill, 1929; Herrick, 1939; Windle, 1944; and others). It has also been shown that coordinated limb movement develops after prefunctional excision of the sensory nerve supply of the limb itself (Weiss, 1941*d*; Taylor, 1944).

To this extent and to the degree that developmental organization does not depend on experience, central patterning seems to be independent of peripheral influences.

The foregoing, along with data on the autonomous nature of functional organization in the centers has led in some instances to special emphasis on the extent to which the basic patterns of coordination undergo an autonomous central self-differentiation. However, the synaptic relations of the primary sensory and motor neurons form an important part of the central pattern. If formation of these primary synaptic associations is governed by inductive effects from the periphery, then our conception of the extent to which coordination patterns undergo central self-differentiation must be adjusted accordingly. It has not yet been possible to demonstrate the development of functional organization in the nerve centers in the absence of connections on the motor side. Thus the possibility that inductive effects from the motor endings play a role in regulating the formation of neuronal interconnections in the centers has not been excluded. Nor can it be said that the present evidence completely eliminates the possibility that the ingrowth of sensory root fibers into their various central nuclei has some influence on the differentiation therein of functional relations. It has been found, for instance, that aberrant VIII and lateral-line root fibers will induce the differentiation of supernumerary Mauthner's cells in atypical sites where they enter the brain (Piatt, 1947).

Even with such allowances, however, the role of central self-differentiation in the development of coordination patterns still deserves emphasis. The differentiation or specification of the secondary and especially of the higher-order neurons and the consequent patterns of interrelations that they form must depend principally on formative agents within the centers. Differences in the inherent behavior patterns of different vertebrate species from the level of complex in-

stinets down to that of polysynaptic reflex responses must for the most part be attributed to central and not to peripheral influences. In earlier discussions of the chemoaffinity hypothesis (Sperry, 1943c) the induction of central organization starting from the periphery and working inward has certainly been overemphasized.

In nuclear fields like the optic tectum or the striate cortex in which the functional differentiation is correlated with anatomical dimensions in a gradient, field fashion, a basic self-differentiation of the nucleus is indicated. There are many nuclei of this type that may, along with the peripheral structures, be looked upon as foci of primary self-differentiation. On the other hand, there are central nuclei, such as the spinal association centers and the reticular areas of the brain stem, in which neurons of similar functional type appear to be scattered in a more diffuse manner among other neurons of diverse functions. In such regions it is possible that specification is more dependent upon terminal contacts, as with the limb motor neurons. Neuron specification may thus arise from intrinsic self-differentiation or from extrinsic inductive actions. The latter may sometimes be effected over considerable distances through axon and dendrite contacts. Both types of specification are probably involved in varying degree in many nuclei.

Functional Reinforcement of Adaptive Patterns

It has been a common conception that synaptic linkages are adjusted in development on the basis of functional adaptiveness. Usually it has been supposed that synaptic associations are laid down initially in a diffuse, excessive, and fortuitous fashion, after which there occurs a selective reinforcement of the adaptive linkages with atrophy and degeneration of the maladaptive linkages. In the learning process in the mature animal, some kind of selective retention on the basis of functional effects does take place, of

course, and it has been an easy step to infer its occurrence in development also.

In most vertebrates, however, up to and including the lower mammals (Sperry, 1945c), the learning capacity, after it has reached its peak in the adult, is still unable to effect any rearrangement of the basic integrative structure of the nervous system. Even in the primates learning appears to be largely cerebral. It effects no changes in the inter-neuronal relations of cord and brain stem (Sperry, 1947c). To assume that the elementary integrative relations are organized in the first place through function is thus to assume that the nervous system in its imperfect, immature condition, and under circumstances unfavorable in many respects for functional adjustment, is able to handle a type of learning of which it is incapable later on.

It is conceivable, in this regard, that neural tissue might be more plastic in the developmental stages. Learning and growth together might, through a series of irreversible steps, produce integrative structures that, when completed, would no longer be subject to functional reorganization. However, the learning capacity of the nervous system is much more than a mere passive plasticity of a highly impressionable tissue. It is more comparable to the active functional ability of a complex machine. The self-regulative, operational organization of the nervous system, not just the character of its protoplasm, is what enables it to utilize its experience selectively to improve upon its own structure. Complex self-regulative mechanisms must first be constructed in ontogeny before adaptation by learning can begin to take place.

The selectivity of learning is difficult to account for in early development. The fact that not all excitation patterns, but only the adaptive ones, reinforce themselves must be explained. Some background of organization must be present for different excitation patterns to have different reinforcement value. Otherwise all reactions would

tend to reinforce themselves indiscriminately. The establishment of a central organization capable of distinguishing adaptive from nonadaptive excitation patterns must therefore logically precede any selective adjustment on the basis of functional effects.

The point in nervous development at which sufficient organization is attained to permit selective reinforcement on the basis of functional adequacy might conceivably be an early one, but the evidence indicates not. In mammals it is doubtful if any appreciable patterning of synaptic associations is achieved by function before the cerebral cortex has become differentiated and has established its subcortical connections. As this is one of the last steps of nervous development, it may be concluded that the bulk of the nervous system must be patterned without the aid of functional adjustment. From the developmental and anatomical point of view, the synaptic modifications that are later imposed by the learning process constitute a rather minute refinement in the nervous structure, so inconspicuous, in fact, that the exact location and even the nature of these learned adjustments still await demonstration.

The foregoing concerns function as a patterning factor in the organization of neuronal connections and does not apply to function as a general condition necessary to healthy growth. Development in many instances, however, is remarkably independent of function, even in this latter sense. The experiments of Harrison (1904) and others demonstrate the orderly formation of the amphibian nervous system well through the swimming stage under deep anesthesia. It is the positive toxic effects of the anesthesia, presumably, rather than the absence of function per se that prevents development from proceeding much farther under these conditions. Rabbits reared to the age of six months in complete darkness have been found to have neither gross nor histological defects detectable anywhere in the visual system, including the cortical projection area

(Goodman, 1932). A general tendency is evident in other organ systems, as well as in the nervous system, for development to be independent of function and to anticipate the needs of function. But function sometimes becomes a necessary element later on, after it has once started.

The stage at which function becomes a formative factor and its relative importance in neurogenesis obviously varies greatly in different species. Function plays its paramount role in the postnatal development of man. Where for a long period both function and maturation are operative together, the contributions of each to the final structure become interrelated in complex manner. In attempting to interpret the defective development of vision in chimpanzees reared in the dark from birth (Riesen, 1947), for example, it is extremely difficult to untangle the relative roles played by the three different factors: inherent maturation, function as a specific organizing agent, and function as a nonformative but necessary condition. One would hardly expect the lack of light in these cases to cause disorderly development of the cortical projection of the retinal field. However, retinal degeneration and inability to respond normally to light for almost a month have been observed in fish kept in the dark for more than two years (Breder and Rasquin, 1947; Ogneff, 1911). In certain cave salamanders, the larval eyes of which normally undergo regression at metamorphosis, the eyes will become quite normal if the larvae grow to adulthood in the light (Walls, 1942).

Finally it is usually impossible to assess the relative importance of maturation and of learning with reference to behavior, because most behavior depends upon a combination of neural structures, of which some may be inherently organized and others organized by experience. The issues are considerably clarified by restricting the problem to the organization of the neural structure itself. In this case the patterning of certain parts can be ascribed entirely to inherent growth

forces, whereas in others the learning factor may be involved in varying degree.

Hormones and Maturation

In infraprimate mammals and especially in lower vertebrates it is evident that many of the reactions associated with reproduction, such as nest building, mating, and giving birth to, feeding, and caring for the young are largely inherent in character. The maturation of these particular reaction patterns, some of them extremely elaborate, is of especial interest because they appear so late in life and because their appearance is correlated with the perfusion of the nervous system with specific chemical agents. Similarly in the metamorphosis of anuran amphibians there occurs a relatively late maturation of a whole series of new behavior patterns dependent in part, at least, upon hormonal action.

A precocious localized maturation of the lid-closure reflex has been induced in frog tadpoles (Kollros, 1942) by implanting thyroid pellets into the hindbrain. Other lines of evidence suggest that the reproductive hormones likewise may act directly and selectively upon the nerve centers (Beach, 1947). There is also considerable specificity in the behavioral effects of the male and female hormones. This selective response of particular neural mechanisms to biochemical agents represents another indication of chemical differentiation within the centers. To it may be added a host of related phenomena involving selective susceptibility of different neuron types to the action of various drugs, toxins, histological stains, metals, viruses, bacteria, etc.

The exact manner in which hormones act on the centers is not known. It is fairly certain with regard to the sex reactions of many mammals, at least, that the patterns of nerve cells involved are well differentiated and their functional relations basically arranged early in development, long before the increased concentration of hormone brings the mechanism into functional ma-

turity (Beach, 1947). It is usually assumed that the hormone influences the excitation threshold of specific patterns of neurons, the structural relations of which remain fixed. However, in view of Speidel's (1940-41) suggestions regarding the lability of central associations, and in view of the duration of the latent period between the onset of hormone administration and its effect on behavior, it is possible that growth and readjustment of synaptic relations may also be involved.

Neurogenesis and Specific Nerve Energies

The experiments on synaptic development and regeneration have here been interpreted entirely on a connectionist basis. This discussion has been presented in terms of the classical assumption that the integrative action of the nervous system is dependent upon refined selectivity among neuronal linkages. However, there has arisen of late a good deal of skepticism concerning this traditional connectionist theory (Bethe, 1931; Gerard, 1941; Goldstein, 1939; Koffka, 1935; Köhler, 1940; Lashley, 1942; Weiss, 1936, 1941*d*, etc.). Accordingly it should be stressed that there is as yet no final proof that neuron specificities determine the growth of anatomical relations. In regeneration of the optic nerve, for example, it has not been directly observed that fibers from different retinal quadrants form different central connections. This is still inferential, and at least one other interpretation is theoretically possible; i.e. it is conceivable that the central connections are laid down in a profuse and random fashion and that the subsequent specificity of response derives from some sort of specificity in the nature of the impulses carried by the different fiber types.

At the turn of the century Hering (1913) argued in favor of the existence of qualitative specificity among the excitatory energies conducted by different types of nerve fibers. It was his contention that the pattern of the central pathways excited was determined not merely by the existing anatomical connec-

tions and their threshold phenomena but also by selective sensitivity of central neurons to specific types of afferent energies. He believed that the individual nerve impulses differed intrinsically in their physicochemical properties. As an alternative he mentioned that the specificity might also reside in frequency differences, in which case the specific energies of the nerve fibers would appear as special resonance capacities and the central patterns would be determined by selective attunement of the various neuron types to different frequencies (see also Head, 1920). Later, similar concepts were invoked (Weiss, 1928, 1936, 1941*d*) as a possible explanation of homologous response in supernumerary amphibian limbs. The "homologous" or "myotypic" action of muscles atypically innervated seemed to rule out specific anatomical connections on the part of the motor neurons and to indicate instead a selective physiological sensitivity to specific excitatory agents, one for each muscle, within the limb centers.

All our experiments on the formation of synaptic associations could be interpreted on a similar physiological basis rather than in terms of the growth of specific anatomical connections. Discussion of this alternative possibility has been purposely postponed until now in order to avoid confusion and repetition. Once the connectionist explanation is clear, it becomes a relatively easy step—should future findings necessitate it—to translate the results and conclusions into terms of specific nerve energy or resonance phenomena. The connectionist interpretation is emphasized at present only because the great mass of neurological data fall more readily into this traditional scheme. Furthermore, with a connectionist explanation of homologous response now available, the original reasons for resorting to a resonance hypothesis have been largely removed.

For the sake of completeness mention should be made of another possible basis of interpretation. It is conceivable (Sperry, 1943*c*) that neurons might regularly form

and maintain an excess of connections, but that only a selective minority of the synapses ever become functional. The interneuronal affinities might affect the structure of the synapses to make certain ones capable of transmitting excitations and others not. Functional specificity would still depend on selective anatomical associations rather than on resonance phenomena or specific nerve energies, but only minute differences in synaptic structure would be involved instead of complete presence or absence of synapses.

SUMMARY

A survey of the evidence supports the thesis that the inherent patterning of neuronal linkages is achieved by embryonic processes similar to those responsible for the grosser phases of neurogenesis and for the development of other organ systems. Among these developmental processes those of embryonic differentiation, determination, and induction deserve special mention. In the genetic structuring of the integrative circuits developmental forces reach their peak of refinement and complexity.

Just as the cells of the early embryo differentiate into a variety of strains to form the diverse tissues of the adult body, so the cells of the nervous system undergo a similar, though more subtle, differentiation among themselves into a multitude of neuron types. Not only the nervous system but the associated peripheral tissues as well, the musculature and its tendons, the dermis, the fascias, the ligaments, the periosteum, the retina, the cochlea, etc., are subject to a refined qualitative differentiation or specification far beyond what is visibly manifest.

After the prospective nervous tissue has become differentiated from other tissues and has formed the neural tube, the basal or motor portion of the tube differentiates from the sensory or alar portion and the gross cephalic regions become distinct—this and the following by way of illustration and without regard for the exact order of these

events. An eye field emerges in the diencephalic region, and in the spinal cord a brachial and a hind-limb field are differentiated. The main subdivisions of the brain begin to take form, and more localized foci of differentiation subdivide these into their major nuclear fields. By transplantation methods it can be demonstrated that these various local fields differ from each other in their constitutional properties.

Differentiation continues until in many nuclei it approaches the level of the individual nerve cell. For example, in the optic field of the midbrain the cells in any given locus differ from those in all other loci. The nearer together the neurons, the more alike they remain in constitution, but even neighboring cells may differ to some extent, depending upon the steepness of the differentiation gradient across the nucleus. The development of Mauthner's neuron in the medulla illustrates an extreme example in which a single nerve cell consistently differentiates in visible manner from among its fellows to acquire specific structural and functional characteristics.

This refined specification of the neurons makes possible the formation of selective synaptic linkages on the basis of a chemoaffinity. By virtue of their specification the advancing tips of growing nerve fibers form synapses only with particular ones of the various kinds of neurons they encounter in their outgrowth. The formation of precisely designed integrative circuits thus becomes possible without the aid of functional adjustment. Synapses may be neatly arranged even in regions that appear under the microscope to be only disorderly tangles of axons, dendrites, and cell bodies. The chemical interrelations of the nerve cells must be extremely complicated. This is doubly true where axons maintain inhibitory linkages in addition to their excitatory synapses. According to the chemoaffinity principle a neuron could not maintain dissimilar axon linkages on the two sides of the midsagittal plane, in the absence of a left-right specification of

corresponding cells on each side. In the few examples studied, including neurons of the optic tract, the tectobulbar tract, and the dorsal roots, the fibers seem to form with equal readiness the same pattern of synaptic associations on either side of the midline. A left-right selectivity, especially among the commissural neurons, however, has not been excluded and is not inconceivable.

The induction of cell differentiation through contact with other cells and tissues, common throughout development, takes on a special aspect in the nervous system. Owing to the tremendous elongation of the neuron processes, induction effects may occur over long distances between widely separated cells. It becomes possible for a group of neurons to be similarly specified through similar termination even though their cell bodies are scattered diffusely among other neurons of diverse character. Neuronal differentiation thus tends to be released from some of the limitations of topography that apply to the development of other organs. Much greater diversity and refinement is possible than where induction depends upon immediate contact of the cell bodies themselves.

It has been emphasized that these qualitative specificities operate in conjunction with many other factors, and the combined action of all of them determines the final pattern. The unquestioned importance of stereotropism and of topographic and chronological relations must be taken for granted throughout. Certain other formative factors such as trophic dependencies, saturation and denervation effects, excitatory threshold adjustment, etc., are also involved, but as yet they are little understood.

Some of the salient features in the patterning of certain elementary integrative circuits are considered as far as the experimental evidence permits. These concrete examples illustrate the manner in which developmental mechanisms may operate without the aid of function to insure precise

neuronal connections. Proper peripheral-central linkages, for example, are assured in many instances by having the central connections dependent upon specificity induced in the nerve fibers by their end organs.

Judging from the variation in other aspects of development among different species of vertebrates, we would hardly expect the details of these processes, as observed in the amphibians, to be maintained throughout the vertebrate series. The general plan of development and the general nature of the maturational mechanisms involved, however, presumably are not subject to any abrupt or radical modification in phylogeny.

The foregoing has been concerned almost exclusively with the development and maturation of the integrative *structure* of the nervous system. The broader problem of the maturation of *behavior* with its corollary problems regarding the relation between neural structure and function have been avoided.

Our repeated reference to the role of anatomical connections in shaping response patterns need not lead to an exaggeration of the importance of this factor relative to others. Dependence of orderly function upon the neural architecture by no means excludes dependence upon other factors. The fluctuating patterns of facilitation and inhibition, which are continually playing through the anatomical structure, constantly condition in varying degree the character of the response. Particularly with respect to the temporal organization of behavior over increasing periods of time, the regulative role of these dynamic factors rapidly increases in interest and importance. Caution is also necessary with regard to implications concerning the nature and specificity of synaptic connections. For the most part it is possible merely to infer that the qualitative specification of neurons is closely correlated with differences in their synaptic associations. Little can be said concerning the exact nature of these synaptic differences.

Ontogenetic Development

LEONARD CARMICHAEL

Tufts College

In this chapter we shall consider the changes in behavior that take place during the early growth of the individual.

Maturation Affects Behavior

Emphasis is given here to "maturation" — to the growth changes in those aspects of activity that involve the adjustment of the living organism to its environment. Howells (1945) has said: "‘Maturation’ is simply development in which commonly observed differences between individuals are correlated with previous differences in the inner organism rather than in the environment."

It should be remembered that maturation is a name for many different growth processes. Maturation does not *cause* the changes that take place as organisms grow older. Rather the term properly designates the varied growth processes that produce the observed changes in organisms as time passes. The question then arises: what criteria can be used to distinguish the changes in behavior attributable to *maturation* from the changes attributable to learning?

If a given type of behavior develops universally in all or nearly all apparently normal organisms of similar physiological make-up, it may usually be thought of as due to growth rather than to individual learning. But exceptions to this criterion will at once occur to the reader. For example, certain habits of response, such as the behavior of the arm in carrying food to the mouth, are in part learned. They are learned alike by

a child in New York City and by a child in the jungles of New Guinea. Some parts of many reactions may be made up of acquired habits, even though the reactions may be universal in all normal members of a species. Some years ago Smith and Guthrie (1921) coined the word "coenotropes" for such common habits.

Some responses occur through maturation without ever becoming universal, for there are inborn or "inherited" neural mechanisms, basic to certain acts, that may never be activated during the life of a given individual. For example, certain aspects of the mating responses of female guinea pigs may never occur if the animals are reared in isolation, where the specific stimuli necessary to elicit such responses are absent.

A second criterion distinguishing maturation from learning may be described as follows: an observed change in the behavior of an organism that has not yet matured to the point at which habit formation can take place may be attributed to maturation. Like the first criterion, universality, this second criterion is not always applicable.

A third basis for the separation of maturation and learning is the fact that organized behavior sometimes appears for the first time in an organism that has not yet had an opportunity to learn the act in question. Such behavior is clearly due to maturation. An interesting example of such a response is the fact that newly hatched loggerhead turtles escape 3 to 5 days after

hatching and without social guidance crawl directly to the sea and swim immediately for the open ocean. This response is probably visually determined by light reflected from the surf (Daniel and Smith, 1947).

To apply these criteria requires a definition of what constitutes environmentally determined *learning*. Although an identification of this basic psychological process is not easy, it may be suggested that all true learning involves a change in the organism such that specific stimulus conditions call out a response that would not have been called out by these same stimuli in the absence of previous activity by the individual. Although learned responses are of central interest to many psychologists, the study of behavior originating through maturational processes is necessary to complete the picture of the developing organism. One reason that the growth of behavior in early fetal life is so important for psychology is that these changes are typical of the alterations of behavior that are almost certainly independent of learning (Carmichael, 1938).

For the sake of convenience, all changes that take place before birth are usually regarded as resulting from maturation. But changes resulting from maturation must not be thought of as stopping at birth. Changes in behavior that result from maturation may continue long after the onset of changes resulting from learning. It may be that a newly learned response will in certain instances give novel expression to otherwise inborn patterns of response. Examples may make this clear. Some mammals, apparently by maturation, develop a preference for low levels of illumination. A purely learned habit, such as the manipulation of a lever, may, however, be used by these organisms to express this essentially inborn light-avoiding response. Thus the particular expression of this behavior in a given organism may require that the "lever habit" be learned. We may force the individual in question to learn a skill in order to display its still apparently unlearned brightness-avoidance reactions.

An example of the relation of learned and unlearned behavior is given in an experiment by Howells and Vine (1940). Bantam and leghorn chicks hatched in the same incubator later learned more easily to go to like than to unlike chicks. Howells and Vine interpreted this to mean: "The nature and amount of learning is not wholly the product of experience, but learning is accelerated or retarded for different types of individuals in different situations because of the directive influence of innate factors" (p. 547). (See also Keeler, 1948.)

Another experiment emphasizes that there are innately different behavior characteristics in ducks and chicks. In their first response to water, ducks enter readily; chicks show a strong disinclination to enter. Since environmental factors were constant, the observed behavior was apparently a result of innate constitution of the "nature" of chicks and ducks. Schoolland, who conducted these experiments, remarked:

This difference in initial response to water, and in the relative "ease of learning" to enter, in the face of equivalent environmental experience from birth, affords striking evidence for viewing structure, function, predisposition, and discriminative or cognitive ability as integral aspects of innate organization differentiating animal behavior. [1942, p. 280.]

Individually learned language and other forms of behavior employing symbolic responses may be linked with inborn emotional responses. Under certain conditions an essentially inborn emotional pattern may be enriched, as it were, but not necessarily fundamentally "caused" by the individual's newly learned skills of language and other motor expressions. The thwarted motorist who loudly calls out to another driver and then presses his throttle to the floor in order to pass the offending car is using many learned responses. But inborn neural mechanisms, developed by maturation, almost certainly act in releasing his emotional behavior.

At every stage of ontogenetic development organisms are, of course, total, behaving entities, exhibiting many psychological and behavioral capacities. Many names have been given to special groupings of these capacities. The adaptive behavior of higher animals in certain situations is called *intelligent*. Other types of behavior are called *instinctive*. Similarly, organisms sometimes display reactions that are named *emotional* and others that are said to demonstrate the presence of basic *drives*. All such classes of behavioral acts must be seen for a first time in the continuum of development. Such acts are also observed to change after their initial appearance. This may be better put by saying that, as growth continues, acts once observed are supplanted by other acts exhibiting some novel and some old aspects.

In this chapter, therefore, an effort will be made to suggest the zero point and the subsequent developmental changes of some typical segments of human behavior. We may hope in this study to enrich our understanding of what may be called the embryology of mind (Carmichael, 1941). It is in the period before birth that the onset and development of maturational behavior can be seen in its clearest form. The large number of studies devoted to the growth of behavior after birth are not reviewed here. This literature has been summarized elsewhere (see Pratt, 1946; Gesell, 1946; McGraw, 1946). It should be noted, however, that the further toward adult life the organism progresses, the more difficult it is to assert with assurance that a given behavior change is the result of maturation rather than of learning.

Stages in the Development of Behavior

Ideally, at each level of development there could be presented a complete behavioral psychology of the organism. Actually, such completeness is seldom possible. In the early phases of development many of the experimental tools appropriate to the study of complex behavior cannot be used. Con-

ditioned reflex and other learning methods can seldom be applied to fetal organisms. Hence, the only experimental method that has been applied extensively in early stages of behavioral growth is the determination under controlled conditions of whether or not given stimuli can release a response.

Students of the development of behavior in fetal life have typically selected a series of more or less arbitrarily chosen developmental stages for consideration. The total capacity of the organism at each of these chosen stages is then described. In this chapter general observations on the growth of human behavior will be given first, and later the part played by the senses in the release and control of these responses will be singled out for special consideration.

Difficulty of Comparing Organisms

Comparisons of the developmental stages of different mammals, including man, are important. Such comparisons, however, may easily be misleading. For example, the young of the opossum are born after a gestation period of about 14 days. The young of the guinea pig are born after a gestation period of about 64 days. In some few respects the life processes of the newborn opossum are similar to those of a 14-day-old guinea pig fetus operatively removed. In most respects, however, the two organisms at this age are very different. And at normal birth time the newborn guinea pig and the newborn opossum are also very different. At birth the 14-day opossum can perform only a few essential acts; the 64-day guinea pig, when first exposed to independent life, is almost as competent behaviorally as it will ever be. How then can these two fetal types be compared except by giving the total life history of each?

In testing the intelligence of different species of adult animals, it is difficult for the comparative psychologist to set problems that are equally "meaningful" for both groups of animals. Almost every test seems to favor the particular motor or sensory ca-

capacity of one species rather than the other. Cats and spider monkeys are born to be interested in different things and to respond in distinctive ways to their environments. To compare the problem-solving ability of cats and spider monkeys requires many safeguards and some arbitrary conclusions. In the same way the comparison of fetal animals of different species is subject to many pitfalls.

A cautious approach must be observed even in comparing early developmental stages of a given organism by methods known to be appropriate in eliciting behavior in later fetal stages of the same organism. A fetal organism in which the inhibiting effect of the cerebral cortex of the brain has hardly developed at all is a very different organism from the same individual at a later developmental stage when such cortical control is well established.

The First Human Behavior Act

With these warnings in mind let us turn to a consideration of the onset and early growth of behavior in man. The various procedures employed in determining the age of human fetal organisms have been discussed elsewhere (Carmichael, 1946, pp. 96-102). Streeter (1920) and others compiled tables showing the relation of various measurements of the human fetus and menstruation age. By menstruation age is meant age calculated from the first day of the last period of menstruation prior to the onset of pregnancy. In general, insemination age is probably about 10 days shorter than menstruation age. Such tables help in determining the presumed age of the fetus relative to fertilization. For but few of the human fetal organisms studied are there reliable indices of insemination, let alone actual fertilization age. Consequently age will here be given in weeks from assumed time of fertilization as estimated from measured height and the use of appropriate tables. In his extensive studies of early human fetuses Hooker (1944) concluded that the

sequence of ages established by tables relating measurement to age checks well with observed behavioral development.

The period comprising the first two weeks of human growth is often called *germinal*. The next stage, called *embryonic*, lasts until about the sixth week. The final stage of about 33 weeks is described as *fetal*. Infants born before full term are called *premature*. Children born before they are about 26 weeks old ordinarily do not live. Babies not born by the end of the normal term are called *postmature*. It has been accepted by legal opinion that a child may remain in the mother's body for more than 47 weeks (Carmichael, 1946, p. 100).

Heart Beat

The first reported movement in the embryonic mammal is the rhythmic beating of the primitive heart. This heart response is at first purely muscular. The mechanism of nervous control of the heart cells does not develop until later. The rhythmic contractions of human heart cells begin during the third week in what will later be the ventricular region (Williams, 1931, p. 163). The intrinsic rhythm is determined by the metabolic processes of these muscle cells (Goss, 1940). In older fetal organisms heart rate may be used as an indicator of sensitivity prior to the emergence of fetal reflex movements (Sontag and Richards, 1938; Rose, 1947).

The striated or body muscles of the human fetus also develop to the point at which they can be directly stimulated before they are controlled by nerve impulses (Coghill, 1929; Minkowski, 1928; Bolaffio and Artom, 1924). This direct response to external stimuli by muscles before neural control is established is spoken of as the "independent effector" stage of the response mechanism (cf. Parker, 1919).

The Ontogenetic Zero of Mental Life

If we do not consider heart beat or the independent action of muscles as the initial

stage of *behavioral* development, what shall we consider as its onset? The answer commonly given is that this first activity, above what may be called the zero point of response, is established when receptor stimulation first elicits a definite muscular reaction that can be shown to involve activity of the central and peripheral nervous systems. At this stage certain muscles must be ready to respond; there must be functional maturity of at least some connecting mechanisms of the central nervous system; and sensory and motor peripheral neural elements and receptors must be functional.

In some organisms so-called spontaneous behavior may appear before this full mechanism is functional. This means that the central nervous system and the peripheral motor nervous system may be functional before the receptor mechanism is ready to respond to stimulation. There appears to be no evidence that such spontaneous behavior typically appears in the human fetus before at least some receptor mechanisms are functional.

In a fetus of about 7½ weeks, Hooker (1944) and Fitzgerald and Windle (1942) observed true receptor-released response. It is possible, but not clearly demonstrated, that fetuses supposed to be as young as 6 weeks old have been observed to move (see Yanase, 1907; Strassmann, 1903).

Using a quantified pressure stimulus, Hooker showed that touching the region about the mouth results in a contralateral flexion of the neck. This seemingly occurs without participation of the upper extremities. Fitzgerald and Windle (1942) described the first response of a comparable fetus in very similar terms. Soon after this first response, the zone of receptors that can elicit behavior expands.

The primitive responses that have just been described constitute the first stimulus-released behavior of which the human organism is capable. These reactions are thus the first reactions above the absolute onto-

genetic zero (the state prior to that in which stimulation releases behavior).

The Problem of Fetal Condition

Human fetal specimens are usually available for study only when it has been necessary to interrupt pregnancy. This means that many observations are recorded in the presence of general anesthesia given to the mother. Since many general anesthetics pass readily through the placenta, they may to some extent narcotize the fetus before it is removed. On the other hand, Hooker (1944) found that novocain, in its various forms, appears not to affect fetal movements when used either as a spinal or as a local anesthetic. Some of the fetuses he studied had been removed during operations in which anesthetics of this type only were used.

Fitzgerald and Windle (1942) studied human fetal material that was not anesthetized or narcotized. Some of their observations were made while the fetus continued to receive oxygenated blood from the intact placenta. Under these conditions, in three fetuses of approximately 8 weeks' post-insemination age, excitability was high. Quick arm, leg, and trunk movements were called out by tapping or pressing on the amniotic sac. These reactions occurred individually and in various combinations. They did not involve a total reaction of the organism unless the stimulus was very strong.

These investigators hold that, by the eighth week of development, if the fetus has an adequate supply of oxygen, if it is unanesthetized, unanesthetized, and in other ways undamaged, its neuromuscular apparatus is capable of active functioning. They also believe that some receptors or synapses are more easily rendered nonfunctional by anoxia than others. Arm and leg responses are abolished in asphyxiated specimens after the time when stimulation applied to the skin of the face still calls out trunk flexion. In this stage of asphyxiation, strong stimulation calls out mass movements involving trunk, arms, and legs. This observation

suggests, along with other evidence (Barcroft and Barron, 1937, 1939), that much early mass movement of the fetus is a function of decrease in oxygen in the blood and concomitant overstrong stimulation.

Fetal Behavior of Infrahuman Mammals

Observations on the fetuses of infrahuman mammals are important as a basis of comparison for human fetal responses. Especially in early fetal life there is a greater similarity in structure and function between human and other mammalian fetuses than appears after birth (Corner, 1944).

Typical of the procedure used to study fetal behavior in lower animals is that used by Bridgman and Carmichael (1935) who studied 47 litters of guinea pig fetuses. These litters developed in maternal animals that had been mated in the laboratory. Insemination age of these fetuses was therefore known exactly. In preparation for an experiment the mature female was given deep ether anesthesia at the appropriate number of days and hours after insemination. The spinal cord of the mother was then severed in the cervical region. A preliminary incision was made in the skin and tissues of the abdomen. This incision was clipped together. The maternal animal was then allowed to recover fully from the anesthetic before being tied upon a frame and lowered partly into a bath of physiological saline solution held at the constant temperature of the blood of the organism. The fetuses were then exposed, stimulated, observed, and photographed by a moving picture camera. Stimuli of various sorts were used, such as calibrated hairs that exerted known pressures.

In the experiments intended to determine the nature of the very first responses, 146 fetuses from the 47 litters were studied. This study made it clear that insemination age is not an absolutely accurate basis on which to predict behavioral capacity. Certain older fetuses remained nonmotile and exhibited less advanced behavior than did some of the

younger ones. Length and weight seemed to provide a better index of behavioral development than age. Hooker (1944) suggested that this is also true of human fetal material. Presumably this would not be true of healthy individuals of genetically pure stock, but the guinea pigs used were from an ordinary mixed laboratory colony.

The youngest of the guinea pig fetuses studied (621 hours) were nonmotile; they made no active responses with their body muscles. When they were observed under a binocular microscope it was possible to note that passive body vibrations were brought about by the jarring of the fetal body by the beat of its own heart.

In some nonmotile guinea pig fetuses appropriate electrical stimulation led to direct muscle response. This occurred at a time when stroking, flipping of the limb, or patting did not elicit responses. Fetal muscles that showed brief active movements could later be brought to respond to faradic stimulation when active receptor-initiated movement ceased to be elicitable.

First Responses of Animal Fetuses

The very first movement in the large series under consideration occurred in an organism of 622 postinsemination hours. This first response and others like it had special characteristics. Typically, in the youngest fetuses the response could be made once or twice only. Stimulation of such young fetuses was best accomplished, before the amniotic sac was opened, by pressing the sac walls with a hair so as to touch the fetus lightly.

When several responses could be elicited in young motile fetuses, there was a long refractory or "fatigue" period between the times when stimuli could effectively call out response.

The earliest responses observed were neck flexions. The very first was a slight ventral flexion of the neck which produced head bowing. In a fetus only 1 hour older a dorsal neck bending and a slight but active flexion

of one forelimb took place. The articulation of this limb movement was at the shoulder. In fetuses 1 hour older still, dorsal, ventral, and lateral neck flexions were observed, as well as additional forelimb flexions. The similarity of these responses and the early responses of the human fetus should be noted.

It is hard to overemphasize the small magnitude and the transitory nature of these earliest reactions in the guinea pig. The earliest observed responses seemed to be discrete. The head and limb responses apparently were not part of any general primitive pattern of behavior. The early limb and neck reactions did not take place at the same time. As fetal age increased, however, some responses occurred which may be called "patterned." These reactions seemed to be organized in a regular and predictable sequence both in time and in locus. At later ages very strong or long-continued stimulation seemed to call out more generalized behavior in the total organism.

Human Responses in Older Fetuses

At about 8 weeks the reflexogenous zone of the cutaneous surface of the human infant spreads from part of the upper lip and the wings of the nose to the whole upper lip, the chin, and a short distance down the neck (Hooker, 1944, p. 22). The characteristic response of the human fetus at this time is still stereotyped and mechanical in nature. Windle and Fitzgerald (1937) have shown that the elements of the reflex arc in the central nervous system are laid down during the sixth week, but spinal cord arcs are not complete before the eighth week. Hooker says, in commenting on this stage, "each stimulation in the reflexogenous area evokes a response which, within the limits of ordinary biological variation, is identical with every other one secured" (Hooker, 1944, p. 25).

Carmichael (1934) showed that in the fetal guinea pig there is a definite and almost fixed relation between the place stimulated

and the response elicited. The repertory of stimulus-released behavior of each organism is limited by the stage of growth of the receptor and neuromuscular mechanisms. The nature of the response elicited during much of fetal life seems to be determined by what may be called the pushbutton action of specific areas of the receptor surfaces. This generalization applies best to cutaneous areas, but it is also suggestive in understanding the specific responses released in unborn mammals by the activation of other receptor mechanisms.

In the fetal guinea pig it appears that almost every receptor area can be thought of as having some particular response associated with it. In 60 fetal litters of known insemination age over 90 reflexogenous areas were stimulated, whenever possible, by stimuli of known intensity, and the behavior released by each point stimulated was listed. A remarkable generalization then appeared: a distinctive pattern of behavior is related to almost every point stimulated. Although it is true that these patterns changed somewhat with the age of the fetus and were at times masked by other concomitant responses, the *specificity of response to locus stimulated* is one of the principal generalities issuing from the developmental study of behavior.

In later stages of development these specific responses can be seen in new temporal patterns. One who has studied the whole course of the development of any unit of such responses cannot fail to see a relation between the old and familiar specific stimulus-released reactions of the organism in the now more-complex behavior patterns. This is tantamount to saying that in the intricate and adaptive behavior patterns of late fetal and postnatal life there is an organization of reactions which have previously been seen as specific responses to stimulation.

Now, turning again to the human fetus we may note that the first responses clearly determined by receptors other than those in the skin are reactions to stimulation of sen-

sory end organs in the muscles, joints, or tendons. Such proprioceptive stimulation seems to follow the stretch of the limb muscles at about 9½ weeks (Hooker, 1944), and this type of stimulation is effective before the whole cutaneous area has become sensitive. In this connection it should be noted that Hogg (1941) showed that the cutaneous nerves and nerve endings are immature when they are first capable of eliciting response. No encapsulated endings are present when cutaneous receptors are first able to release behavior.

By 11 weeks stimulative cutaneous reflexogenous zones have spread over the whole upper extremity, and responses are often complex. At this age the sole of the foot first becomes sensitive to stimulation. Trunk extension is noted. When the palm of the hand is stimulated, a quick finger closure occurs (see Hooker, 1944, pp. 26ff). Other important observations on the responses of very early human fetuses have been made by Minkowski (1922), Woyciechowski (1928), Bolaffio and Artom (1924), and Hooker (1936, 1939). These observations have been summarized by Carmichael (1946).

During fetal life the same stimuli applied to the same areas may call out differing but still quite specific responses as the various connecting levels of the central nervous system mature. Thus Minkowski (1926) showed that the first response to stimulation of the sole of the foot is probably an independent effector response that follows the direct stimulation of the muscles through the thin skin (see Dewey, 1935). This reaction does not involve neural elements. The next level of reaction in a fetus of 3 to 4 months is believed to involve connections in the spinal cord. This response shows a dorsal flexion of the toes. As the central nervous system continues to mature in the midfetal period, connections in the midbrain become effective, and the pattern of response of the toes changes again: the big toe is often extended while the other toes flex. As still higher centers become functional in late

fetal life, the response becomes variable, sometimes showing a spreading of the toes. With the development, ordinarily after birth, of cortical dominance, the typical Babinski reflex (big-toe extension and flexion of other toes) disappears and is replaced by the adult plantar reflex (the contraction of all toes). In adults the presence of the Babinski reflex is sometimes indicative of a lesion of the pyramidal tracts of the brain and spinal cord (Pratt, 1946). This illustrates a view proposed by Jackson (1884) that in behavioral phenomena the dissolution of a function is often in reverse order to its evolution.

At about 12 weeks the eyelids, although still tightly closed as in the newborn kitten, have begun to respond to stimulation by what will later be a wink. Eye movements underneath these closed lids can be detected at this period also.

Preliminary experiments on guinea pig fetuses (Carmichael, 1946) suggest that at first eye movements are not related to stimulation by light but rather to activities initiated in the nonauditory labyrinth. In these experiments very fine silver wire electrodes, hooked into the skin about the eyes, made it possible to observe shifts in the so-called corneo-retinal potential caused by eye movements (see Carmichael and Dearborn, 1947).

These observations suggest that the eyes first move as part of general postural reactions to movements of the body in space. Vestibular nystagmus appears to be primary in the mammalian organism and to precede optokinetic nystagmus. More work is called for in this field.

Behavior Becomes More Complex at 13 Weeks

By 13 weeks almost the whole skin area of the human fetus is sensitive to stimulation. The top and the back of the head alone remain insensitive (Hooker, 1944). At this time almost every joint of the body that is ever to move has gained mobility, and when stimulation is strong the student may

well think that he is observing what some writers have called a "generalized matrix of behavior" from which will later develop differentiated and specific responses. This impression would be strengthened if later he saw very specific responses elicited by weak stimuli applied to certain receptor areas. But here appears a basic problem of scientific method. The new patterns of response are unique in their temporal and other characteristics, and from one point of view they are not composed of previous responses. On the other hand, the practiced observer can see that there is nothing new in them when he considers them as units. In considering total patterns of response, we must not forget the importance of vestibular and proprioceptive stimuli in establishing the postural tonus of the body. The muscles mediating a movement of the shoulder joint of a fetus respond to activities resulting from the cutaneous stimulation of the palm. When the head is turned to one side, this response may not be the same as when the head is turned to the other side. Sherman and Sherman (1925) demonstrated that when the sole of the foot is stimulated the posture of the toes may determine whether the reaction of the toes themselves will be extension or flexion.

At about 13 weeks stimulation of receptor fields of one side of the body regularly leads to the response of a member on the other side of the body (Hooker, 1944). Such contralateral responses can sometimes be observed in a more limited way by the ninth week (Fitzgerald and Windle, 1942).

Development at 14 Weeks

Hooker (1944) has said that 14 weeks is an important point in development. Reflexes and movements are at this age more "graceful and fluid." Except for respiration movements, voice, the true grasping reflex, and a few others, the fetus shows most of the specific patterns of response that can be elicited in the neonate. In fact, at this time the fetus may show a subtlety and

variety of responses that are quite impossible in the newborn child. It should not be forgotten that before birth the fetus lives in a liquid medium of almost the same specific gravity as its own body. There, like a man under water, it can carry out responses that it cannot duplicate after birth.

After 14 weeks there are still many subtle changes in the capacity for response. At 15 weeks a hair stimulus carefully applied to the palm of the hand will lead to a closing of the fingers, which remain, as it were, closed upon the stimulus. This means that the grasping reflex in a form similar to that seen in the newborn child is in operation.

By the fourteenth week, or even by the twelfth week, the first rhythmic movements of the chest begin. These movements, sometimes named for the German obstetrician Ahlfeld, are almost certainly related to the responses that will later be necessary in breathing. But how are they caused, and do they have utility in fetal life except as a preparation for later breathing? Ahlfeld (1890) found that these responses varied from 38 to 76 per minute, showing that the breathing mechanism is essentially in working order long before it is needed. It has been suggested that these movements form a sort of auxiliary pump to help the heart (Brown, 1915; Walz, 1922), and it is considered likely that a decrease in the oxygen available in the fetal blood is one of their causes. These movements do not normally lead to the aspiration of amniotic fluid (Windle, 1941). During the last 20 weeks of pregnancy, continuous observations for 5 or 6 hours show a relation between chest movement and the metabolic rate of the mother, a correlation of 0.6 with the increase in metabolic rate over measurements taken 52 to 197 days earlier (Richards, Newbery, and Fallgatter, 1938).

Air Breathing and the Premature Infant

By 22 weeks some prematurely delivered fetuses are capable of briefly sustaining respiration when stimulated in the air. Much

study has been given to the factors that lead to the onset of air breathing at birth. It seems certain that the increase of metabolites and carbon dioxide and the lack of oxygen in the blood are important in causing the first gasps. These gasps ordinarily occur after placental circulation is interrupted (Corey, 1931). External stimuli such as the drying of the skin and its cooling are also important in initiating the first breath. If a baby on delivery does not start breathing a slap is sometimes effective (Huggett, 1930). Movements of the respiratory type seem to arise from the release in an inhibiting center in the forebrain (Barcroft et al., 1940).

Abel and Windle (1939) found circulation of blood in the lungs during late fetal life. This circulation is enough to take care of oxygenation on the assumption of respiration. There is thus no sudden increase in pulmonary circulation at birth. In the fetal guinea pig the lungs are solid, glandlike organs in which the alveolar spaces constitute only about 2 per cent of the total mass. By the end of the first hour after birth the lungs have expanded and the alveolar spaces then occupy 40 per cent of the lungs (Whitehead, Windle, and Becker, 1942). For the implications of intra-uterine respiration in the development of the fetal lung, see Potter and Bohlander (1941) and Zettleman (1946). A detailed study of breathing rhythms in fetal and newborn animals has been made by Barcroft (1947). Using the sheep, an animal with a gestation period of 5 months, he has been able to show a continuum in breathing movements from the first spasm seen on the 34th day, through the onset of rhythm on the 40th day. Segregation of chest movements began on the 45th day and the onset of inhibition of this movement in the period between 50 and 60 days. Here again we see the development of the basic mechanism of a great action system before the system can function in the economy of the organism.

If for any reason respiration is not properly established at birth, asphyxiation results.

Experiments on guinea pigs show that, even if breathing is later established, a delay in establishing breathing may result in so-called *asphyxia neonatorum*, which can produce permanent degenerative changes in the brain (Windle and Becker, 1943). The extreme susceptibility of nervous tissue to oxygen lack is well known. In one experiment pups were born of mothers deprived of normal oxygen supply before delivery. One of the pups developed convulsions 5 weeks after delivery, and another 6 weeks after delivery. It has been suggested (Fender, Neff, and Binger, 1946) that this asphyxia neonatorum may play a part in the development of some cases of epilepsy in human beings.

Now, to return to the general behavior of the human fetus, we may note that by 22 weeks the eyelids separate. It is rare, even after the eyelids have separated, however, to have the eyes open spontaneously or as a result of any stimulation by light that has so far been applied.

Endocrines in Fetal Development

The function of the endocrines in fetal life is still imperfectly understood. In general it may be said that the endocrine functions are concerned with growth and metabolism rather than directly with overt behavior as such. But, as previously emphasized in this chapter, it is not easy to separate the development of a structure and a function in fetal life.

The principal endocrine function of the pancreas is found in the secretion of the cells of the *islets of Langerhans*. There has been much consideration of the role of this secretion—fetal insulin, as it is called—in prenatal life. One difficulty met in such studies is the determination of when the effects of insulin on the fetus are a result of the secretion developed in the fetus itself and when they are a result of the insulin provided by the mother. In the study of responses related to the growth of the fetal nervous system an investigator fortunately need not fear that the specific nerve impulses he is

considering may have started in the maternal rather than in the fetal central nervous system. But in the study of the endocrines no such assurance can be taken for granted. There has therefore been much study of the problem of the passage through the placenta of the various products of different endocrine glands. In the case of insulin it has been shown that the administration of this substance to pregnant cats near the normal period of birth failed to reduce the blood sugar level of the fetuses. At earlier periods of fetal life this result was not secured. Other complex relations between insulin and fetal metabolism have been worked out in mammals. It is apparently true (Windle, 1940) that the relations found in one mammal are not necessarily also true of other mammals.

The suprarenals exhibit a special function in fetal life. At the time of birth they are 0.02 per cent of the total weight of the body. In the adult they are only about 0.01 per cent. In the first week after birth this gland loses one-third of its birth weight. The full significance of this change is not known. It may well be related to the presence in fetal life of maternal sex hormones transmitted through the placental barrier. The medulla of the suprarenals is embryologically as well as functionally distinct from the cortex of the suprarenals.

Pankratz (1930) suggested that the onset of behavior may be related to the beginning of functional activity in the secretion of the suprarenal medulla. In a later study this same investigator (1931) emphasized the fact that this condition may be important in man as well as in the rodent, on which his first studies were made.

Willier (1939) has well summarized the development of sex-related hormones in the fetus. Male gonads produce male sex hormones in fetal life. This secretion probably begins about the seventh week in man. In the female the ovary is histologically recognizable by about the eighth week. This slight difference in time in the growth of sex

hormone-secreting structures suggests that possibly the internal secretions of the male sex glands begin before those of the female. This observation is reminiscent of a very ancient belief. In the canon law of the medieval church it was considered that the time of quickening of the male fetus was 40 days and that of the female 80 days (Goeckel, 1911).

The extent to which the mother's own sex hormones and her other endocrine secretions influence the growing fetus and the difference in such influence on the development of male and female fetuses has been the subject of much study and some speculation. The mammary glands of both boys and girls may secrete milk — so-called witch's milk — for a short time after birth. It seems almost certain that this lactation is stimulated by the same endocrine mechanism that leads to the maternal lactation (Pratt, 1931).

Studies have been made of iodine in fetal and maternal blood streams. It seems clear that the thyroid, which is essential in making available so-called hormone iodine to the organism, is functional in man by the sixth month. In some mammals it seems that the fetus must manufacture all its own iodine. In the human organism the mother's iodine seems able to pass through the placental barrier and become available to the fetus. It has been shown that the maturation of typical behavior patterns in the fetal rat may be delayed if the maternal organism is in a hyperthyroid state during part of pregnancy (Rose, 1947).

The fetal hypophysis elaborates several active principles, but their exact function in growth is in some doubt. The growth-promoting factor of the anterior lobe of the hypophysis appears rather late in fetal life. (For a bibliography and fuller treatment of fetal endocrine glands, see Windle, 1940).

There has been some study of the relation between the development of acetylcholine and the onset of behavior. It is believed that acetylcholine plays an important part in the chemical relation between different

neurons and in the relations between neurons and muscle cells. Kuo (1939) showed that the first neurally determined responses in the chick embryo do not appear until after acetylcholine has been developed by the organism. This suggests that the first reflex-like response of the chick may be dependent upon this so-called chemical mediation. Youngstrom (1941) also found a relation between acetylcholine and related chemical substances and the development of motility.

"Anticipatory Function" and the Quickening of the Fetus

We may propose a generalization concerning fetal development: the *law of anticipatory function*. It may be stated as follows: *functional capacity may be demonstrated experimentally in many action systems of the growing organism well before the time when the function in question is normally called upon to play an active and significant part in the vital economy of the organism.*

We have seen above that cutaneous stimulation can release responses in a human fetus at about 8 weeks of age. In contrast it may be noted that there is no sure evidence that human fetal movement can be detected in the course of normal development in the mother's body before the fourteenth week, when movements have been detected by the stethoscope. At about the seventeenth week movement can usually be felt by the mother (Windle, 1940, p. 165; Feldman, 1920). Many observations on the "quickening of the fetus" were made before modern scientific techniques were available. Even the great physiologist Harvey noted that a mother can feel the kick of her unborn child (Needham, 1931).

Lindsley (1942) not only recorded electrically the beat of the fetal heart but also took fetal electroencephalograms. These latter records were made by placing electrodes on the abdomen immediately over the fetal head when the head was found in a convenient place. There have been a number of other studies of the electrocardiograms of

fetuses (see Geiger, Monroe, and Goodyer, 1941). Newbery (1941) measured the principal types of fetal activity as noted by the mother. Frequencies for hiccoughing, kicking, and squirming during the 5 months previous to birth were determined in this study. Kicking showed the most continuous increase in the 5 months preceding birth.

Sir Joseph Barcroft (1938) pointed out that a definite change takes place in the sheep fetus during the late prenatal period. The gestation period of the sheep is approximately 144 days. Barcroft says:

It seems to me a very remarkable thing that, while as yet the foetus has only passed one third of its intra-uterine life, it should possess a nervous system capable of dictating not only movement, but the specific movements which the animal will undertake shortly after birth, capable of dictating the movements of respiration which, though they will not be required for another hundred days, must at once come into play when the sheep is born and on which its survival depends, capable of coupling the locomotor and respiratory functions in harmonious activity, and capable of sense insofar as it can appreciate its relation to gravity and react to tactile stimuli. [1938, p. 26.]

Barcroft says further, however, that by the 50th day all this activity is beginning to change in the fetus of the sheep. The organisms from this time on become more quiescent. Their responses become limited. Spontaneous movements are much less in evidence. This change, Barcroft suggested, is due to the fact that by the 50th day the fetal circulation has begun to provide a less adequate supply of oxygen for the use of the fetal brain. It may be said indeed that the latter part of the fetal life in the sheep is one of growth of receptors, nervous system, and muscles, as well as of all other organ systems, but it is not a period when the special receptors release much general bodily activity. In cat fetuses it has been shown that in a deficiency of oxygen there is at first an increased responsiveness to light

tactile stimuli, but this and other functions are lost with further anoxemia (Windle and Becker, 1940).

Hooker noted that at a comparable period there is also relative quiescence in the activity of the human fetus. This change begins at about the 16th week. After this time the fetus shows a marked decrease in spontaneous activity as well as in the responses that can be released by appropriate stimulation. Reactions become, in Hooker's term, sluggish (Hooker, 1944, p. 30). This sluggishness is almost certainly due in part to a decrease in the oxygen available in the blood. The growing dominance of the inhibiting function of the cerebral cortex during this period should also not be forgotten.

The facts just described show that, in the study of the control of behavior by the fetal senses, positive evidence is more important than negative evidence. The observation of a specific response at a particular age is an observation of importance. When stimulation elicits no response, however, it is not safe to conclude that in the same fetus under other conditions, or at an earlier time, responses could not have been elicited. Least of all is it appropriate to assume that, because a response cannot be elicited, the basic neural mechanism for the response is not yet mature.

As previously noted, behavior is called "spontaneous" when it is not easily traceable to specific stimulation. Thus it is a name for ignorance. So-called spontaneous behavior may result from a number of antecedent conditions, such as an alteration in the internal environment of the organism. It may also result from hidden or unobserved stimulation of receptor mechanisms such as those in the muscles, tendons, joints, or in the nonauditory labyrinth of the inner ear.

Modification of Behavior by Learning

In the normal fetus learned behavior is seen only in a very modest way, if at all. Ray (1932) presented a preliminary report on fetal conditioning, but his results were

not fully conclusive. This is also true of the study of Sontag and Wallace (1934). Spelt (1938) seems to have established conditioned responses in the intact human fetus (ages 6½ to 8½ months) by the use of auditory stimuli as the unconditioned stimulus and *tactile* vibration of the maternal abdomen as the conditioned stimulus. The position of the fetus was determined by X-ray examination, and movement was observed by tambours placed on the abdomen of the mother. Stimulus presentations consisted of vibration followed 5 seconds later by the loud sound. After 100 paired presentations, responses to tactile vibration were elicited. Conditioning of this sort is not easy to accomplish. It may be said that the stimulus release of learned behavior is not typical of fetal life.

The present writer, in some unpublished studies, attempted to produce conditioned responses in prematurely delivered fetal guinea pigs. No positive results were secured. Marquis (1931) was able to establish conditioned sucking reactions to the sound of a buzzer in 8 of 10 newborn infants in 5 days of training, and Wenger (1936) also established conditioned withdrawals in the first few days of life. But these reactions were not stable. Wickens and Wickens (1939) question whether neonatal conditioning is not essentially what has been called pseudoconditioning. In their experiment 24 infants under 10 days of age were studied. A control group received twelve stimulations with shock to the sole of the foot alone for 3 consecutive days. The experimental group was given the sound of a buzzer and shock. *Both* groups gave similar positive reactions to the buzzer alone after training, but none of them had responded before training. "Extinction" and "spontaneous recovery" were the same for both groups.

There is a good deal of evidence pointing to individual differences of capacity of fetal organisms. Studies tend to show that there is a positive relation between fetal activity as reported by the mother and performance

at 6 months on the normative items of the Gesell scale (Richards and Newbery, 1938). This fact may well be considered in evaluating so-called fetal learning.

Other Modifications of Fetal Behavior

Another modification of the organism by previous activity is seen in the establishment, after response to a stimulus, of a state of temporary inactivity or a "refractory period" during which subsequent stimulation is ineffective (Carmichael, 1934)

The phenomenon of "summation of stimuli" is also demonstrable in some fetal organisms. One application of a just supraliminal stimulus may not call out a response, whereas repeated stimuli of the same sort may cause a breakover into overt activity (Carmichael and Smith, 1939).

Notwithstanding the fancies of a few writers, we may dismiss the idea that complex, voluntary, centrally initiated behavior of the so-called "voluntary" type is ever seen in fetal life. Rather, responses that are observed in the fetus, and that may be considered to be on a continuum with later voluntary activity, may in actuality be related to other antecedent conditions, such as oxygen change, or to actual but concealed stimulation.

Influence of the Internal Environment

Tracy (1926), in a series of experiments on fish embryos, made observations that are relevant to the question of the nature of stimulation and of spontaneous behavior. Toadfish larvae, after hatching, typically lie quiescent at the bottom of the tank. Closer observation shows, however, that at different times these embryos make sudden movements. Tracy concluded that these spontaneous reactions are related to cumulative changes in the blood of the organism. He suggested that at certain times the nervous system of the small larva is directly stimulated by a change in the amount of oxygen in the blood, or by the concentration of metabolites — the waste products of previous

cell activity. The consequent reactions may be a result of direct stimulation of the nerve centers or of the stimulation of specialized receptors in the blood vessel system. It may also be that these responses involve a modification of existing thresholds of excitation in the central nervous system. This threshold change may render effective what were previously ineffective peripheral stimuli.

Tracy himself drew some interesting conclusions from his studies. He suggested that, if external conditions were held constant, the activity of organisms might be largely determined by their own life processes. The whole organism would then "beat" in its environment, much as the primitive heart cells beat in the environment of the fluids and tissues in which they are developing. This suggests that, were it not for changes in the external environment, behavior would be rhythmic, as it is in an excised muscle maintained under certain conditions in a balanced salt solution. It is interesting to note that in Tracy's studies the internally determined movements sufficiently changed the relations between the organism and its environment so that more effective oxygen supplies became available to it. Tracy concluded by saying: "From the beginning, and more or less continuously during its whole existence, the animal is driven through its environment as a result of stimuli which arise periodically in connection with its metabolic processes" (1926, p. 345).

As the external receptors become functional, they are utilized by the internally driven organism to initiate actions that, temporarily at least, alter the internal environment. This in turn leads to a change in the drive, or need state, of the organism. In these observations we see a parallel between early behavior, determined in part by oxygen need, and the later responses initiated by the various need states in the neonatal and in the adult organism.

No such clear, rhythmic behavior as that noted by Tracy in the toadfish has been observed in the mammalian fetus. It must

be emphasized, however, that the mammalian fetus is never just a passive system of external receptors, nervous system connectors, and muscles. When an external stimulus is brought to bear on a functional receptor in a living fetus, there are inevitably many cells and systems of the organism already in activity. For example, as noted above, mechanically initiated movements of the whole body are brought about by the beating of the heart cells. In the bird's egg, at certain stages of development, the active beating of the wholly extraembryonic amnion keeps the embryo in constant activity. The embryo is like an organism being tossed in a living blanket (Kuo, 1932).

Other Internal Activities

The central nervous system is also of course in a state of continuous activity. Jasper, Bridgman, and Carmichael (1937) were able to show that some electrical rhythms of the brain of the fetal guinea pig are abolished by tying off the umbilical cord. This fact indicates that the brain in the normal fetus is rhythmically active in late fetal life. There is also some evidence that long-term physiological rhythms, such as those of sleep and wakefulness, are present during fetal life and in early infancy (Pratt, 1946). Becker et al. (1940) demonstrated that the guinea pig fetus begins to swallow amniotic fluid at about the 42nd day of gestation, and that peristalsis begins at about the 16th day. Swallowing and gastrointestinal activity have also been noted in the fetal monkey. The rate of swallowing of amniotic fluid increases and the emptying time of the fetal stomach decreases as pregnancy progresses (Speert, 1943). Yanase (1907) has studied peristaltic intestinal movements in fetal guinea pigs, cats, rabbits, and men.

Blinking movements are sometimes seen in premature human fetuses. Carmichael (1934) has seen a series of blinks following a single stimulus applied to a late fetal guinea pig. These reactions are probably in part centrally determined. The frequency

and other characteristics of blinking movements in the adult cannot be fully accounted for, it is now generally believed, by peripheral factors. It seems probable that the rhythm of blinking is in part the result of a rhythmicity in a specific brain center that results in a periodic discharge of impulses through the seventh nerve (Carmichael and Dearborn, 1947, p. 96).

What are thought to be rhythmic fetal hiccoughs have been identified by various students. Norman (1942) identified what he believed to be hiccoughing in one out of seven of his records of fetal activity. Such reactions vary in rate from 10 to 45 per minute.

The existence of intrinsic rhythms in the fetus shows that the release of behavior by external stimulation may be a function of complex determiners, including the phase of the body rhythms of the fetus. Consequently it seems the more remarkable that the responses called out by stimulation are as specific as they are and as closely related to the character and intensity of the external stimulus as they have been observed to be.

Because of the great variability of internal conditions, the rhythmicity of the fetus, the possibility of interference with the oxygen supply of the fetus, and the possible persistence of the effect of an anesthetic given to the maternal organism, one definite conclusion is justified. Valid statements about any type of fetal response as typical of a given period must be based upon a statistical treatment of many observations. Because of the scarcity of human fetal material, a real statistical approach has so far been almost impossible. Better statistical controls have been possible in the study of cats and guinea pigs, but even here our procedures are far from perfect. Fully adequate studies are most laborious. They require the sacrifice of many fetal litters. The experimental animals must be mated in the laboratory at known times and in known phases of female receptivity. Stocks of genetic purity are desirable. The process quickly assumes the

aspect of a long-range quest in which patience is a required virtue.

The Sense of Touch

In reviewing the activity of the cutaneous senses in fetal life, we will find it convenient to treat separately pressure, temperature, and pain.

In the preceding pages cutaneous stimulation has frequently been discussed. Reference has already been made to the fact that the first stimulus-released activity of the fetus follows tactual stimulation of the region near the lips. With individual variations, this skin sensitivity develops by spreading over the face and progresses toward the rump. An exception to this so-called cephalocaudal progression is the fact that the top of the human head remains insensitive almost until birth (Hooker, 1944).

After the cutaneous areas have become sensitive, self-stimulation is possible. Whether such self-stimulation is necessary to the development of coordinated movements is an interesting question. Holt (1931, pp. 37-43) developed a theory that this sort of stimulation is of basic importance in development, but the present writer knows of little empirical evidence to support this view.

The character of the cutaneous stimuli is significant in determining the type of behavior elicited. Many investigators have noted that punctiform stimulation produces different responses than does areal stimulation. Minkowski (1922), Coronios (1933), Windle and Griffin (1931), Carmichael (1934), and Hooker (1936) all observed that stroking often leads to a specific response when a single touch by a stimulus hair is completely ineffective. Raney and Carmichael (1934) showed that stimulation of a point on the skin by a single hair often does not elicit response, but that stimulating the same area by a small brush made up of about 10 hairs will frequently bring about response.

As previously noted, the phenomenon of temporal summation of stimuli may be seen

in fetal life. A single touch with a light hair may fail to bring out a response, whereas several touches of the same intensity at the same point may be effective (Carmichael, 1934).

The pressure exerted on the cutaneous receptors is of basic importance. Hooker elaborated this point (1944, p. 20). As long ago as 1882 Genzmer noted that different responses were elicited in premature infants by weak and strong cutaneous stimulation. Carmichael and Smith (1939) attempted a quantitative study of the relation between pressure and the specificity and generality of response in fetal guinea pigs. A series of calibrated esthesiometers of the von Frey type were constructed by taking hairs of various diameters and fastening them to handles. The areas located on a chart prepared in advance were first stimulated with the lightest esthesiometer that would elicit response. After a suitable rest period these areas were stimulated again with heavier pressure. The results may be summarized by saying that in each age group studied the more intense stimuli elicited more active and more general responses than did the lighter stimuli.

Reference has already been made to the remarkable consistency in the responses elicited by weak stimuli applied to particular reflexogenous zones. This fundamental fact is nowhere more clearly demonstrated than in the constancy of response resulting from the stimulation of cutaneous receptors in the exposed mucous membrane surfaces of the body. Touching of the lips, of the internal lining of the nostrils, or of the anus leads to quite specific and consistent responses. These responses change very little as the fetus becomes older, except that in the late fetus more complex and adaptive responses may occur following the primary response. For example, sucking responses several times repeated may follow a slight lip twitch in the late fetus on stimulation of the lip, whereas in a younger fetus such a stimulus might elicit only the twitch of the lip muscle.

Temperature Sensitivity

Almost a century ago Kussmaul (1859) and Genzmer (1882) felt that they had demonstrated that prematurely born infants responded differentially to warm and cool. Preyer (1885), Canestrini (1913), Blanton (1917), and Peiper (1928) made similar observations. Pratt, Nelson, and Sun (1930) made more controlled experimental observations in this field. These collaborators report that in newborn infants reaction is much more intense to stimuli that are cooler than the body surface than to stimuli that are warmer.

Carmichael and Lehner (1937) studied the role of warmth and cold in releasing behavior in a series of 40 guinea pig fetuses ranging in age from 28 to 62 postinsemination days. An apparatus was prepared that provided six stimulus temperatures. Three (47, 67, and 85 degrees C) were above the physiological zero of the organism, which was taken to be 37.5 degrees C. Three (27, 17, and 5 degrees C) were below the physiological zero. After the fetus had been exposed and observed in a preliminary manner, six spots were stimulated in random order by liquids of the temperatures just noted. These areas were (1) the vibrissae area, (2) the ear, (3) the shoulder, (4) the rump, (5) the forepaw, and (6) the hindpaw. After each stimulation the fetus was again immersed in the saline bath, which was held essentially constant at 37.5 degrees C.

In summary, it may be concluded that temperature stimulation is effective in releasing responses during most of the motile fetal period of the guinea pig. Furthermore, the greater the difference between the temperature of the stimulus and the physiological zero of the organism, the greater the relative number of responses released by the stimulus. This seems to hold, whether the stimuli are above or below the physiological zero. At the youngest ages studied there appeared to be a slight tendency for cold stimuli to be relatively more effective than

warm stimuli. No comparable study of temperature sensitivity in the human fetus appears to have been made.

Cutaneous Pain

Ever since the writings of the philosopher John Locke (1690) the capacity of experiencing pain has been attributed to the fetus. A number of observations show, however, that even the application of stimuli that cause gross destruction of the skin and of underlying tissue do not call out pronounced movements. On the basis of this evidence Genzmer (1882) held that the pain sense is poorly developed in the fetus. On the first day after a premature infant's birth, he stimulated it until blood came, but he got no response. The present writer has found that pricking a guinea pig fetus with a needle so as to bring a drop of blood may not be so effective in eliciting a response as would be a fine hair applied to a corresponding point. Similar observations have been made on the cat fetus (Windle and Griffin, 1931). There can be little doubt, however, that the destruction of protoplasm does sometimes bring about violent responses in the late fetus. It has been suggested, moreover, that the general delay in the development of the pain sense may serve a biological purpose. If the pain sense developed early, the pressures and tensions incident to birth would almost certainly result in traumatic pain and shock. There are reports of infants remaining anesthetic to pain stimuli long after birth.

Pratt's (1946) careful summary of the pain sense in the normal neonate led him to the conclusion that, although the sensitivity of the neonate to pain stimuli has been demonstrated, there is lack of agreement regarding the degree of pain sensitivity in the just-born infant as compared with the older infant.

The Proprioceptive Senses

The proprioceptive senses are generally taken to include the receptor mechanisms associated with the muscles, the tendons, the

joints, and the nonauditory part of the inner ear. By the fourth month of fetal life, neuromuscular spindles, which are typical proprioceptors, have been found anatomically (Elwyn, 1929, p. 248). Some psychologists have speculated that the activity of the muscles and the consequent proprioceptive stimulation is important in early life in laying a foundation for the organism's later ability to maintain equilibrium and to judge certain types of spatial relations (Peterson and Rainey, 1910). Coghill (1929) came to the conclusion that proprioceptive control is necessary in bringing about the precise response to stimulation seen in the adaptive behavior of the *Amblystoma*.

A number of investigators of fetal mammals, including Swenson (1926), Angulo y González (1932), and Coronios (1933) noted responses that seemed to them to be dependent upon proprioceptive stimulation. It has been noted above that, in the fetal opossum, sucking, breathing, and crawling are three of the earliest responses evident in this mammal, which is born in an immature condition. These are all responses of the sort that might involve proprioceptive stimulation and control. Tendon reflexes and stretch reflexes and stimuli related to receptors in the joints have been studied by such investigators as Minkowski (1922, p. 723) and Bolaffio and Artom (1924, p. 472).

It seems that much of the so-called generalized behavior of the fetus is in reality made up of responses to proprioceptive stimulation. Stimulation of this sort is brought into being as a result of the activity elicited by some relatively specific muscular responses that may follow cutaneous or other types of exteroceptive stimulation.

The receptors in the nonauditory part of the inner ear, important in the maintenance of bodily posture, also play a part in the righting responses of animals dropped from an inverted position (Warkentin and Carmichael, 1939). Lane (1917) believed that there is a correlation between the development of the semicircular canals, as deter-

mined by histological studies, and the ability of the fetal rat to regain an upright posture when placed on its side. By about the tenth week the nonauditory labyrinth is well differentiated in the human fetus. Minkowski (1922) pointed out, as noted above, that in the fetus supported in the amniotic fluid vestibular stimulation elicits many responses that would not be possible in the newborn organism. This same author was careful, however, not to disregard the possibility that some of these responses may be the result of stimulation of proprioceptors in the neck and related regions. Magnus (1924) emphasized the part of neck-initiated responses in these activities (see also Camis, 1930, pp. 262-268).

Actually it is difficult to say what part the nonauditory division of the inner ear plays in fetal life. That these complexes of receptors are important, however, seems to be generally conceded. In a matter of minutes after normal birth the newborn guinea pig can stand upright. There can be no doubt that this highly coordinated and adaptive behavior is a function of proprioceptive as well as exteroceptive mechanisms. There is also good reason to conclude from the study of the air-righting reflexes of various mammals that the sensory control of posture continues to develop for some time after normal birth.

The Organic Senses

The activating responses associated with hunger and thirst apparently develop during fetal life. Hess (1922) pointed out, however, that early premature fetuses are less able than late infants to show the somatic signs of needing to be fed. The sucking reflex basic to ingestion of food in the newborn child is also developed long before birth. Food-ingesting activities are associated with many apparently random movements until in postnatal life they become patterned into more useful responses. The organic receptors associated with the cardiovascular system are also ready for activation during fetal

life and are presumably vigorously activated immediately after birth.

Taste

According to Parker (1922) taste buds develop in the human fetus during the third month. Taste receptors are actually found to be more widely distributed in the early fetus than in the adult. Parker found evidence of a retraction of the sensory field of taste during development. There seems to be evidence that salt, sour, and bitter, as against sweet, can be discriminated at birth (Carmichael, 1946; see also Pfaffmann, 1936).

Smell

Experimental work on the sense of smell in newborn infants has been summarized by Canestrini (1913), Peiper (1928), and Pratt, Nelson, and Sun (1930). It is fairly clear that during fetal life itself the receptors for the olfactory tract may be stimulated by amniotic fluid. On the other hand, they are probably not brought into differential activity for lack of a differentiated stimulus.

The so-called common chemical sense is often confused with smell. This sense is seen typically in the activation of the trigeminal nerve, and it is not olfactory in the ordinary meaning of the term. Stimulation of common chemical receptors in the nasal tract in the newborn child may bring about relatively violent reactions, such as sneezing. Ammonia is a typical irritant to this sense (Carmichael, 1946).

Hearing

Anatomical works on the structure of the ear of the late fetus (Hess, 1922) make it clear that there is no reason why the ear is not sufficiently developed to allow stimulation before birth (see summary by Pratt, Nelson, and Sun, 1930). In fact there is growing evidence that the human auditory receptors can be stimulated under certain circumstances during normal prenatal life. The auditory stimulus must then pass through the body wall of the mother, and

through the liquids and membranes surrounding the fetus. Forbes and Forbes (1927) reported a definite response by an unborn child to the sound produced by striking the bathtub in which the pregnant mother was bathing. And, as already noted, a similar response has been used as a basis for the study of conditioning in human fetal organisms. Preliminary studies seem to indicate that the human fetus can be stimulated by a wide range of tones from 20 to 5000 cycles per second while in utero (Bernard and Sontag, 1947).

Rawdon-Smith, Carmichael, and Wellman (1938) studied the electrical responses from the cochlea of the fetal guinea pig. After the ear was exposed, a suitably insulated electrode in a flexible holder was placed in contact with the external surface of the bone at the base of the exposed cochlea. The youngest fetus in which a cochlear response was secured had an age of 52 postinsemination days, but this is probably not the earliest age at which the response can be elicited. In the 52-day fetus a small response (2 microvolts) was obtained for a stimulus of 600 cycles per second and an intensity of approximately 100 decibels above the human threshold. Declining responses were obtained to tones below this and above 2000 cycles per second. Later fetal organisms gave electrical responses amounting to as much as 100 microvolts.

McCrary, Wever, and Bray (1937) also studied the electrical responses from the cochlea of the postnatal opossum while the organism was still living in the pouch. By studying sound-initiated reflex startle patterns and by electrical tests they demonstrated a development of the auditory sense. The first startle responses to sound stimuli were seen at about 50 days. When the electrical activity of the ear was studied at 59 days, it was found that sensitivity was greatest in the middle range, with a maximum at about 2000 cycles per second. By 82 days the maximum had shifted to 7000 cycles per second. At all ages studied in the

pouch-young opossum, the relation between the electrical response and the intensity of the stimulus is essentially linear, which suggests that these young organisms have a surprisingly efficient acoustical apparatus.

Vision

Embryologists point out that, by the second or third week of the embryonic period, changes have begun in the human fetus that are antecedent to the development of the eye (Keibel and Mall, 1910). Although it is unlikely that the fetal eye is ever strongly stimulated before birth, it may well be that, when the head of the late fetus is in just the right position, very strong light applied to the abdomen of the mother might lead to a visual response. Kussmaul long ago (1859) discovered that in a 2-months premature infant the difference between light and dark could be determined by specific reaction. Peterson and Rainey (1910) have confirmed this observation. This does not mean that the visual mechanism is structurally mature at birth, for there is evidence (Pratt, Nelson, and Sun, 1930) that the optic nerve and related structures are not fully developed even at normal birth.

Visual responses in fetal organisms can best be detected by electrical means and by observing reflex behavior, particularly the pupillary reflex (Hess, 1922). Care must be exercised (Parker, 1919) in interpreting such studies, however, not to confuse true neurally determined iris reflexes with the independent stimulation of the muscles of the iris by light. Other techniques, such as stimulation by moving striations of light and dark, have been used to study vision in developing animals (Warkentin and Smith, 1937; and Warkentin, 1938).

By way of summary it may be said that the anatomical development of the visual sense begins very early and continues throughout normal human fetal life and into postnatal life as well. It is unquestionably true that this sense has developed to a point at which some responses can be elicited long

before there is any reason to believe that in the normal environment such responses have biological utility. The development of this receptor mechanism is thus a notable example of the law of anticipatory function.

The Genetics of Behavior

CALVIN S. HALL

Western Reserve University

Six years after the inauguration of modern experimental psychology by Gustav Theodor Fechner, Gregor Johann Mendel founded the science of genetics by executing a brilliantly designed series of studies on the garden pea. It is a curious fact that these two life sciences which grew up in the same period of history have rarely worked closely together. Genetics has concerned itself almost exclusively with morphology; it has paid scant attention to behavior. Psychology, on the other hand, although it has taken a lively interest in heredity, has too often attempted to investigate the relation of behavior to genetic constitution by methods of pre-Mendelian vintage.

A real genetics of behavior promises to emerge, however, as psychologists continue to adopt the procedures of modern genetics, and as geneticists turn their attention more systematically to behavior. This encouraging trend will ultimately give status and stature to an interdisciplinary science of *psychogenetics*. The psychogeneticist of the future will presumably be trained in the methods and techniques of both genetics and psychology.

A survey of the present accomplishments of this hybrid discipline is the task of this chapter. It reviews the methods of genetics and their application to the investigation of the genetic basis for psychological traits, and it recounts some of the initial attempts to establish a genetics of behavior. It is not primarily concerned with the nature-nurture

argument, nor does it attempt to evaluate investigations of human heredity. In the writer's opinion, the genetics of behavior must be worked out on species that can be subjected to controlled breeding. At the present time this precludes human subjects.

The main objectives of psychogenetics are four in number: (1) to discover whether a given behavior pattern is transmitted from generation to generation, (2) to determine the number and nature of the genetic factors involved in the trait, (3) to locate the gene or genes on the chromosomes, and (4) to determine the manner in which the genes act to produce the trait.

HEREDITY AND BEHAVIOR

The first objective, to find out whether heredity plays a part in the determination of a psychological characteristic, may be realized best by the method of selective breeding and by the method of comparison of different strains, breeds, or species. The method of selective breeding is the more arduous of the two. The comparison of strains already established, e.g. wild versus tame strains of rodents, is relatively simple.

Selective Breeding

Selective breeding consists of mating animals that display the desired trait and of selecting for breeding from among their offspring those that express the trait. If the trait is regulated by heredity, continued se-

lection for a number of generations in a uniform environment will result in a strain that breeds more or less true for the character under study. Selection for more than one value of the trait may be made. In a trait that expresses itself alternately, e.g. susceptible or not susceptible to audiogenic seizures, two strains, susceptible and resistant, may be established concurrently by selective breeding. If the trait is one that expresses itself in degree on a continuum, e.g. maze learning, selection of a number of different values of the trait may be made. In practice, selection for a "quantitative" trait is usually limited to the extremes of the distribution, e.g. fast and slow maze learners.

Maze learning. Tryon (1940, 1942) was able to prove, by selective breeding, that maze-learning ability in the rat is inherited.

Tryon describes his experiment as follows:

An experiment was begun in 1927 that had as its purpose the establishment by selective breeding of a pure line of maze-bright and a pure line of maze-dull rats. Each animal was run nineteen trials through a seventeen-blind T maze. His score was the total number of

entrances into blind alleys. The breeding schedule consisted in mating together the brightest rat within each of the brightest litters, the dullest within each of the dullest. Rigorous environmental controls were effected (1) by instituting standard procedure of animal care and of breeding, (2) by using an automatic mechanical device for delivering the animals into the maze without handling, and (3) by employing an electric recorder for the scoring of each rat's maze run. These controls have remained constant for eleven years. Selective breeding has continued for eighteen generations. [1940, p. 112.]

Tryon's parental generation consisted of an unselected, heterogeneous population of 142 rats. The distribution of their scores appears on the top line of Fig. 1. As Tryon states, "the breeding schedule consisted in mating together the brightest rats within each of the brightest litters, the dullest within each of the dullest." These F_1 rats were run on the maze, and the resultant distribution of scores appears on the next line of Fig. 1. The same breeding procedure was followed for each successive generation.

* Critical ratio.

Gradually the two groups, maze-bright and maze-dull, pulled apart, and in F_7 there was practically no overlapping between them.

Tryon's experiment has been repeated by Heron (1935) with similar results. *Voluntary activity.* Rundquist (1933)

FIG. 1. Selective breeding for maze-learning ability in rats. (Tryon, 1942.)

Tryon writes, "There appears to be a law of diminishing returns, for after the F_7 negligible effects of selective breeding are noted" (1940, p. 114).

used the method of selective breeding to investigate the role of heredity in voluntary activity of the rat. Voluntary activity is defined as the number of revolutions turned

by the rat in a revolving drum. Rundquist selected for high activity and for low activity and was able to establish two strains that displayed some consistency, from generation to generation, in the two extreme

manifestations of the trait (Table 1). It is interesting to note that during the first four generations selection within each strain was not practiced. Instead Rundquist mated together the most active rats even though

FIG. 1 (continued).

they might have had inactive parents, and the most inactive rats even though they might have had active parents. As a consequence of selection regardless of ancestry, no differentiation between the groups occurred from F_1 through F_4 . If selection is to be effective in producing strains that breed true, it is necessary to continue breeding within the family lines that have been initially selected from the parental population.

Emotionality. A third example of selective breeding for a psychological trait is the investigation of emotionality in the rat by Hall (1938). Hall established that defecation and urination in a strange situation are valid measures of emotionality (1934). The procedure consists of placing a single animal in a brightly lighted circular enclosure 7 feet in diameter, for 2 minutes a day for 12 days. A record of urination and defecation on each trial is kept. The range of scores varies from 0 (no instance of either urination or defecation) to 12 (the rat defecates or urinates during every trial in the field). The parental generation, consisting of 145 rats, was a heterogeneous group. The high-scoring rats were mated together to start the emotional strain, and the low-scoring animals were bred *inter se* to initiate a nonemotional strain. In succeeding generations the highest scoring animals of the emotional strain were interbred and the lowest scoring animals of the nonemotional strain were interbred. The results appear in Table 2. The emotional strain becomes, on the average, more emotional until the ninth generation, when the mean becomes stabilized at approximately 10 and the standard deviation at a little over 2. Selection for nonemotionality yields less systematic results. The averages and variabilities fluctuate in a random fashion within rather narrow limits. It is significant that the maximum effects of selection for nonemotionality are realized in the first generation, whereas it takes nine generations for the emotional strain to become stabilized.

F_{12}	47	10.40	2.18	31	1.65	2.53	15.91

Further comment upon this point will be reserved for a later section.

The consistency within some litters of the emotional and nonemotional strains may be illustrated by two examples of parent-child resemblances. Two F_9 rats with scores of 10 and 12 had a litter of nine whose scores were 12, 12, 12, 12, 12, 12, 11, 11, and 10. Two nonemotional F_9 rats with scores of 0 and 0 had a litter of six whose scores were 0, 0, 0, 0, 1, and 1.

To the investigator planning a selective breeding experiment the following suggestions and cautions may prove useful. (1) Since an experiment of this nature usually requires many years and many dollars, the investigation of psychological traits of primary importance should be given priority. (2) The investigator should make certain that the measure or measures employed are reliable and valid. Tryon (1942) has discussed this point thoroughly. (3) Uniform procedures for raising, handling, and testing the animals are essential, since variations in procedure may distort conclusions. Temperature, feeding schedules, the type of food,

the amount and kind of handling, litter, size, the type of living cages, the age at which the animals are tested, and numerous other details must remain constant from generation to generation. The animals should also be kept free of parasites, for, as Russell (1941) reminds us,

... some differences that have been attributed to genetic causes may be due to parasites. Because of the limited number of parents, there is a relatively high probability that an inbred line will become uniformly infected, particularly with parasitic organisms that are transmitted from mother to offspring. [P. 347.]

(4) The health and vigor of the strains should be maintained at a constant level. Selection for uniform vigor as well as for the trait under study will help to insure the maintenance of the strains. (5) Fertility is another important requisite. Obviously the loss of a strain through sterility must be avoided. Fertility must be maintained even at the risk of the confusion that would be introduced into the genetic picture if the trait investigated should turn out to be correlated closely with fertility. However, the danger of such confusion is probably not great, for Wright (1922) has shown that variations in fertility and vigor are determined largely by environment. In practice only fertile animals should be selected for breeding. (6) The transmission of a trait from generation to generation may appear to be genetic, whereas in reality it is due to an extragenetic factor. The mode of transmission may be some prenatal or postnatal influence of the mother on the young. The prenatal influence can be determined by transplanting the fertilized egg to a host mother of a different strain. The postnatal influence can be investigated by placing the neonates with a foster mother.

In sum, the psychogeneticist must always remember that in studying trait inheritance he puts himself in the difficult position of

trying to prove a negative: that the trait in question is *not* due to extragenetic factors. He adds to the plausibility of his conclusions in direct measure as he controls the effects of all extraneous influences.

Strain Differences

A strain is defined as a group of individuals of a species that have a common lineage resulting from either natural or artificial selection and inbreeding. The extent of common ancestry determines the degree to which the strain is inbred. Close inbreeding, viz., brother-sister matings, for a number of generations eventually produces a pure strain. The animals of a pure strain are genetically identical except for the segregation of sex chromosomes. A pure strain will breed true for genetically determined traits, unless mutations occur. The animals of a strain that is not homozygous (pure), but in which some inbreeding has occurred, will tend to possess certain common characteristics that differentiate them from animals of other strains. Hence, by comparing the behavior of different strains, whether pure or not, we gain some information regarding the influence of heredity on behavior.

Wild and tame strains. Wild and tame strains of certain species, such as the dog, have been in existence since the Stone Age. The domesticated type differs markedly from the wild form in temperament. In rodents the viciousness of the wild animal stands out in sharp contrast to the docility of the tame form. Yerkes (1913), Coburn (1922), Stone (1932), and Dawson (1932) have made quantitative measurements of the difference in wildness and savageness of wild and tame rats and mice, and their results corroborate those evident to casual observation. Since the two strains breed true for wildness and tameness, it is evident that this difference has a hereditary basis.

Audiogenic seizures. Differential susceptibility of various strains of rats and mice to

convulsions produced by auditory stimulation has been noted by a number of investigators. Farris and Yeakel (1943) found that wild gray Norway rats, descendants of a captive wild strain maintained by King, reacted with greater frequency and severity to an air blast than did a sample of the inbred Wistar albino strain. Griffiths (1944), however, reports that not one animal out of 141 trapped wild Norway and Alexandrine

of these two investigations are in need of further elucidation.*

Maier (1943) found a difference between two strains of rats in his colony. In one strain 79 per cent of 116 animals tested reacted to the jingling of keys, whereas in the other only 29 per cent of 130 rats were susceptible. Martin and Hall (1941) obtained differences in susceptibility to audiogenic seizures between two strains of rats,

FIG. 2. A comparison of emotional defecation and urination in Norway and albino strains of rats. (Farris and Yeakel, 1945.)

rats displayed either hyperactivity or convulsions when stimulated by an air blast, key jingling, or a Galton whistle. Most of the rats were tested within a few days after they were trapped. Instead of displaying fear, they attacked the metal nozzle of the air hose. Griffiths suggests that the difference between his newly trapped non-susceptible wild rats and the highly susceptible King wild strain which had bred in captivity for from 46 to 49 generations may be due to conditions peculiar to domestication; for example, dietary deficiencies produced by laboratory stock diets, confinement in small cages, lack of practice in meeting new situations, and endocrine changes occurring during captivity. He also suggests that the King strain may have been selectively bred for sensitivity to sounds of high frequency. The contradictory findings

one that had been selectively bred for emotionality, the other for nonemotionality. More frequent and more serious seizures were displayed by the rats of the nonemotional strain.

In the foregoing investigations it is not at all clear just how inbred were the strains compared. One study (Hall, 1947) has been reported comparing two *pure* strains of mice maintained at the Jackson Memorial Laboratory. Mice of the Little *dba* strain (line 1) manifested many more audiogenic seizures and with greater severity than did mice of the Little *C57* black strain (line 6).

Emotionality. Gray Norway rats, descendants of the forty-third generation of the

* Another hypothesis (Patton, 1947) is that a necessary, though perhaps not sufficient, condition for audiogenic seizures in rats is middle-ear infection (Editor).

King captive wild strain, proved to be more emotional than Wistar albino rats (Farris and Yeakel, 1945). The test of emotionality used was defecation or urination during a 2-minute period on each of 12 days in a circular enclosed field (Fig. 2).

Tryon has reported briefly (1942) that there are personality differences between his two strains of rats. The rats of the maze-bright strain are more emotionally disturbed in nonmaze situations than are the maze-dull animals, whereas just the opposite is true in the maze proper, where the dull animals display more emotional upset.

These two studies confirm the finding that emotionality (or nonemotionality) is an inheritable trait in the rat.

Aggressiveness. It is fashionable to reject an instinct of pugnacity in favor of a frustration-aggression hypothesis. Social scientists are prone to assert that men fight for economic or political or social reasons or because they were taught to fight as children, not because there is anything inherent in man's nature that makes him aggressive. The Freudian theory that aggressiveness has its roots in the constitutional impulse has not been widely accepted outside psychoanalytic circles.

That aggressiveness (fighting) has a genetic basis is supported by three studies. Hall and Klein (1942) compared two strains of rats for aggressiveness. One strain had been selectively bred for emotionality (fearfulness), the other for nonemotionality (fearlessness). Two rats were placed together in a cage for 5 minutes, and they were rated for aggressiveness according to the following scale:

THE KLEIN-HALL SCALE OF AGGRESSIVENESS

- 0 No interest in each other except occasional slight nosing.
- 1 Frequent vigorous nosing. No blocking, shoving, crowding, or any other display of hostility.
- 2 Occasional blocking, shoving, or crowding.

- 3 Frequent blocking, shoving, or crowding of opponent. The aggressor keeps after the other animal throughout the period.
- 4 Slight wrestling and/or assuming a dancing position in which the rats clasp each other while standing nose to nose.
- 5 Fierce wrestling. They jump, roll, and turn all over the cage very rapidly.
- 6 Fierce wrestling. A rat bites the other hard enough to draw blood.

Three groups of male rats, 10 in a group, were tested. Each rat was paired with every rat in its group *twice*, once in its own living cage and once as a visitor to the other rat's home cage. The 15 nonemotional rats initiated 326 attacks as against 68 initiated by the 15 emotional rats. The severity of the attacks by the nonemotional rats was, on the average, twice that of the emotional animals. The investigators concluded that the basic determiner of fighting is a genetic one.

Scott (1942) observed differences in aggressiveness among three *pure* strains of mice maintained at the Jackson Memorial Laboratory. Observations were made under the following conditions: A strange male mouse was introduced into the home cage of the mouse to be tested, and behavior was recorded for a 10-minute period. As soon as a fight started, the visitor was removed in order to avoid fatal injuries. The visiting mouse was selected from a pure stock (Bagg albino), and a new mouse was used for each observation.

Scott, in lieu of quantitative data, presents the following impressionistic descriptions of the behavior of the three strains selected for study.

The *C57* blacks (subline 10) always showed immediate interest in the intruding male and made many contacts, at times apparently licking and cleaning him. There was no evidence of aggressive behavior, although they fought back when attacked. The *A* albino males made very little preliminary contact with the intruders and usually at-

tacked them within a couple of minutes. Finally, the *C3H* agouti males tended to sniff briefly at the intruder and then to keep to the opposite side of the pen for several minutes. During this time the fur fluffed up and the animals breathed in a labored fashion. If the intruder had not attacked in the meantime the *C3H* males eventually

after birth, so that each dam reared both black and albino offspring together. This did not produce a difference in fighting ability; the black mice reared by an albino foster mother were still superior, and the albino mice reared by a black foster mother were still inferior.

FIG. 3. A comparison of the types of "hypotheses" displayed in a multiple discrimination box by strains of rats selectively bred for brightness and dullness in maze-learning ability. (Krechevsky, 1933.)

started a fight, usually preceded by a series of feints and withdrawals. [Pp. 12-13.]

A quantified study of the aggressiveness of three of the Jackson Laboratory inbred strains of house mice was performed by Ginsburg and Allee (1942). Each mouse was paired with every other experimental mouse, and the winner of each bout was recorded. The *C57* black mice won the greatest number of fights, followed by the *C3H* agoutis, and the *C* albinos proved to be the most inferior in fighting ability. In order to control for the possible influence of the mother on the aggressiveness of her offspring, litters born by black and by albino females on the same day were split shortly

In the light of these findings, continued insistence upon the acquired nature of aggressiveness and the exclusion of the genetic contribution is unwarranted.

"Hypotheses." Krechevsky (1932) has conclusively proved that during the pre-resolution period in discrimination learning the rat displays systematic rather than random choices among the alternatives offered it. He has termed this systematic behavior an "hypothesis." In order to discover whether genetic factors play a part in the type of hypothesis selected, Krechevsky (1933) ran groups of Tryon's *F7* maze-bright and maze-dull strains in a multiple-discrimination box. He also tested a group of heterogeneous ani-

mals. The problem set the animal had no solution, since the correct pathway through the box was varied at random from trial to trial. It was possible for the animal to have eight different "hypotheses," four of which were visual and four spatial. The results are depicted graphically in Fig. 3. Krechevsky concludes,

... there is a definite indication that the "bright" strain of animals, when placed in a

FIG. 4. Illustrating the definition of the angles θ and α in geotropic orientation in young rats. (Crozier and Hoagland, 1934.)

difficult (non-solvable) situation, attempt spatial "hypotheses" in trying to solve the problem, the "dull" animals attempt non-spatial (visual) "hypotheses," and a non-selected group try about as many spatial as visual "hypotheses." In other words the kind of "hypotheses" which an animal can bring with him to a problem situation is to some extent hereditarily determined. [Pp. 108-109.]

Geotropism. Young rats are negatively geotropic; i.e. they will crawl up an inclined plane (Crozier and Hoagland, 1934). The rat's path up the plane forms an angle with the horizontal which is a function of the angle of inclination (Fig. 4) and is described by the formula,

$$\cos \theta = a - b \sin \alpha$$

where a and b are constants. Three different strains of rats, A , B , and K , each of genetic uniformity, were tested for the form of the functional relations. The form of the function is the same in the three strains, but the

numerical values of the constants are characteristic for each strain. Figure 5 shows that the intercept constants and the slope factor are clearly different for the two races, A and K , although the form of the function is the same. The slope factor is the same for strains A and B , but the threshold intercept is higher. The three strains differ in two respects, namely, slope and intercept constants.

Temperature preferences. If a mouse is presented with a wide range of cage floor temperatures from which to choose, he will select after some trials a particular temperature in which to rest and sleep. This temperature is referred to as his "thermotactic optimum." Herter (1936) found dif-

FIG. 5. Data from several series of observations with young rats of three strains, K , A , and B , which illustrate strain differences in geotropism. (Crozier and Hoagland, 1934.)

ferences between the temperatures preferred by wild and albino strains of mice. The thermotactic optimum of the albino strain is 34.36 ± 0.12 , and that of the wild strain is 37.36 ± 0.12 degrees C.

Speed of reaction. Utsurikawa (1917) invented a simple device for measuring the rat's speed of reaction. One end of a small box rests on legs; the other is suspended from

a spring. Movements of the rat in the box move the spring, and these vertical displacements are recorded on a kymograph. A bell was used as the stimulus, and the speed and intensity of reaction were measured. Utsurikawa tested two strains of rats, one inbred and the other outbred, and found that the inbred rats reacted more quickly and with greater intensity than the outbred animals. Vicari (1929) measures speed of running in a simple two-unit maze. Different strains of mice differed in the average speed with which they traversed the pathway.

This summary of experiments involving selective breeding and strain comparisons is intended to be illustrative rather than complete. Heredity is pervasive. The major dimensions of temperament, viz. emotionality, activity, aggressiveness, reactivity, have their source in the germ plasm. Intelligence as measured by maze learning and by the use of "hypotheses" has a genetic basis. The fact that temperature preference is inherited suggests that 'interests' and 'values' may be originally determined by genetic constitution.

It is likely, on theoretical grounds, that heredity is a factor in all psychological traits. The justification for this broad generalization rests upon the organismic or holistic viewpoint which has gained prominence in recent years. According to this doctrine, as applied to behavior, any act is an expression of the whole organism. Since the chromosomes are constituents of the organism — indeed, they are the principal differentiated structures of the primary organism, the fertilized egg, as well as of each cell in the multicellular individual — they must be of extensive organismic significance. Genetics has proved this to be true for morphology and some physiological functions. It has yet to be fully documented for psychological characteristics.

It needs to be reiterated that the building of a science of psychogenetics does not deny the role of modifiability, which is itself an inborn property of living organisms. Is there anyone who doubts that profound alterations

can be made in the structure, function, and behavior of living organisms? With each addition to his knowledge, man gains an increment of power to change the world and himself. The genes themselves are subject to alteration by external forces, e.g. X-rays, radium rays, ultraviolet light, and heat rays. It should be emphasized, however, that, if a change is to be instituted through education, therapy, or stimulation by various forms of energy, the effectiveness and precision of the alteration will depend primarily upon our knowing the nature of the raw material that is to be altered. Psychogenetics is the study of this raw material.

GENETIC ANALYSIS OF BEHAVIOR

In order to have a genetics of behavior it is not sufficient merely to show that psychological traits, like morphological features, have a genetic foundation. Genetic analysis is also required. The number of gene pairs that contribute to the expression of the trait and the presence or absence of dominance in each pair should be identified. A slight beginning in this direction has been made; more rapid strides will follow as investigators make increased use of highly inbred strains — strains that have reached maximum homozygosity. Calvin Stone (1947) has observed,

To many of us who have worked for a long time in the field of comparative psychology it is a matter of shame and regret that only an amateurish beginning has yet been made by psychologists in the utilization of pure lines of animals in fundamental research in the nature-nurture area. [P. 344.]

Geneticists assert that in order to work out the genetics of quantitative traits, such as maze learning, highly purified and genetically homogeneous strains are essential. Since quantitative traits are the ones that most interest the psychologist, let us consider more at length the method of obtaining these

essential pure strains (see also the excellent account by Russell, 1941).

Inbreeding

The objective of inbreeding is to produce a homozygous strain, one in which all the animals are identical genotypes except for the segregation of the X and Y chromosomes.

there are only two parents for each generation and these parents are always brother and sister. When a pure line has been established, complete relaxation of inbreeding should be avoided: it will tend to perpetuate any heterozygosity that may be introduced by mutation. However, in order to make available a large number of homozygous

FIG. 6. The percentage of homozygosity in successive generations under three systems of inbreeding. (Russell, 1941.)

The rate at which homozygosity is reached varies with the closeness of inbreeding. Self-fertilization, which is possible only in certain plants, results in virtual homozygosity after eight generations. Brother-sister matings produce approximate homozygosity in about thirty generations, and double first cousins in about forty-five generations (Fig. 6). When the inbreeding is as far removed as second cousins, the percentage of homozygotes does not materially increase from generation to generation.

Inbred strains of laboratory mammals have been produced almost exclusively by brother-sister mating. Under this system

animals, inbreeding in an isogenic line may be temporarily halted; but it is always advisable occasionally to bring the inbred line back to a single pair of parents by discarding for breeding purposes all but a single brother-sister pair.

Russell (1941) has issued a warning regarding the risk of an accidental outcross of an inbred line.

Since a high degree of homozygosity is obtained only after many generations of inbreeding, a single unfortunate outcross may undo years of work. In a mouse colony in which different lines are maintained, an accidental outcross may occur as a result of

faulty pens, into which stray animals can enter, or the returning of animals to the wrong pen after removal for any purpose. Risk of the latter can be reduced to a minimum by handling different lines and sublines at different times and by keeping them in separate parts of the laboratory or cage rack, certainly not in adjacent sections of wooden boxes. When several inbred lines are to be started it is desirable to mark them with different coat colors or other genetic characteristics, contamination of which will be readily recognized. [Pp. 344-345.]

Selection for a particular characteristic is often combined with inbreeding. In selective inbreeding it is desirable to start with a parental generation of maximum heterogeneity in order that all the alleles (genes occupying corresponding loci on homologous chromosomes) of all factors that influence the trait may be represented. Furthermore it is a wise practice to start a number of sublines from the parental generation, since the expression of the trait in some animals may be nongenetically controlled. If two animals, i.e. a brother and sister, in which the trait is nongenetic should be selected, the desired genetic factors would be lost, and the investigator would have to begin all over again with a heterozygous population. If he starts with a number of sublines, he can discard those that do not produce offspring like themselves. Selection and brother-sister matings within each subline should be rigorously followed and crosses between sublines studiously avoided if complete homozygosity is desired. One subline may not be genetically identical with another subline, since it is probable that different genetic patterns become fixed within each subline. Starting a number of sublines from the original parental generation helps also to insure against the strain's dying out. When genetic uniformity has been attained in the several sublines, it is then possible to retain one line and discard the others.

In order to work out the genetics of a psychological trait it is necessary to obtain

two or more pure strains that differ in their expression of the trait. These strains may be secured by selective breeding, or they may be obtained by finding differences in a trait between strains that have been inbred for other purposes or in which there has been natural inbreeding. Since many inbred strains of mice have been developed and are now available, particularly from the Jackson Laboratory at Bar Harbor, Maine, it would be fruitful to investigate other psychological traits in these strains already at hand.

Another advantage of employing pure lines is that the occurrence of a mutation that might influence a behavior trait is more easily noticed. If the mutant form differs in behavior from the pure strain, we are informed of the additional fact that the trait is controlled by a single pair of genes.

Unit Characters

A trait conditioned by a single pair of alleles is called a unit character. It is sometimes assumed that, because psychological characteristics are predominantly quantitative in their expression and are distributed normally, they must be determined by many genetic factors rather than by one or two pairs. On the other hand, several unit characters of distinct psychological significance have been discovered. Other unit characters will doubtless be identified as progress is made in psychogenetics.

A unit character is identified by making various types of crosses and comparing the results with those that would be theoretically expected if a single pair of genes were operating. If two pure strains, *A* and *B*, display a dichotomy in behavior, *M* and *N*, the first step is to hybridize the two strains. If the trait is a unit character, the hybrids can behave in only one of three possible ways: *M*, *N*, or intermediate between *M* and *N*. If they all manifest behavior *M*, resembling thereby the parent strain *A*, the allele conditioning *M* is dominant over the allele conditioning *N*. If the F_1 's resemble the other parent strain *B*, the allele for *N* is dominant

over the one for M . Finally, if the hybrids are intermediate in behavior between M and N , the pair of genes are said to blend; that is to say, they contribute equally to the trait and no dominance exists.

The second step is to mate the F_1 's *inter se* to obtain the F_2 's. If dominance exists, a ratio of three animals resembling the dominant strain to one animal resembling the recessive strain is expected among the F_2 's. Two backcross matings, F_1 with the dominant strain and F_1 with the recessive strain, will yield ratios of 1:0 and 1:1 respectively, for a unit character.

Russell (1941) observes that even when these ratios are obtained they are not critical criteria for the presence of a single pair of genes.

There is a common belief that a character occurring only in alternate categories (as opposed to the other extreme: a continuous distribution) must be due to alternate genes in the same way that agouti and black coat color are. This has sometimes led to a hunt for a single major gene difference as the cause of a character difference that shows no, or little, overlap in two inbred strains. . . . Such a hunt is all right if it is critical. It can only be critical if cognizance is paid to the fact that, owing to the common occurrence of biological thresholds, of all-or-none processes in development, many characters are necessarily alternate in expression. Many genes may be involved, the effects of some combinations falling below the threshold, while the effects of the others fall above. If this fact is realized it will be appreciated that apparent dominance in the F_1 of a cross between strains, a 3:1 ratio in the F_2 , and a 1:1 ratio in the backcross, are not critical criteria of the presence of a single major pair of genes. Many genes may be involved and the above generations happen to be cut by a threshold of effect into approximately the above proportions. . . . *The critical experiment is to test the genetic nature of the types apparently segregating in the backcross or F_2 by breeding them with the "recessive" stock.* [P. 346, italics Hall's.]

Several examples of unit behavior characters will be presented.

Audiogenic seizures. Two pure strains of house mice which differed greatly in the number and severity of audiogenic seizures were crossbred according to the steps outlined above, including the crucial test suggested by Russell (Witt and Hall, 1949). The results of the several types of matings are summarized in Table 3. The observed percentages conform closely, except for the critical backcross (the last cross in Table 3), to those that would be expected if audiogenic seizures are a unit character. The divergence of the critical backcross suggests that there may be some modifying factors. If there are such modifying factors, they are of minor importance since the other crosses yield progeny who react as though audiogenic seizures were inherited as a *single dominant gene*.

The genetics of audiogenic seizures has been investigated in the genus *Peromyscus*, which includes the deer mouse and other white-footed mice of North America. The genetic analysis differs from that found by Witt and Hall for the common house mouse of the genus *Mus musculus*. Dice (1935) and Watson (1939) conclude from their investigations that epilepsy, as they label the behavior that is conventionally called "audiogenic seizure," is a recessive character. Dice's conclusion is based upon meager data. Epileptic males mated with normal females yielded 15 offspring, all of whom behaved normally when they were exposed to jingling keys. The backcross of the F_1 's to epileptic males produced 48 offspring, 12 epileptic and 36 normal. This obtained ratio of 1:3 diverges greatly from the expected ratio of 1:1, were the trait a recessive one.

Watson used many more mice in her investigation. A summary of the most pertinent results appear in Table 4. The 12 mice of the Palouse River stock who should have reacted, but did not, Watson terms "normal overlaps." A normal overlap is a mouse who is genotypically epileptic but pheno-

typically resistant to auditory stimulation. By correcting the backcross and F_2 progeny for the percentage of normal overlaps (6.1), the obtained percentages conform very closely to those that would be expected on the assumption that audiogenic seizure (epilepsy) is inherited as a *single recessive* gene in *Peromyscus maniculatus artemisiae*.

The contrasting results obtained for *Mus musculus* and *Peromyscus maniculatus artemisiae* demonstrate that for two genera the genetic constitution underlying the same type of behavior may be different. In the former genus the gene for audiogenic seizures is a dominant; in the latter it is a recessive. Modifying factors may, of course, be present in both.

Investigations of the genetics of audiogenic seizures in rats have yielded contradictory results. Maier and Glaser (1940) found that their data, obtained from crossing (1) susceptible with susceptible, (2) susceptible with resistant, and (3) resistant with resistant, fitted the assumption that the trait was a dominant one. The percentages of offspring reacting with seizures from the three types of crosses were 74, 52 and 0, respectively. However, Maier (1943), in a later investigation, did not confirm the Maier and Glaser findings. He concluded that the genetics of audiogenic seizures is complex rather than simple. However, since in neither study were uniform strains used, the results are necessarily ambiguous. The same criticism applies to Griffith's (1942) attempt to unravel the genetics of audiogenic seizures in rats. He divided his animals into an *H* group which reacted on 50 per cent or more of their 60 standard preliminary trials and an *L* group which reacted on less than 50 per cent of the trials. The results of $H \times H$, $H \times L$, and $L \times L$ crosses suggests, according to Griffiths, two pairs of genetic factors.

Finger's (1943) experiment does not help to elucidate the genetics of audiogenic seizures in the rat. He made various crosses and obtained the results shown. He observes

	PERCENTAGE	
	No.	SUSCEPTIBLE
Susceptible \times susceptible	58	66
Susceptible \times resistant	63	73
Resistant \times resistant	22	68

that "it appears very doubtful that the tendency (to react with a seizure) is inherited as a simple Mendelian dominant."

As a result of using impure strains of rats, three different types of genetic constitution have been postulated for audiogenic seizures: a simple dominant (Maier and Glaser), two pairs of genes (Griffiths, 1942), and multiple factors (Maier, Finger). It should be clear, from this example, that a genetics of behavior cannot be developed by utilizing strains of unknown genetic constitution.

Thermotactic optimum. As previously mentioned, different strains of mice may prefer different temperatures. A cross between a wild strain whose average thermotactic optimum was 37.36 degrees C and an albino strain whose preferred temperature averaged 34.36 degrees C resulted in an F_1 whose preference, 34.76 degrees C, resembled that of the albino strain. Other crosses were made. A summary of all the results is presented in Table 5.

These findings, according to Herter (1936, 1938*a, b*), indicate that the thermotactic optimum is dependent upon a single pair of genes, the gene causing the lower optimum being dominant over its allelomorph causing the higher optimum. The small number of animals observed is a weakness of this study. However, should this finding be corroborated, it would suggest that other preferential or choice behavior might have a simple genetic basis.

Mutations in Inbred Strains

The value of maintaining and systematically observing inbred strains is enhanced by the fact that any mutation that occurs will be more readily noticed in a uniform stock than in a heterogeneous one. In support of this statement, the important findings of King and Donaldson (1929), King (1939),

TABLE 5

CROSSES BETWEEN STRAINS OF MICE WITH DIFFERENT TEMPERATURE PREFERENCES (AFTER GRÜNEBERG)

	No. of Individuals		No. of Deter- mina- tions	Average Thermotactic Optimum in Degrees C	Range of Averages for Individual Mice
	Obtained	Expected

Type 2 (recessive)	12	14	600	37.32 ± 0.12	36.74-37.80

and Keeler and King (1942) of the Wistar Institute may be cited. Wild gray Norway rats were trapped, and they constituted the parental generation from which numerous filial generations were bred. Many mutations, expressed in coat colors, occurred during the maintenance of this uniform, although not entirely purified, strain. In 1942 Keeler and King published an account of the differences in behavior of these mutant strains. The following character sketches were formulated from independent descriptions made by five observers who were familiar with the strains.

Mutant albino. When not tamed they are as wild and vicious as the original gray Norway rats. When tamed they resemble the tamed Norway in their tendency to bite when handled.

Cinnamon (brown pigment). They are easier to tame than grays, but they may revert to their original wildness. They are ordinarily more peaceful than grays, but, when they do fight, they fight as well as the grays.

Curly. They are difficult to catch even after they are tamed. They ordinarily do not bite when held, but they can never be entirely trusted.

Stub. These animals are always fighting one another. They do not mind their own

business as do the gray rats, but throw themselves against the cage when anyone approaches.

Albino waltzers. They are easier to tame than mutant albinos from which they were derived. When tamed they rarely bite their handler.

Black. The black strain does not have to be tamed, since they are tame by nature. If very excited they may click their teeth, but they are not apt to bite.

Although these descriptions are impressionistic, one of these mutant strains, the black, is unique in comparison with the others. This difference in behavior of the wild and savage gray Norway rat and the tame and docile black rat is ascribed by Keeler and King to the mutation of a single gene in the original Norway strain. They write:

A survey of eighteen stocks shows that most of the naturally tame strains of albino rats now employed in American scientific laboratories were tamed principally by the black gene or by the black and piebald genes combined, the coat color effects of which genes are masked by albinism as we have stated above. Most of the stocks not bearing the black gene are probably tamed principally by other mendelian genes such as pink-eyed yellow, red-eyed yellow, hairless,

and ruby-eyed dilute, because strains containing these genes singly are, in our experience, invariably tame. [1942, p. 249.]

This is a dramatic finding. The popular theory of domestication asserts that tame strains of animals came into existence as a consequence of the accumulation of a host of gene mutations, each mutation contributing an almost imperceptible amount to the final result of the domesticated strain. According to Keeler and King, a single mutation transforms a wild form into a domesticated one. A major evolutionary step is mediated by a minor gene-change. They state, "*It is also clear that the basis of temperament and behavior is inherited in gene controlled patterns, the effects of a single gene being distributed irregularly throughout the whole field of response, like dabs of a particular color in a polychrome print*" (1942, p. 246).

It should be borne in mind that this discovery was made possible by having available for observation over a number of generations a relatively homozygous line.

A number of mutations that express themselves in bizarre neuromuscular disorders have been found in inbred strains of house mice. The mutant forms, all of which are recessive, the genetic symbol, and a brief description of the behavior of each form follow.

Waltzing: (*v* for *valse*, French). As described by Yerkes in 1907, the behavior consists of "(1) movement in circles with all the feet close together under the body, (2) movement in circles, which vary in diameter from 5 to 30 cm., with the feet spread widely, and (3) movements now to the right, now to the left, in figure eights." Exclusive circling in one direction does not occur, although preference for right or left turning does appear.

Shaker 1: (*sh-1*). The salient feature is a nervous head movement which consists of rapid, successive, upward jerks of the head.

Shaker 2: (*sh-2*). This form is phenotypically indistinguishable from shaker 1.

That the genes for shakers 1 and 2 are different has been established by crossing *sh-1* with *sh-2*. If they were the same recessive gene, all F_1 's should express choreic head movements. Actually, all F_1 's are quite normal.

Jerker: (*je*). This mutant is also indistinguishable from both shakers, but that it is a different gene has been confirmed by appropriate crosses.

Pirouetting: (*pi*). As first described by Woolley and Dickie (1945), the behavior is that of rapid whirling in circles of small diameter.

The mouse swings its head sharply to one side, places the inner forefoot back toward the rear foot, toes turned out, and seems to place the opposite forefoot in such a position that it aids in pushing the mouse into a small diameter rotation. The mice whirl incessantly for long periods of time. [Pp. 282-283.]

It is regrettable that comparative psychologists have not had or availed themselves of the opportunity to make routine behavior measurements of inbred strains of rodents. Such strains have been in existence in this country and in Europe for some years and have provided the biogeneticist with some of his best material. Numerous gene mutations, affecting principally such morphological characters as coat color, hair texture, size and body form, and diverse skeletal features, have been described by Grüneberg for the mouse. In his 412-page book, fewer than four pages are devoted to behavior.

Multiple Factors

When several sets of genes contribute to the determination of the same character, they are called multiple factors. Formerly it was assumed that multiple factors have equal and cumulative effects on the character, but it is now well established that dominance may also be present. The existence of multiple factors is indicated when the F_1 's are uniform and intermediate be-

tween the two parental strains in behavior and the F_2 's are extremely variable.

Tryon (1942) believes that a theory of multiple factors explains the fact that a continuous unimodal distribution is usually found when a population is measured for a psychological trait. He writes:

We shall describe this theory by showing how it may account for individual differences in maze-learning ability. It is assumed that there is a large number, k , of genes determining this ability. First, consider one of these genes, A, which exists in two degrees of expression, A and a . An individual of homozygous constitution, AA , is brighter than one of aa constitution, and a heterozygous individual, Aa , lies between the two. No dominance is assumed. But there are k such genes, A, B, C, D, ..., each possessing the same properties as those described for A. Thus an individual of constitution $AABBCCDD$... would be the brightest possible in maze ability; $abbccdd$... the dullest; and $AaBbCcDd$... would be average. All degrees of ability would be possible: $aABBCCDD$... next to brightest, $aaBCCDD$... next, $aabCCDD$... next, and so on. Thus the continuity of individual differences is adequately explained. Under random mating, the types of individual that could exist and the frequency of each can be found from the product of $(A + a)^2 (B + b)^2 (C + c)^2 (D + d)^2$ In the resulting series the terms show the various genotypes, and their coefficients the frequency of their occurrence. The result is a *normal distribution curve*, if k is large enough. Hence, the wide, continuous, and unimodal dispersion of individuals in the P generation ... [see Fig. 1] whose parents were randomly mated is adequately accounted for.

According to this theory, the effects of selective breeding result simply from the gradual sorting into one race of all the large-lettered genes for brightness, and into the other, all the small-lettered genes for dullness. In a final bright pure line, all individuals would be $AABBCCDD$..., and their progeny would be exactly like them; analogously, in the dull pure line, all would be

$abbccdd$... and would breed true for dullness. [P. 349.]

Although Tryon has made a plausible case for the importance of multiple factors in the genetics of behavior, as yet his view can be supported by very little concrete evidence. To date, more unit characters than multiple factor traits have been isolated. Tryon's own investigation of the inheritance of maze-learning ability has produced equivocal results. Those of Brody (1942) and of Hall (unpublished material) are equally inconclusive. These three studies contain inherent weaknesses which will be brought out in the following discussion.

Maze learning. Tryon crossed his 'bright' and 'dull' strains to produce an F_1 and intermated the F_1 's to secure an F_2 . If the lines were pure at the time of hybridizing, the F_1 generation would show uniform maze performance and the F_2 generation would display wide variability in maze learning. The F_1 progeny were not uniform; they were just as variable as the F_2 rats (Fig. 7). These results mean that the strains were not pure at the time they were crossed. This is to be expected because of the type of inbreeding Tryon followed. Instead of a single line of brother-sister matings, each strain actually consists of a number of sublines. It is not likely that different sublines will be genetically identical; different hereditary patterns will ordinarily become fixed within each subline. Accordingly, if a heterogeneous sample of rats from several bright sublines are mated with an equally heterogeneous sample from various dull sublines, the F_1 progeny obviously will vary widely in maze performance. Moreover, if Tryon had permitted a certain amount of crossbreeding between sublines while he was developing the two strains, genetic homozygosity within each strain would not have been achieved. Close inbreeding within a single line is essential for the establishment of pure lines.

Voluntary activity. The ambiguity that results from crossing strains that are not

homozygous for the trait being studied is revealed by Brody's study (1942) using Rundquist's active and inactive strains of rats. Brody crossed active F_{21} females with inactive F_{21} males and inactive F_{21} females

generations are presented in Table 6. Only one systematic trend appears in the results for both generations. F_1 backcrossed to the active strain produces offspring that resemble the active parent strain, whereas the

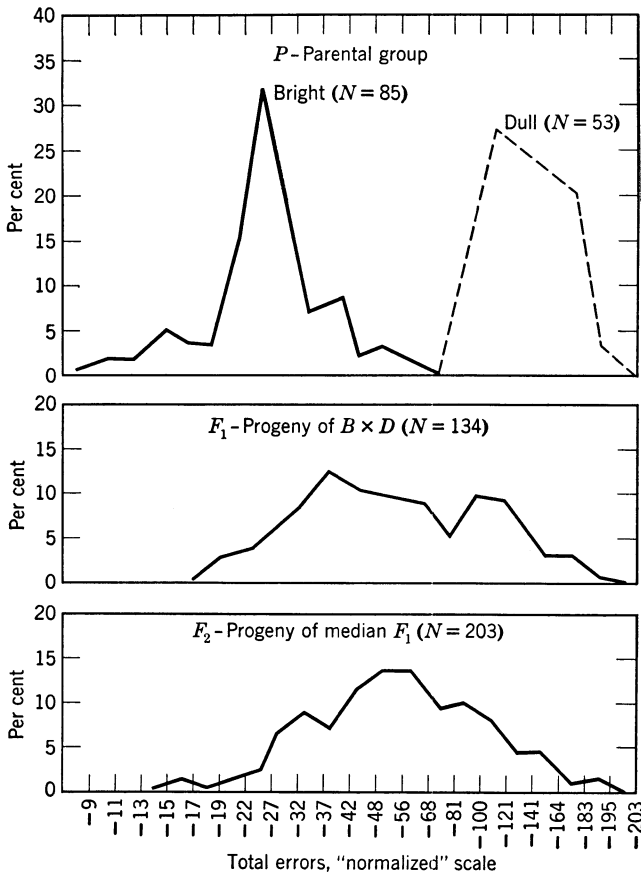

FIG. 7. The results of crossing two strains of rats selectively bred for brightness and dullness in maze-learning ability. (Tryon, 1940.)

with active F_{21} males. Since the offspring of these reciprocal crosses did not differ significantly in their activity, they may be lumped together. The F_1 progeny were bred together to obtain an F_2 . The F_1 rats were also backcrossed to (1) rats of the active strain and (2) rats of the inactive strain. The same breeding program was carried out with a sample of the F_{22} generation. The results of these several crosses for the two

progeny of $F_1 \times$ inactive strain resemble the inactive parent strain. This suggests that more of the contributing genes are dominant for higher activity level. Other than this, the data are inconclusive. By some legerdemain I am unable to follow, Brody concludes that "... the two strains differ with respect to a single gene rather than with respect to multiple factors The gene apparently behaves as a dominant

TABLE 6

A SUMMARY OF RESULTS OBTAINED FROM CROSSES BETWEEN ACTIVE AND INACTIVE STRAINS OF RATS (AFTER BRODY, 1942)

(Revolutions in thousands for 15 days)

	Mean	S.D.	×	Mean	S.D.
F_{21}	Active females			Inactive males	
	125	37		10	14
F_{21}	Inactive females		×	Active males	
	14	20		140	54
	Females			Males	
F_1	116	56		75	43
F_2	69	66		33	44
$F_1 \times$ active	129	69		55	57
$F_1 \times$ inactive	41	67		2	4
F_{22}	Active females		×	Inactive males	
	169	54		11	19
F_{22}	Inactive females		×	Active males	
	17	24		110	51
	Females			Males	
F_1	81	60		22	28
F_2	143	80		42	47
$F_1 \times$ active	182	43		95	61
$F_1 \times$ inactive	53	52		11	13

in the males and as a recessive in the females" (1942, p. 23). This type of gene, which is dominant in males and recessive in females, is called a *sex-influenced* factor.* An example of sex-influenced characters, which are quite uncommon, is baldness in man. Brody's findings do not seem to justify the conclusion that the difference between the Rundquist strains results from a single sex-influenced gene pair. That there is a genetics of activity cannot be questioned, but until strains homozygous for activity and inactivity are available the genetics of this important trait will remain unknown.

Emotionality. Hall (unpublished data) made three crosses for the F_{10} , F_{11} , and F_{12} generations of his emotional and nonemotional strains of rats. The results are presented in Table 7. Had the two strains been pure, the variability of the hybrids would

* A sex-influenced factor should not be confused with either a *sex-linked* or a *sex-limited* factor. A sex-linked factor is one that is carried in the sex chromosomes and may be either dominant or recessive. A sex-limited factor is one that is capable of expression in one sex but not in the other.

TABLE 7

A SUMMARY OF THE RESULTS OBTAINED FROM CROSSES BETWEEN EMOTIONAL AND NON-EMOTIONAL STRAINS

Generation	No. of Offspring	Defecation-Urination Scores	
Emotional × nonemotional		Mean	S.D.
$F_{10} \times F_{10}$	32	4.53	3.84
$F_{11} \times F_{11}$	22	2.81	2.15
$F_{12} \times F_{12}$	27	3.00	2.55

have been smaller than that found. These results duplicate those of Tryon, since the means and standard deviations closely resemble the heterogeneous parental population, whose mean and standard deviation was 3.86 and 3.54, respectively. It was deemed unfruitful to make further crosses with impure strains. The most that can be inferred is that the alleles for nonemotionality are dominant over those for emotionality. The dominance of the nonemotional factors would explain (1) the skewness of the distribution of scores for the parental generation; i.e. there was an overbalance of low-scoring animals; (2) the rapid effects of selection in the nonemotional strain (Table 2); (3) the slower effects of selection for emotionality (Table 2); and (4) the greater resemblance of the scores of the hybrids to the nonemotional animals than to the emotional rats.

In view of the negative results obtained by Tryon, Brody, and Hall, the multiple-factor theory as applied to the genetics of behavior traits remains unproved. Since the negative results were obtained by faulty methods, it is probably only a matter of time before evidence for the theory will be provided. It is certainly the most plausible theory by which to explain the genetics of traits that conform to the normal probability curve.

THE MAPPING OF CHROMOSOMES

In view of the embryonic state of psychogenetics any extensive discussion of this topic at this time would appear to be premature. With the exception of some of the neuro-

muscular disorders, e.g. waltzing, shaker, and pirouetting, there is no information regarding the location of the genes on the chromosomes for behavior characters. Consequently this objective of psychogenetics will be discussed only in general terms.

When two or more factors are located on the same chromosome, they are said to be *linked*. The evidence for linkage is provided by the way in which characters hang together. Thus in the house mouse, the two characters, waltzing and jittery, appear together, whereas waltzing and shaker 1 do not. The factors for waltzing and jittery are assigned to the same chromosome (No. 10) whereas waltzing and shaker 1 are assigned to different chromosomes (Nos. 10 and 1, respectively). However, linked factors do not invariably stay together, and because of this it is assumed that there is an exchange of homologous parts between the chromosome pairs early in the maturation of germ cells. This is called *crossing over*. The amount of crossing over provides the basis for locating the genes more or less accurately on the chromosomes. A large amount of crossing over implies that the two genes are far apart on the chromosome; a small amount implies that they are close together on the chromosome.

Snell (1945, for example, found that there was 26 per cent crossing over in an F_2 population bred from an F_1 generation heterozygous for waltzing and jittery. This is a high value for crossing over and suggests that the two genes are widely separated on the same chromosome. Their location as given on a chromosome map of the mouse is at the two ends of chromosome 10 (Staff, Jackson Laboratory, 1945).

Aside from shaker 1, shaker 2, waltzing, and jittery, no other genes for behavior characteristics in the mouse have been mapped.

HOW GENES PRODUCE BEHAVIOR TRAITS

“Between the presence of the genes in the chromosomes and the appearance of the de-

veloped characters in the individual organism there exists a gap which is not yet thoroughly understood” (Snyder, 1940, p. 356). This is Snyder’s opening sentence in his chapter on *How Genes Act*. In the same chapter he summarizes the known genetic effects in development:

... a complete complement of chromosomes as well as a normal environment is necessary for development; early differentiation is probably effected primarily by gradients imposed from without upon a cytoplasm already under the control of genes; later differentiation takes place through interactions of genic substances in differential gradients, the whole process being a continuous one of reciprocal reactions between genes and cytoplasm in progressively differing gradient fields; and finally the action of the genes may take the form of enzyme production, elaboration of reactive chemical substances, or modification of the plane or frequency of cell division in localized areas. [Pp. 364-365.]

It is not within the scope of the present chapter to weigh and evaluate the conflicting hypotheses regarding the action of the genes. The exact nature of gene action will be worked out by the cooperative efforts of geneticists, cytologists, and embryologists.

It is within the province of psychogenetics to inquire about the bodily structures and functions which regulate behavior and which are in turn regulated by the genes. For it should be apparent that the genes cannot control directly a psychological trait, e.g. maze-learning ability; they can only exert an influence through the mediation of physical structures.

Few clear-cut studies correlating genetic constitution, bodily structures, and behavior have been reported. Herter’s (1938) investigation of the thermotactic optimum is a model in this respect. Having discovered that the temperature preference of the mouse is dependent upon a single pair of genes, he then sought an answer to the question: upon what physical feature does this preference rest? He found that body

temperature as taken rectally was not the factor, since the wild strain, which preferred the higher temperature, had approximately the same body temperature (37.39 degrees C) as the albino strain (37.68 degrees C), which chose the lower temperature. Also, the temperature of the belly differed only slightly: 32.93 degrees C for the wild mice and 31.14 degrees C for the albino mice. Herter then examined the skin and fur of the belly and ascertained that the density of the fur and the thickness of the epidermis differed in the two strains. The wild mice had about 70 hairs per unit square as compared with about 46 hairs for the albino mice. The skin of the wild mice was markedly thinner than that of the albino animals. The F_1 progeny obtained from crossing wild \times albino resembled the albinos in thermotactic optimum, hair density (51.66 hairs per unit square), and thickness of epidermis. In a backcross of F_1 mice to the wild strain, 12 mice with a preferred temperature of 34.56 degrees C had an average hair density of 52.75, and 8 mice with a thermotactic optimum of 37.10 degrees C had a density of fur of 70.94. Undoubtedly the preferred temperature is controlled by the density of the belly fur and the thickness of the belly skin, and it is these features that are determined by the genes.

Many differences in behavior are probably mediated principally by neurohumeral mechanisms. Yeakel and Rhoades compared the weights of several endocrine glands, viz. adrenal, thyroid, and pituitary, of the emotional and nonemotional strains of rats selectively bred by Hall. Significant differences both for absolute weight of the glands and relative weight, i.e. gland weight divided by body weight, were obtained. The emotional males had heavier adrenals and thyroids than the nonemotional males. There was no appreciable difference in the weight of the pituitary for the males of the two strains. The emotional females had heavier thyroids and pituitaries than the nonemotional females, but the difference for the adrenals did not

reach the criterion of significance. If it is assumed that heavy glands produce more hormones than light glands, then it may be surmised that the emotional rats are emotional because they are primed by their blood chemistry to react emotionally. Their chemique produces a lower threshold for the evocation of fear as compared with the threshold of the nonemotional rats. Such speculations are interesting, but only a more intensive and critical search for the precise *modus operandi* of the genes upon emotionality, similar to that performed by Herter on thermotactic preference, will provide exact knowledge.

Rundquist and Bellis (1933) compared the respiratory metabolism of the F_{15} generation of active and inactive strains of rats using the Ebeling-Corey method for determining metabolism. The average number of calories per gram body weight per hour for the two strains by sex are given in the table. The

	ACTIVE STRAIN		INACTIVE STRAIN	
	No.		No.	
Males	29	8.25	16	6.28
Females	20	8.70	22	6.45

differences between the means are statistically significant. The higher metabolic rate of the active strain is to be expected and suggests that the inherited structural feature upon which voluntary activity is based is the thyroid.

No difference in the brain weights of maze-bright and maze-dull rats was found by Silverman, Shapiro, and Heron (1940).

Lashley (1947) has recently surveyed the available knowledge of the inheritance of structure in the nervous system in relation to behavior. Actually very little is known about this subject. It has been established that "the brain is extremely variable in every character that has been subjected to measurement" and "some of the more conspicuous structural differences have been shown to be hereditary" (p. 333). These inherited differences include brain size, fissuration, absence of corpus callosum, and the

irregular twisted fibers of the corpus striatum in athetosis. Although the relation of these macroscopic features either to behavior or to genetic constitution has not been clearly revealed, Lashley feels that the structural variations must have functional significance.

It is not conceivable that the inferior frontal convolutions of two brains would function in the same way or with equal effectiveness when one contains only half as many cells as the other; that two parietal association areas should be identical in function when the cells of one are mostly minute granules and of the other large pyramids; that the presence of Betz cells in the prefrontal region is without influence on behavior. [P. 333.]

CONCLUDING REMARKS

The foregoing sections have presented a brief review of the nature and potentialities of the interdisciplinary science of *psychogenetics*. As an organized and dependable body of knowledge of the inheritance of psychological traits, psychogenetics is as yet more a promise than an actuality. The experimental work in this area is fragmentary, and what has been done has sometimes failed to utilize the proper methods of genetic analysis. Specifically, psychologists have not always realized the importance of employing pure strains of animals in their investigations of quantitatively expressed traits. This is an oversight that can easily be rectified since pure strains of some mammals, notably mice, are available.

As the science matures we may confidently expect it to free itself of distracting excursions into pseudo-problems, chief of which has been the heredity-environment issue. This issue is one of the legacies inherited by psychology from philosophy, and it has plagued experimental psychology for nearly a hundred years. Nativism versus empiricism, McDougall's instinct psychology, Watson's adoption of a strict Lockean viewpoint,

the anti-instinct polemics of the 1920's, the nature-nurture controversy of the 1930's, culminating in the publication of *The Thirty-Ninth Yearbook* of the National Society for the Study of Education (1940), are but a few manifestations of this age-old debate. Although hindsight is always easy, it now appears that if the energy, not to mention the money, that has been expended in casuistry and the collection of amphibolous data had been devoted to carefully designed psychogenetic investigations, we might now have a substantial body of knowledge about the genetics of behavior. If such knowledge were in existence, it would then be possible to evaluate by experimental methods the role of modifiability in altering innate constitution.

The writer has attempted, in this chapter, to avoid speculation and argument from analogy. For instance, the whole question of sex differences has been omitted because its discussion would have to be largely inferential. There is no doubt that innate sex differences in psychological traits exist: the aggressiveness of the male rat versus the pacificism of the female, contrasting courtship and copulatory patterns, and maternal behavior, to mention a few. These disparities have been traced to the action of gonadal hormones: androgen, estrogen, and progesterone. It is now well established that the male secretes some female sex hormone and the female secretes some male sex hormone, which fact precludes a sharp dichotomy between the sexes. All this information is extremely valuable, but it does not belong in a chapter on the genetics of behavior. One might infer that these established sex differences were controlled, primordially, by the sex chromosomes, but this inference has yet to be confirmed.

In order to have a science of psychogenetics it is not sufficient to determine merely that certain behavior traits are genetically transmitted. This is the first step. Genetic analysis, the mapping of chromosomes, and the specification of the *modus operandi* of

the genes are also necessary functions of the psychogeneticist. In short, psychogenetics must imitate biogenetics.

One might ask, what will psychogenetics contribute to our understanding of the individual? The answer is that it may well be of tremendous value in clarifying the dynamics of behavior. The individual is a purposive, striving, selective, adjusting, animated organism. He does not spring to life just because stimuli from the outside world fall upon him. Nor does he lapse back into passivity and desuetude at their termination. There are inner forces that regulate, control, and precipitate his responses to the world. Psychologically these forces are called motives, intentions, values, interests, attitudes, and sentiments. Physiologically they are hormones, neural impulses, and chemical states. Genetically they are forces residing within the chromosomes. These genetic forces must be extremely important in shaping the psychological destiny of the individual. Any structures that can produce such varied forms as the flea and the elephant, the starfish and the kangaroo, the shark and the rabbit, must be potent causes of individuality within a species. Accordingly, an understanding of psychogenetics is a prerequisite for the development of a dynamic psychology.

Growth Curves

NATHAN W. SHOCK

National Institutes of Health and Baltimore City Hospitals

Growth is one of the fundamental properties of living things. Broadly defined it represents the irreversible changes in size or function that occur with time. Although most of these changes represent increments in substance or in function, this is not always the case, as will be shown later in the discussion of certain physiological characteristics.

Although, according to this definition, any plot of size or function against time constitutes a growth curve, it is customary to regard as growth only that portion of the curve concerned with changes taking place prior to the attainment of a protracted plateau. Learning curves are usually excluded from discussions of growth because they are concerned with only a restricted portion of the total life span of the organism. Furthermore the primary parameter in a learning curve is number of trials, which may be related to time in an arbitrary manner, depending on the design of the experiment.

Basically growth refers to increments in the number of cells or elements in the organism. In multicellular organisms, such as man, however, it is impossible to count the individual cells, so that growth phenomena are usually related to increases in mass, volume, or surface area. Psychologists have broadened the concept of growth to include increments in functional capacities as well. Thus one may speak of mental growth as well as physical growth. Growth has both static and dynamic aspects. One may be

interested in the amount of a substance or in the state of a function at a given time, or one may consider the rate of change in substance or function.

Growth Curves

A growth curve is a graph or plot of size or function against time. It usually includes a major portion of the life span of the organism or cellular colony. This chapter will consider questions that can be answered by growth-curve analysis. It is important to recognize that many questions about the growth process cannot be answered by a study of growth curves alone: it is clear that a human adult cannot be described simply as a child of increased dimensions. Many developmental changes take place with growth: changes in functions, proportions, interactions, etc., which cannot be adequately described by simple growth curves. There are other questions, however, to which a study of growth curves can provide significant answers.

First of all, it is possible to determine the amount of growth in size or function at a given time either for individuals or for groups of individuals. Further analysis of growth curves makes it possible to determine the rate of change of growth over a finite time interval. Using mathematical procedures, it is possible to estimate instantaneous rates as well. Comparison of growth curves can also be used to measure the effects of various environmental factors on the growth process.

For example, much of the experimental work on the effects of diet, vitamins, and hormones depends upon the use of growth curves. Growth curves may also be of value in testing hypotheses about the underlying processes involved (Morales and Kreutzer, 1945; Hutchens, Podolsky, and Morales, 1948). Other practical uses of growth curves are presented in a later section.

THEORY OF GROWTH CURVES*

Rational Equations

The rational description of how a multicellular organism changes in time t requires the choice of a parameter of description $\psi(t)$ with the following characteristics: (1) ψ must depend only upon the activity of living cells, and (2) ψ must be such that all other parameters can be unambiguously expressed in terms of it (Shock and Morales, 1942). The one parameter that can best satisfy these conditions is total cell number (N).

Living cells always exhibit the phenomena of metabolism and irritability, although not all the substance of the cell contributes to or takes part in these essential processes. Yolk stores, fat stores, or water stores within the cell are no more "living" than the same substances outside the cell; but as the amounts of these substances in a cell change with time, the parameters of mass, surface, and volume may also change. It is, therefore, clear that such parameters as mass and surface area can express in only an indirect sense the phenomena of growth or life. Furthermore, indices of metabolism and irritability vary in time as a result of physiological processes not associated with growth itself, such as exercise and temperature. The process of cell division, on the other hand, is unquestionably associated with living protoplasm in a direct way, and it must there-

fore be concluded that the measure of cell division, namely, the number of cells (N), is a basic parameter for a theoretical analysis of growth.

Let us postulate that two factors are responsible for changes in N as t increases: (1) a factor ϕ , which resides within the cells and is present even if the cells are infinitely removed from one another, and (2) a factor θ , which is the interaction between cells. Assuming that these two effects are additive, we may write

$$\frac{dN}{dt} = \phi + \theta \quad (1)$$

If there is no interaction between cells, it is reasonable to suppose that at any one time the increase in cell number is proportional to the number of cells present. However, the constant of proportionality generally changes with time and should be a function of it. Thus

$$\frac{dN}{dt} = f_1(x_1, x_2, \dots, x_n, t)$$

where the x 's are physical parameters and t is time.† Since the coefficient of N may depend upon N as well as upon t , we may write

$$\phi = A(N, t) \cdot N \quad (2)$$

Although the interaction effect θ must somehow depend upon the number of cells present, the dependence need not be linear. Hence we may write

$$\theta = B(N, t) \cdot N^k \quad (3)$$

† The reasoning whereby t is introduced into the right-hand member of the equation is as follows: physical functions are determined at any instant by the values of physical variables and depend on time only insofar as the latter depend on time. Thus it may be that a parameter, x_i , changes in time,

$$\frac{dx_i}{dt} = f_2(r_1, r_2, \dots, r_m)$$

whence

$$x_i = f_3(x_{i0}, t)$$

where x_{i0} is the value of x_i at the zero point of time. Substituting in the equation for N , x_i is replaced by x_{i0} , t , and similarly for other parameters. The right-hand member thus becomes rigorously meaningful with the zero point of time operationally defined and can be evaluated for any given t .

* The assistance of Dr. Manuel F. Morales in the preparation of this section is gratefully acknowledged.

where in the simplest case the exponent k is some constant. Assembling equations 1, 2, and 3, we may write

$$\frac{dN}{dt} = A(N, t) \cdot N + B(N, t) \cdot N^k \quad (4)$$

This represents the fundamental equation of growth. The effect of many of the phenomena that affect growth can be estimated by this form of equation simply by making reasonable assumptions about the functions A and B . It may be shown that all the important rational growth equations, and two of the equations heretofore regarded as empirical, can be derived by making logical assumptions with regard to the functions A and B . These functions A and B represent the intrinsic growth factor and effects of interaction between cells, respectively.

Case I. Linear proliferation: universally deleterious metabolite produced by all cells at a uniform rate. Assuming that cells infinitely removed from each other have equal and constant division times, it may be shown that

$$\phi = AN \quad (5)$$

where A is a true constant (with transient or lag effects). If the cells are brought together and if each cell produces a substance that is harmful to every cell in the community including itself, and the proportionality constant is B , then the sum of the harmful effects is BN^2 . This follows because the total number of effects of N cells upon themselves is BN . Furthermore, each cell acts upon $N - 1$ others, so that the number of effects of cells upon their fellows is $BN(N - 1)$. The total number of harmful effects is therefore $BN + BN(N - 1) = BN^2$. Thus

$$\theta = -BN^2 \quad (6)$$

Combining equations 1, 5, and 6, we obtain

$$\frac{dN}{dt} = AN - BN^2 = BN \left(\frac{A}{B} - N \right) \quad (7)$$

Equation 7 integrates directly into

$$N = \frac{\frac{A}{B}}{1 + \left(\frac{A}{B} - 1 \right) e^{-At}} \quad (8)$$

where e is the base of the natural logarithms.

Case II. Linear proliferation: universally deleterious metabolite produced by all cells at a variable rate. In addition to the postulates of case I, let us postulate that the proportionality constant B changes in time as discussed in an earlier paragraph. This variation may be expressed by a power function of t :

$$B = \sum_{s=0}^{s=n} K_s t^s \quad (9)$$

Substituting into equation 1 we obtain

$$\frac{dN}{dt} = AN - N^2 \sum_{s=0}^{s=n} K_s t^s \quad (10)$$

This equation integrates to

$$N = \frac{1}{Ke^{-At} + e^{-At} \int B(t)e^{At} dt} \quad (11)$$

where K is a constant of integration.*

Case III. Constant rate of proliferation: foodstuffs as limiting factor. If we assume a constant rate of proliferation, we may write

$$\phi = \alpha k$$

where α and k are constants separated into two factors for algebraic convenience. Assuming that retardation is due to a shortage of foodstuffs, the retarding interaction factor θ will be proportional to the number of cells present; that is,

$$\theta = -kN$$

The rate equation

$$\frac{dN}{dt} = \alpha k - kN \quad (12)$$

integrates to

$$N = \alpha(1 - e^{-kt}) \quad (13)$$

* The integration given in the original reference (Shock and Morales, 1942) was in error. Thanks are due Dr. John Z. Heason for calling this to our attention.

Case IV. All cells produce a stimulating substance which takes effect according to pharmacological laws: foodstuffs as limiting factor. If all cells produce a growth stimulant, the amount of this substance present at any time is proportional to the number of cells. The effect, however, may be proportional to the per cent increase in the stimulating substance. This relation between dosage and effect occurs frequently in pharmacology and physiology. A parallel effect in psychological phenomena was formulated by Weber and Fechner. According to this principle, the effect of a unit amount of substance is proportional to the logarithm of the amount present, which in turn is proportional to the number of cells. The total effect is then proportional to the effect of unit amount and to the amount present; in other words,

$$\phi = (-C \log A)N$$

As before,

$$\theta = CN \log N$$

Combining according to equation 1,

$$\frac{dN}{dt} = (\log N - \log A)CN \quad (14)$$

which integrates to

$$N = Ae^{Be^{Ct}} \quad (15)$$

where B is a constant of integration.

Transformation to Units of Size

Thus it has been shown that, if we make reasonable hypotheses about the intrinsic and extrinsic factors affecting growth, as outlined in equation 1, we may derive rational equations for growth in terms of cell number. Since the number of cells in multicellular animals is not an experimentally determinable quantity, it is necessary to make certain transformations in these equations in order to apply them to experimental data. The assumptions involved in this transformation will be made explicit. For example, we may consider the relation between the differential and integrated functions derived above and their ana-

logues, using mass M as the essential parameter. We may assume that for the k th cell the average density is \bar{p}_k and the volume v_k , so that the mass is

$$m_k = \bar{p}_k v_k \quad (16)$$

and obviously

$$M = \sum_{k=1}^{k=N} \bar{p}_k v_k \quad (17)$$

Since $M = f(N, t, \bar{p}_k, v_k)$ we may also write:

$$\frac{dM}{dt} = \frac{\partial M}{\partial N} \frac{dN}{dt} + \sum_{k=1}^{k=N} \frac{\partial M}{\partial \bar{p}_k} \frac{d\bar{p}_k}{dt} + \sum_{k=1}^{k=N} \frac{\partial M}{\partial v_k} \frac{dv_k}{dt} \quad (18)$$

Equations 17 and 18 thus give the desired relations. In practice it must be assumed that the cells are homogeneous with respect to mass, density, and volume. Under this assumption we may express equation 18 as:

$$M = Npv \quad (19)$$

Substituting into equation 18, we have

$$\frac{dM}{dt} = \frac{M}{N} \frac{dN}{dt} + \frac{N}{p} \frac{dp}{dt} + \frac{N}{v} \frac{dv}{dt} \quad (20)$$

If, in addition, p and v are constant in time, equation 20 becomes simply $dM/dt = c dN/dt$, where c is a constant, and the four cases we have derived above can be written with the constants referred to mass and time. The mass analogues of equations 8, 11, 13, and 15 are thus

$$M = \frac{\frac{A}{B}}{1 + \left(\frac{A}{B} - 1\right) e^{-At}} \quad (21)$$

$$M = \frac{1}{Ke^{-At} + e^{-At} \int B(t)e^{At} dt} \quad (22)$$

$$M = \alpha(1 - e^{-kt}) \quad (23)$$

and

$$M = Ae^{Be^{ct}} \quad (24)$$

These equations are those presented by other authors in various connections: equation 21 by Robertson (1907-08, 1926-28); equation 22 by Pearl (1925); equation 23

by Brody (1945), Schmalhausen (1928, 1929, 1930), and Jense and Bayley (1937); equation 24 by Gompertz (1925) and Courtis (1929, 1932).*

The first two of these equations have heretofore been derived on the basis of chemical analogues that were admittedly fictitious;

between an integral form and a differential equation, the interpretation of the constants in equations 21 to 24 is not unique, although the meanings ascribed to them in the foregoing derivations are certainly one possible set. Because of this inherent lack of uniqueness in the mathematical approach, the

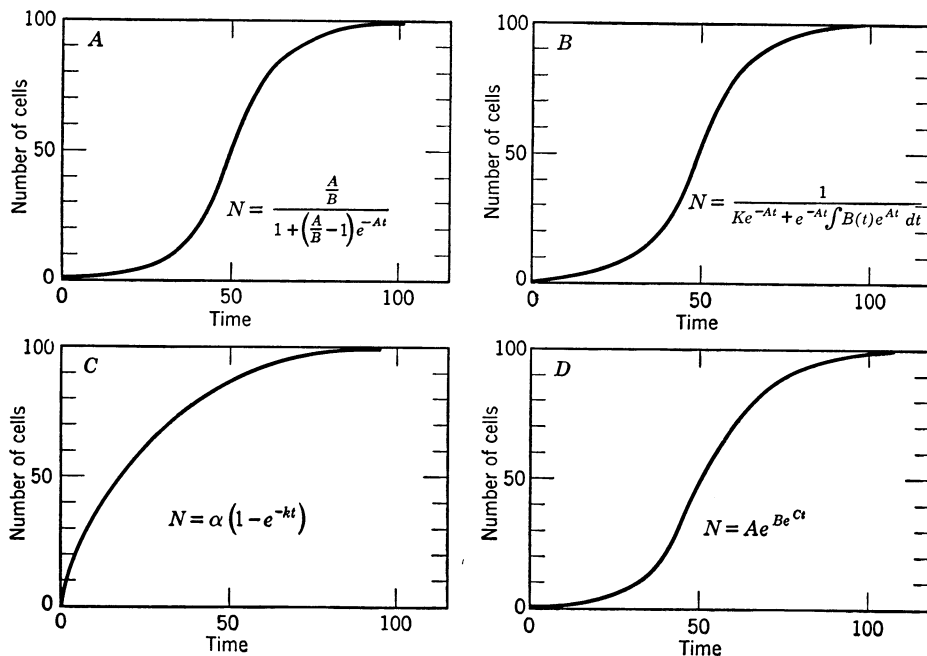

FIG. 1. Theoretical growth functions derived rationally.

the last two have up to now been regarded as purely empirical.

Limitations of Interpretations of Rational Growth Curves

It should be pointed out that an infinite number of growth equations could be developed from the fundamental equation above. It would be necessary simply to alter the hypotheses and the functional relations proposed for the intrinsic and extrinsic factors. Since there is a many-to-one correspondence

* Details of statistical methods for fitting experimental observations to each of these curves may be found in the references cited. See also Cowden (1947).

nature of the growth process cannot be determined by this method alone. Furthermore, the unreliability of measurements, or the heterogeneity of the sample in an experimental situation, may be so great that a precise statement of whether the observations do or do not fit a given formulation cannot be made. For example, J. Gray (1929) presents two curves fitted to the same set of observations; in one the inflection point is at $x = \frac{1}{2}a$, and in the other $x = \frac{1}{3}a$. Both curves fit the data within the limits set by the errors of observation.

The characteristics of form and shape of the theoretical curves derived from equations 21 to 24, respectively, are illustrated in Fig. 1.

Of the four theoretical curves, three are in general S-shaped (Fig. 1A, B, D), and the fourth is logistic (Fig. 1C). The first of these (Fig. 1A) is symmetrical about the point of inflection, whereas the second (Fig. 1B) is not. These four types of curves have proved most useful in the analysis of growth data, and many examples may be found in publications of Brody (1945), Courtis (1929, 1932), Crozier (1926), Davenport (1926-27), Kavanaugh and Richards (1942), Merrill (1931), Robertson (1907-08, 1926-28), Schmalhausen (1928, 1929, 1930), and von Bertalanffy (1934, 1938), etc. Although close fits to growth data for various animals may be cited (Brody, 1945), no single curve has been found that completely describes the entire growth period of the human. For this reason, human growth has been regarded as progressing in two (Davenport, 1926-27) or three (Robertson, 1926-28) cycles, each of which must be described by its own equation.

We may now turn to a consideration of the uses of various types of growth curves in experimental investigations.

AMOUNT OF GROWTH AT A GIVEN TIME

Anthropometric Measurements

Numerous references to studies of anthropometric measurements of growing children and animals may be found in the literature (Krogman, 1941; Meredith, 1936a, 1943). Measurements range from those of height and weight to segmental measurements of practically every part of the body (Dearborn, Rothney, and Shuttleworth, 1938; Gray and Ayres, 1931; Meredith, 1936a, 1943; Shuttleworth, 1937, 1938a, 1938b, 1939; Simmons, 1944; Stuart, 1939, 1942, 1946; Thompson, 1946). Growth curves have been constructed showing the average value of such measurements for groups of individuals at various ages. Figure 2 showing the average weight of American school children is an example of this type of curve. Similar curves exist for such anthropometric measurements as stem length, sitting height, leg length, arm length, shoulder width, hip width, chest circumference, arm circumference, leg circum-

FIG. 2. Growth in weight. Average curves for boys and girls. (Data from Davenport, 1926.)

ference, and many others. There was a time when curves like those in Fig. 2 were used as a standard of comparison to assess the growth status of individual children. It soon became apparent, however, that factors other than age alone are important in determining the growth of an individual child. Consequently this method of assessment was augmented by setting up so-called standards of weight in terms not only of age but of other characteristics such as height or body widths (Baldwin, 1925; Pryor and Stolz, 1933; Wetzel, 1944, 1946) and physiological maturation (Shuttleworth, 1937, 1938a). The chief usefulness of this type of curve lies in the evaluation of the effects of various dietary and endocrine substances on the growth process, as will be discussed in a subsequent section.

It has been found experimentally that the standard deviation of measurements of any particular body characteristic changes systematically with age (Davenport, 1931). This is particularly true of measurements on human subjects: the standard deviations of measurements made during the adolescent period are significantly greater than those of measurements made either in early childhood or in early adulthood. Such a finding could result only from individual differences in the chronological age at which the adolescent growth spurt occurs (Shuttleworth, 1937, 1938a). Let us turn then to a consideration of individual growth curves.

Individual Growth Curves

The accumulation of serial measurements on the same child from birth to maturity is extremely laborious. Although data of this kind may be found in the literature covering certain age periods, such as birth to three years (Davenport, 1937; Davenport and Drager, 1936; Jents and Bayley, 1937) or during the adolescent period (Dearborn, Rothney, and Shuttleworth, 1938), measurements of individuals over the entire growth period are extremely rare (Gray and Faber, 1940; Guttman, 1915; Scammon, 1927).

Figure 3 illustrates growth in height and weight from two studies (Scammon, 1927; Gray, 1941). Examination of these curves reveals significant differences between the growth of individual children as compared to the average curve. It has been shown that the prediction of the expected growth or the ultimate adult size of the individual can be made with much greater accuracy from the individual growth curve than from average curves alone (Bayley, 1943; Jents and Bayley, 1937). The chief limitation on the value of the individual growth curve lies in the experimental error attached to the serial measurements, and unfortunately for certain measurements, such as circumferences, the error may be relatively large (Meredith, 1936b).

Psychological Functions

For the most part psychologists have considered mental growth in terms of the average test performance of children at increasing ages. In some instances, raw scores have been converted to mental age scores, and curves have been constructed showing the relation between average mental age and chronological age (Ebert and Simmons, 1943; Freeman and Flory, 1937). Although such curves are useful in determining the performance of an individual child with respect to others of the same chronological age, they may not represent a growth function that can be compared with growth in other characteristics since they do not meet two essential criteria of "ratio scale" measurement: namely, a zero point and units of uniform size. This is particularly true when we attempt to characterize the growth of an abstract phenomenon such as intelligence. It is clear that raw scores in performance tests do not determine an absolute zero of the function measured, since the zero test score does not necessarily indicate the complete absence of the ability tested. Furthermore, we have no direct means of knowing that the difference in ability represented by the raw scores of 10 or 20, for example, is

the same as that between the raw scores of 90 and 100. Thus, although raw scores make it possible to place individuals in rank order on "ordinal scales," they cannot be used for more sophisticated analysis involving the calculation of product moment corre-

cessive age groups made it possible to plot absolute mean test performance against absolute variability and to determine by extrapolation the absolute zero of the scale (Thurstone, 1928). This is possible because the absolute variability of test intelligence

FIG. 3. Individual growth curves of height and weight. Squares: weight of girl (data from Gray and Farber, 1940). Dots: height of boy (data from Gray, 1941). Open circles: height of boy (data of Buffon, 1827, from Scammon, 1927).

lation or coefficients of variation (Stevens, 1946; also, see Chapter 1).

Intelligence

These problems of mental measurement have been attacked by Thurstone (1925, 1928), who sought to obtain a uniform unit of measurement by a method of "absolute scaling." Details of the statistical procedure cannot be presented here, but the essence of the technique is the use of the standard deviation of the performance of one age group as a unit of measurement (Thurstone, 1925). The discovery that, with uniform conditions of selection, there is a linear relation between the absolute variability and the mean test performance of suc-

cessive age groups made it possible to plot absolute mean test performance against absolute variability and to determine by extrapolation the absolute zero of the scale (Thurstone, 1928). This is possible because the absolute variability of test intelligence must be zero when the mean test performance is zero; that is, the variability cannot be negative. Armed thus with an absolute zero and a uniform unit of scale measurement, it was possible for Thurstone and Ackerson (1929) to construct the mental growth curve shown in Fig. 4. These investigators derive several fundamental facts concerning the laws of mental growth: (1) The mental growth curve has a positive acceleration up to the age level of about 10 years. (2) The mental growth curve is asymptotic to an adult level. (3) The mental growth curve has an inflection point somewhere in the age range of 9 to 12. (4) The inflection point comes earlier for bright children than for dull children. (5) The

mental growth curve is asymptotic to absolute zero. (6) The absolute variability of test intelligence increases with age until adult intelligence is attained.

These findings contradict the hypothetical growth curve of mental age or raw scores, which is usually shown to have a negative acceleration from birth onward and no inflection point. It is unfortunate that the

FIG. 4. Mental growth curve based on standard scaling of Stanford-Binet test scores. (Data from Thurstone and Ackerson, 1929.)

technique used in this study has not been applied to tests of performance in other mental functions. The generality of the absolute scaling method devised by Thurstone makes it possible to apply the same technique to other performance tests. Many of the inferences about the relation between mental and physical growth may be subject to question, since raw scores, sigma scores, or mental age scores have been used in most studies (Simmons, 1944; Bayley, 1940). For comparisons between mental or performance test data and other growth characteristics, it is obvious that methods leading to comparable scales must be utilized for both kinds of data. This represents a major field for future development by psychologists.

Intellectual Achievement

Growth curves of physical performance, such as strength (Jones, 1944), motor skills

(Jones and Seashore, 1944), etc., may be drawn to describe changes with age, since the criteria for measurement are satisfactorily met. However, growth curves of mental performance, such as reading skill, spelling ability, etc., are usually based on raw score values that have not been scaled. For this reason many of the studies of growth in different types of mental performance are subject to question.

If, however, sigma or standard scores are calculated for each type of mental performance, comparisons of growth curves can be made, provided the mean of a single age group is used as a reference point and the standard deviation of that group is used as the unit of measurement. If sigma scores are calculated in terms of deviation from the mean value of each age group, the trend due to age is of course eliminated. Therefore it is necessary to use one age group as the standard to which others are referred. The validity of results obtained by this method depends in large measure on the size and random character of the standardizing group, since the assignment of scale units is based on the assumption that the *form* of the distribution of scores is *known*.

Physiological Functions

Growth changes in physiological functions such as pulse rate, blood pressure, basal oxygen consumption, etc., have in general been presented as average growth curves by age groups. Such curves have been used chiefly to assess the deviations of individuals from the average values for a given age group (Shock, 1944, 1946a, b; Greulich et al., 1942; Henry, 1944). It is important to note when dealing with physiological variables that the changes with age may include negative as well as positive increments. For example, Fig. 5 shows the average values of oxygen consumption per unit of surface area as a function of chronological age. These values attain a maximum at the age of 3 to 4 years, followed by decreases through

FIG. 5. Physiological growth curve. Average basal metabolic rate (calories per square meter per hour) as a function of chronological age. (Dots: data from Boothby, Berkson, and Dunn, 1938. Open circles: adjusted values of Lewis, Duval and Iliff, 1943.)

maturity (Du Bois, 1936; Boothby, Berkson, and Dunn, 1936; Lewis, Duval, and Iliff, 1943).

It may be pointed out that physiological functions are not fixed or static but vary from time to time. Consequently, the measurements include not only variability in technique but biological variation of the organism from moment to moment. The standard deviation of physiological measurements is commonly greater than that of anthropometric measurements. It may be found that other physiological variables alter the values of the physiological measurement and that these other variables are not highly correlated with chronological age. Thus the use of individual curves of development may bring to light findings that are not apparent from average curves (Davenport, 1931). This may be illustrated by a comparison of the average change in metabolic rate with that of an individual over the adolescent period. Figure 6 shows that for an individual the change in metabolic rate with age may be quite different from that shown by the average curve. In this instance, a rapid fall in metabolic rate occurred within the 6 to 12 months following the beginning of menstruation (Shock, 1944).

Weinbach (1937, 1938a, b, 1940) fitted growth curves to certain physiological observations such as the duration of the Moro

FIG. 6. Average growth curve of basal metabolic rate compared with curve for an individual female. (Data from Shock, 1944.)

reflex in infants, brain potentials, and time of climbing slopes of varying degrees of inclination. The variability of the observations is so great that the curves fitted can be regarded only as a rough gradation technique.

In a later publication Weinbach (1941) fitted the same equation ($M = M_m - M_m e^{-kt}$) to both alpha-rhythm observations and brain weight. The fact that the calculated growth rates for both phenomena (brain weight and alpha rhythm) are the same is not proof that the two phenomena are dependent on each other or in any way connected.

ESTIMATES OF GROWTH RATE

Since growth is a dynamic process, one of the important questions for study is the rate at which this process occurs. The rate of growth is expressed in terms of the increment per unit of time. If one knows the functional relation between the amount of growth or the size and time, the rate at a given instant is obtained by differentiating the equation with respect to time, that is to say, by solving the equation $W = F(t)$ for dW/dt . Since this functional relation, $W = f(t)$, is usually unknown, certain other estimates have been proposed by students of the problem.

Raw Increments

One solution to the problem of estimating the growth rate is to compute the increment between two successive measurements. This calculation may be expressed as $(W_2 - W_1)/(t_2 - t_1)$, where W_2 and W_1 are the larger and smaller measurements, respectively, and t_2 and t_1 the respective ages. This expression of the rate of growth suffers from certain disadvantages; for example, the arbitrariness of the unit of time taken for the measurement. Thus, if measurements are made at monthly rather than at yearly intervals and the rates expressed as increments per month, a set of rates will be obtained entirely different from that calculated on the basis of annual increments (Scammon, 1930). Similarly a unit increment in weight, for instance, does not have the same significance when added to individuals of different orig-

inal weights. Thus the addition of 1 pound of weight to the 6-pound infant is not equivalent to an increment of 1 pound in a child weighing 50 pounds. In order to meet this difficulty, increments may be expressed in terms of the per cent of the weight at the beginning of the interval.

Percentage Increments

The procedure of reporting growth rates by computing the ratio of the gain in weight

FIG. 7. Instantaneous growth rates for the female rat. (Data from Schmalhausen, 1928.)

to the weight at the beginning of the time interval, $100 \times (W_2 - W_1)/W_1$, as originally introduced by Minot (1908), is obviously influenced to a large extent by the time interval over which measurements are made. Brody (1945) has shown that by shortening the time interval and by using the mean weight for this time interval as the denominator, a closer approximation of the growth rate may be obtained. A further refinement in the calculation of growth rates has been introduced by Schmalhausen (1929), who has calculated the instantaneous relative growth rate as follows:

$$K = \frac{\ln W_2 - \ln W_1}{t_2 - t_1}$$

where \ln signifies the natural logarithm. This so-called instantaneous growth rate has been computed for the rat as shown in Fig.

FIG. 8. Growth rates for the female rat. (Data from Brody, 1945.)

7. In reality this process is one of fitting a series of logarithmic curves to the growth data and obtaining the slope of the logarithmic curve over finite time intervals. As indicated in Fig. 8, growth is represented as a discontinuous process with changing growth constants.

Instantaneous Rates

The Schmalhausen technique gives a different rate constant for various parts of the growth curve. On the other hand, it is clear that, if a rational equation for the growth process is derived as outlined in the theoretical part of this chapter, the estimation of the growth rate at any time (t_i) is simply a matter of differentiating the appropriate equation and substituting the value of t_i into the differential form. However, the growth of human beings does not lend itself to a simple formulation, and consequently no rational equation has yet been developed that can be fitted to the complete growth curve of the human organism, even though a number of equations have been

found satisfactory for various parts of the growth curve (Davenport, 1926-27; Jents and Bayley, 1937). It should be pointed out, however, that, even though a rational equation cannot be developed, a true instantaneous rate can be derived from an empirical equation that has been fitted to experimental data. This possibility constitutes an argument for the fitting of functional relationships, even though they be empirical, to experimental data. Methods used in fitting empirical curves to experimental observations may be found in Brody (1945), Curtis (1932), Cowden (1947), Davenport (1926-27), Guilford (1936), Jents and Bayley (1937), Merrill (1931), Pearl (1925), Robertson (1907-08), and Schmalhausen (1929).

OTHER USES OF GROWTH CURVES

The primary uses of growth curves, namely, the estimation of the amount and rate of growth, have been presented in

previous sections. Space does not permit a detailed discussion of the many specific uses of growth curves in experimental and clinical studies. However, brief mention may be made of some additional problems in which growth curves have been of value.

the diet. Figure 9 illustrates the use of growth curves to demonstrate the effect of changes of diet on growth curves (Brody, 1945). By means of a decreased food supply the rat whose growth curve is shown at the right was kept at a constant body weight

FIG. 9. Effect of undernutrition on growth of the rat. Dots: growth of well-nourished female rat. Squares: growth of inbred female rats. Open circles: growth curve of female rat maintained at constant body weight from age 1.3 months to 17.1 months by undernutrition. At 17.1 months an adequate food supply was provided. The rat began to grow at a rate characteristic of its weight and not of its age. (Data from Brody, 1928.)

Effects of Diet

Growth curves have proved a useful tool in the evaluation of various dietary factors. For these studies the white rat has commonly been used. Average growth curves for groups of animals deprived of specific nutritional elements have been compared with growth curves of animals that have received an optimal diet. The efficacy of the specific nutritional element has furthermore been demonstrated by showing that the growth curves of groups of animals are significantly depressed during periods of deprivation and that a marked change in the slope and direction of the growth curves occurs when the missing element is added to

of 55 grams from the age of 1.3 months to the age of 17.1 months. When an adequate food supply was made available, the rat began to grow at a rate characteristic of its weight and not of its age, indicating that within limits the growth rate of rats is independent of age.

Effects of Hormones

The effects of hormones on growth have been demonstrated by comparing growth curves of animals from which a given endocrine organ has been surgically removed with the growth curve of a litter mate. The restoration of growth rates following the administration of purified hormones has

served as a useful tool in estimating the purity of the endocrine product as well as its importance in regulating growth. Examples of curves showing the effect of the growth hormone of the anterior pituitary gland are presented in the publication of Selye (1947, p. 239).

Seasonal Variations

Figure 10 illustrates a method of evaluating seasonal variations in growth by plot-

for a variety of species, except man (Brody, 1945). Figure 11 shows how such curves for the rat and cow may be superimposed. The extremely long juvenile period of man shows a striking species difference.

Problems of Relative Growth

The changes in the form of animals during growth and development are usually included under the general term morphogenesis. For the most part, studies of

FIG. 10. Seasonal variation of average monthly growth rates in weight of elementary school boys. (Data from Palmer, 1933.)

ting serial measurements on groups of children (Palmer, 1933). It may be pointed out that such fluctuations in growth are more apparent in curves showing increments over fixed time periods and that some evaluation of the results can be made even though the functional relation between growth and age is not known.

Equivalence of Growth among Different Species

Growth curves have proved of value in equating growth rates for animals of widely different mature size and growth rates. Thus, by appropriate alterations of the time scale, it is possible to superimpose growth curves

changes in form have been descriptive in nature. However, certain aspects of changes in form have been quantified in terms of growth curves. In higher organisms these studies have plotted the growth of various parts of the animal in terms of the growth of the entire organism. For a detailed treatment of this problem the reader is referred to the publications of Huxley (1932), Jackson (1928), Scammon (1930), and Thompson (1942).

SUMMARY

In summary it may be pointed out that answers to certain questions may be ob-

FIG. 11. Comparison of growth curves for man, rat, and cow. Time scales adjusted for equivalence. (Data from Brody, 1945.)

tained by plotting growth curves. Among these questions is the use of growth curves to study the effects of various dietary and endocrine factors in the growth process. Such curves represent an experimental technique that has proved most useful in physiology and medicine. Growth curves are also of value in determining the relative status of progress of an individual with respect to a group. Answers to this question may be obtained even though the functional relation between size and age is unknown. The estimation of instantaneous growth rates can be made only where a rational formulation of the functional relation between growth and age has been fitted to the experimental observations. However, a close approximation to instantaneous growth rates may be obtained when only an empirical equation has been fitted to the observations. Further research lies in the direction of formulating hypotheses for which rational equations can be developed

and the testing of these hypotheses by fitting the equations to observational data.

Phylogenetic Comparison

HENRY W. NISSEN

Yerkes Laboratories of Primate Biology and Yale University

In this chapter we shall examine the role of comparative psychology in general biology, and its contribution towards the solution of basic problems of experimental and theoretical psychology. A search will be made for concepts or behavioral mechanisms in terms of which the behaviors of different animals may be compared. This treatment does not promote one or another of the currently active schools; it tries rather to synthesize a systematic, theoretical approach with the naturalistic point of view which looks at behavior in its wider setting and which refuses to exclude from consideration phenomena lying outside an arbitrarily circumscribed area of interest.

FUNCTIONS AND METHODS

Comparative psychology may be defined broadly as the science concerned with similarities and differences of behavior at various phylogenetic levels. Its aims and functions (1) as a branch of biology and (2) as part of experimental and theoretical psychology are closely interrelated.

Comparative Psychology and Evolution

As a biological science, comparative psychology supplements morphological and physiological evidence concerning phylogenetic development and the interrelations of species and phyla. The fragmentary story of evolution is interrupted most conspicuously and exasperatingly at the critical

points of transition from one main grouping to another. One reason for this may be, as Lecomte du Noüy (1947, p. 79) suggests, that the transitional forms evolved quickly and survived only briefly. "Each group, order, or family," he says, "seems to be born suddenly and we hardly ever find the forms which link them to the preceding strain. When we discover them they are already completely differentiated." The present status of our knowledge about phylogenetic origins is admirably summarized by Thompson:

We have long known, in more or less satisfactory detail, the pedigree of horses, elephants, turtles, crocodiles and some few more; and our conclusions tally as to these, again more or less to our satisfaction, with the direct evidence of paleontological succession. But the larger and at first sight simpler questions remain unanswered; for eighty years' study of Darwinian evolution has not taught us how birds descend from reptiles, mammals from earlier quadrupeds, quadrupeds from fishes, nor vertebrates from the invertebrate stock. . . . We may fail to find the actual links between the vertebrate groups, but yet their resemblance and their relationship, real though indefinable, are plain to see; there are gaps between the groups, but we can see, so to speak, across the gap. On the other hand, the breach between vertebrate and invertebrate, worm and coelenterate, coelenterate and protozoan, is in each case of another order, and is so wide that we cannot see across the intervening gap at all. [1942, p. 1093.]

The conclusion is already implicit in these words that evolution, as manifested in structural characteristics, has been a discontinuous affair rather than the continuous process envisaged by Darwin. Thompson proceeds to draw an analogy with mathematics and phenomena of the inorganic world:

An algebraic curve has its fundamental formula, which defines the family to which it belongs; and its parameters, whose quantitative variation admits of infinite variety within the limits which the formula prescribes. With some extension of the meaning of parameters, we may say the same of the families, or genera, or other classificatory groups of plants and animals. . . . We never think of "transforming" a helicoid into an ellipsoid, or a circle into a frequency curve. So it is with the forms of animals. We *cannot* transform an invertebrate into a vertebrate, nor a coelenterate into a worm, by any simple and legitimate deformation, nor by anything short of reduction to elementary principles. . . . A "principle of discontinuity," then, is inherent in all our classifications, whether mathematical, physical or biological. . . . This is no argument against the theory of evolutionary descent. . . . Our argument indicates, if it does not prove, that such mutations, occurring on a comparatively few definite lines, or plain alternatives, of physico-mathematical possibility, are likely to repeat themselves; that the "higher" protozoa, for instance, may have sprung not from or through one another, but severally from the simpler forms; or that the worm-type, to take another example, may have come into being again and again. [1942, pp. 1094-95.] *

This emphasis on large and abrupt variations in evolution is representative of most modern biological thinking. Its implication for comparative psychology is that in behavior also we may expect to find discon-

* Relevant in this connection is the possibility of reversals in the evolutionary succession; D. M. S. Watson (1929, p. 976) expresses the opinion that "it is far from improbable that some Protozoa are the degenerate descendants of multicellular animals."

tinuity—qualitative rather than merely quantitative changes—as we pass from the lower to the higher animal forms. Unlike the early post-Darwinians, who looked for a gradual development of behavioral capacity in the animal kingdom, the comparative psychologist is now relatively free to postulate new capacities or new behavioral mechanisms at various points along the phylogenetic scale, without doing violence to general biological theory. It would be expected, however, that such major psychological emergents would coincide with the major and abrupt changes in structural characteristics differentiating the larger taxonomic groups, especially the phyla. This expectation, we may say now, is not substantiated by the considerations that follow.†

Taxonomy and evolutionary theory in general have been based almost entirely on "formal resemblance" among structural criteria, which often are of a most superficial character. Now there is no a priori reason, and certainly no compulsion, to make the study of mental (i.e. behavioral) evolution subsidiary to the known or inferred facts of structural evolution. A comparative evolutionary psychology could be developed *in vacuo*, strictly and completely "on the behavioral level," à la Skinner (1938). This, however, would be unnecessarily restrictive and would repeat in principle the error of the taxonomists who confine themselves entirely to the structural aspects of evolution.

As Zuckerman (1933) suggested, behavioral data should contribute to an understanding of the historical relations among animals and to a more rational basis for their classification. Zuckerman has already demonstrated how the inclusion of func-

† Thompson's "principle of discontinuity" would suggest also that, in a systematic treatment such as Hull's (1943), species differences could be accounted for merely by changing the "empirical constants" of the equations (Hull, 1945) only within limits; at other points the forms of the equations would need to be changed, or new equations would have to be added.

tional (i.e. physiological and behavioral) data can help to disentangle the confused relations within the order of primates. Lorenz (1937) points out that, although the family of pigeons, Columbidae, form a definite taxonomic group, there is no one distinctive morphological character that is common to all species and that distinguishes them all from other groups. All pigeons, however, are distinguished from other birds by a behavioral criterion, namely, the manner of drinking. Pigeons pump water, whereas all other birds scoop it up. Petrunkevitch (1926) has pointed out "the value of instinct as a taxonomic character in spiders," and other examples are given by Heinroth (1910), Plath (1934), Lorenz (1941), and Adriaanse (1947).

The contribution that comparative psychology can make to the problems of phylogeny is a function of (1) the scope and precision of its data, (2) the adequacy of the behavioral categories under which the data are organized, and (3) the comparability of the data. The second of these problems is especially crucial. What are the "dimensions of behavioral evolution," the behavioral units, mechanisms, processes, or capacities that differentiate, quantitatively or qualitatively, among different levels on the phylogenetic scale? Some of the simpler ones, such as sensory acuity, are relatively easy to identify. But it is the more involved patterning of behavior that is most significant in differentiating the behavior of various animal groups, and it is here that the problem of identification is most difficult.

Given that the aspect of behavior in terms of which two species are to be compared has been satisfactorily defined, problems of technique remain to tax the ingenuity of the experimenter. If an intellectual function is to be tested, all those factors that affect the expression of the function, but that are not part of it, must be experimentally controlled. Conditions of motivation, past experience, and sensory and motor char-

acteristics are among the determinants of any performance, and, unless this entire "assisting cast" is rendered functionally equivalent, the differences in performance in the testing situation cannot be interpreted as reflecting a difference in the function under investigation. In addition, the possibility that a given problem may be solved in different ways by different species is a source of difficulty.

Animal Psychology

Psychological studies using animal subjects* may be grouped according to the purpose of the investigator. Those experiments in which interest is focused on a special *problem*, or on a particular *animal form*, are here considered under the heading "animal psychology."

Animal experimentation. In a large proportion of animal experiments the use of this or that species is incidental or even accidental; a particular animal is chosen because it happens to be convenient. The fact that insects, fish, and birds have been used more than other forms for studies of instinct is attributable to the fact that these animals display instinctive behavior with particular clarity, not because it is absent in other animals. All such animal experimentation is simply an extension of general (human) experimental psychology; the phylogenetic status of the species used is more or less irrelevant.

For certain types of investigation animals have definite advantages over human subjects. Their life span is usually shorter, their entire life history prior to experimentation can be known and controlled, and they may be subjected to operative and other procedures that could not otherwise be used. Most important of all, basic mechanisms that in man are obscured by the complexity of his behavior, as well as by cultural (especially language) factors, may often be

* Except where otherwise indicated, the term "animal" will be used in this chapter to refer to *infrahuman organisms*.

clearly discernible in simpler organisms. These points have been elaborated by Washburn (1936), Katz (1937), Thorndike (1942), Harlow (1942), and others.

Studies of the animal-as-a-whole. A second class of studies is concerned more with a rounded-out delineation of a given kind of animal than with a specific problem in behavior analysis. The method is more often observational than experimental. Such studies are in the tradition of the older naturalists who set about to give complete accounts of every form of animal life. The early emphasis was on morphological characteristics, but ecological and behavioral features are being given increasing attention.*

Most contributions of the so-called anecdotal school (roughly 1852 to 1890) belong to this category, although the anecdotalists were motivated largely by the desire to produce "evidence of reasoning and other characteristically human mental life in the higher animals" (Warden, 1927, p. 147). Field studies by trained observers, casual or incidental observations by ecologists, hunters, and explorers, the reports of animal trainers, zoo caretakers, and veterinarians, and the books written about pets of various kinds also belong here. Some of these are valuable contributions to our knowledge; others are useless or worse. Many of them are guilty of anthropomorphism—or of its opposite extreme (a delinquency for which there seems to be no good term: "brutalization" and "mechanomorphism" say too much).

The importance of *good* descriptive studies of animal behavior must not be minimized. The value of careful observation under natural conditions is indicated by Tinbergen (1942). He points out that the controversy between von Hess and von Frisch regarding color vision in the honeybee is resolved by "knowledge of the whole behavior-pattern" of the species: in its food-gathering activities

the honeybee responds to the colors of flowers, whereas in other situations its visual behavior is guided entirely by relative brightness, as if it were color-blind. In the case of the chimpanzee, Nissen (1931) has suggested that intellectual capacities will be revealed more clearly in the laboratory, where artificially imposed obstacles may be used to encourage the exploitation of those capacities, than in their natural habitat, where the necessities of life are obtained with little effort. The emotional and social aspects of anthropoid behavior, on the other hand, are greatly distorted in captivity and are more validly observed in the field.

Comparative Psychology

We wish to consider now the bearing of all animal behavior work on the central problems of psychology. How may phylogenetic differences and similarities of behavior be used to clarify the important principles of behavior? This, as I see it, is the *raison d'être* of what is called comparative psychology.

The genetic method. The genetic or historical method attempts to find explanations in origins. With the aid of temporal and causal continuity the present is explained in terms of the past. Ontogeny, phylogeny, and culture are the three areas within which behavioral development may occur. The three areas of development are, of course, interdependent: the accomplishments of ontogeny and culture depend, in the first place, on phylogenetic heritage. What the individual contributes to the culture is a function of complex interactions between phylogenetic status, ontogenetic development, and prior cultural accumulation. And some writers such as Hooton (1940) are perturbed about the debilitating effects of cultural influences on the future biological status of the human race.

The credo of the comparative psychologist is well stated by Tolman (1945):

. . . whereas man's successes, persistences and socially unacceptable divagations—that is,

* For brief histories of comparative psychology the reader may consult Warden (1927), Warden, Jenkins, and Warner (1935), or Waters, (1942).

his intelligences, his motivations and his instabilities—are all ultimately shaped and materialized by specific cultures, it is still true that most of the formal underlying laws of intelligence, motivation and instability can still be studied in rats as well as, and more easily than, in men.

Unless there is a continuity or homology of behavioral mechanisms from the lower to the higher animals (including man), there would be no rationale for the comparative method. This does not mean, necessarily, that the higher (later) is *merely* an extension or elaboration of the lower (earlier), although this is and has been a most provocative and fruitful working hypothesis. Quantitative complication may become so great that it produces, in effect, qualitative differences with new, “emergent” properties.

Each level of organization possesses unique properties of structure and behavior which, though dependent on the properties of the constituent elements, appear only when these elements are combined in the new system. Knowledge of the laws of the lower level is necessary for a full understanding of the higher level; yet the unique properties of the phenomena at the higher level cannot be predicted, *a priori*, from the laws of the lower level. [Novikoff, 1945.]

One further point deserves mention: Although the laws that hold on one level may not be adequate to explain all phenomena on the next higher level, the former are never contradicted, reversed, or negated by the latter. “No physical law, any more than gravity itself, not even among the puzzles of stereochemistry or of physiological surface-action and osmosis, is known to be transgressed by the bodily mechanism” (Thompson, 1942, p. 13).

When interest is focused on individual differences within the higher group, it *may* be that these later emergent properties have primary significance in distinguishing between this and that individual or class. In this sense and to this extent only, we may agree with Allport (1947) in his objection

to the “phylogenetic model” and “the animal paradigm for personality and for social psychology.” We can agree that differences of intention among people are of great practical significance. But these intentions are superstructures erected on a phylogenetically inherited foundation. Would the superstructure remain the same, or ever have become what it is, without the foundation? Can anyone conceive of what our “intentional morality” would be like in the absence of food, water, and sex hungers, without competition, without frustration or conflict? Intentions will never be understood without reference to the phylogenetic matrix from which they have arisen. They are the product of a long and tortuous development.

Structure-function correlations and homologies. There is a school of thought in psychology that holds that a psychological (behavioral) event is explained when, and only when, its underlying physiological-morphological basis has been identified. Whether or not we concur with this extreme position, it is undeniable that the demonstrated correlation between “physical” and behavioral phenomena is a long step towards explanation. A psychological theory that is at variance with established principles of physiological (e.g. neurological) action is thereby summarily ruled out, whereas one that does mesh with such principles is *ipso facto* given increased probability.

Within any one species the expression of a given mechanism or process is almost certain to be obscured by other mechanisms, the problem of isolation (experimental or otherwise) being often insuperably difficult. Within that one species it is often impossible to abstract what is essential from what is incidental. But, when the process is observed in various contexts (i.e. species), the irreducible minimum, the essence of the process under consideration, gradually becomes clear. Zuckerman has stated it as follows: “What is obscure in a functional activity of one species, for example man, may be clarified by some peculiarity in the working of the

homologous process in a related species, and problems whose existence had not previously been realized might be revealed by this method of approach" (1933, p. xvi).

The comparison of the behavior of species and of phyla is one of the more important ways in which we may exploit naturally given, ready-made variations. Nature has provided us with well over half a million species that vary, greatly or minutely, in structure *and* behavior. Also, they show greater or lesser similarities, resemblances, homologies, in both aspects. This wealth of materials is ready to be used (1) to help in the definition of fundamental mechanisms or principles of behavior, and (2) in explaining behavior in terms of its underlying physical bases.

Dimensions of behavioral evolution. The literature contains an amazingly small number of studies in comparative psychology — investigations in which two or more species have been compared *directly*. Comparisons are mostly attempts to relate the findings of different workers, using various organisms in more or less similar experimental or naturalistic situations.*

Whether we are impressed more by the similarities or by the differences of behavior within the animal kingdom depends on the scale of observation used. The broader the category, the more do the similarities stand out, and vice versa. All animals reproduce and maintain a relatively constant internal environment, but the specific behaviors as-

sociated with reproduction and with homeostasis differ greatly among species. All animals are sensitive to stimuli, and almost all move from place to place, but the mechanisms of receptivity and of locomotion vary widely. In general the similarities are expressed in terms of function or "purpose"; the differences in terms of mechanisms or efficient causes.

Many criteria for differentiation among the behaviors exhibited at various stages of the phyletic scale have been suggested. Some of these are proposed as continua of quantitative variation from the most primitive to the highest forms. Others refer to emergent characteristics, absent at one level, present full-blown at the next. The following listing of modes, areas, or axes of phylogenetic differences is by no means inclusive but gives a sampling of those that have been suggested.

Anatomical-Physiological Foundations

1. Increasing differentiation of parts and specialization of function. In protista all life functions are incorporated within one cell. Amebas show little permanent differentiation, whereas paramecia have a permanent body axis and a high degree of structural-functional specialization.

In metazoans there is a steadily increasing specialization of cells and tissues, with partial or complete loss of other functions and consequent interdependence of body parts. Complexity and variety of motor patterns increase; locomotion is supplemented by manipulation and vocalization. The relative importance of vision and audition in-

* Among the major American contributions which cover the entire range of the animal kingdom are the books of Washburn (1936) and of Maier and Schneirla (1935). The three-volume work of Warden, Jenkins, and Warner (1935, 1936, 1940) is an invaluable handbook for the field of animal behavior; these volumes contain also comprehensive bibliographies of the literature. Among briefer or more specialized treatments that have appeared since 1930 may be mentioned Lashley (1934), Warden, Jenkins, and Warner (1934), Russell (1934), Moss (1934, 1942), Katz (1937), Munn (1938), Fischel (1938), Bierens de Haan (1940), Werner (1940), Moore (1941), C. T. Morgan (1943). Earlier

classics in the field include Romanes (1881), C. L. Morgan (1894, 1900, 1927), Loeb (1900, 1918), Hobhouse (1901), Jennings (1906), Yerkes (1907), Thorndike (1911), Watson (1914), Kafka (1914, 1922), Holmes (1916), Uexküll (1921, 1926), Child (1924), Herrick (1924), Köhler (1925), Hemplemann (1926), Hingston (1928), Pavlov (1927), and Coghill (1929). The present chapter owes much to these earlier compilations; as a rule, studies already described in them will be treated as "general knowledge," and specific reference to those studies and their authors will usually be omitted in our subsequent discussions.

creases at the expense of the contact receptors; special sensory cells and accessory apparatus are developed. The transmissive-integrative system changes from radial symmetry (sponges, coelenterates, adult echinoderms) to bilateral symmetry (worms, most mollusks, arthropods, vertebrates). The neuroid conduction found in sponges is replaced by the nerve net or syncytium of nerve cells (giving diffuse, nonpolarized conduction with decrement) which is characteristic of coelenterates, echinoderms, and flat worms. Synaptic polarized conduction of neurones is predominant in annelids, crustaceans, insects, and vertebrates.

The nervous elements become increasingly concentrated, and these concentrations become localized at the head end. The linear system (nerve ring of the jellyfish) is replaced by paired chains of segmental ganglia in the annelids. In insects the ganglia coalesce, the main one being dorsal and anterior. Vertebrates have the dorsal tubular system, and within this phylum encephalization and corticalization increase.

2. Decreasing autonomy of parts, and of regenerative capacity. There is, however, an increase in the capacity for one sense modality or one effector to substitute for another.

3. Poikilothermism of lower animals replaced by homoiothermism in birds and mammals.

4. Increasing proportion of immaturity and dependence in the life span.

Cognitive Functions

1. Sensory discrimination. Irregularly increasing sensitivity to environmental energies. "One cannot seek, therefore, in the sense organs themselves for the differences known to exist between human and animal intelligence" (Moore, 1941, p. 100).

2. Perception. Irregular increase in variety of stimulus patternings to which organisms respond differentially. Perception of change in stimulus intensity is universal. Visual distance, size, form perception in

arthropods. More highly developed in many birds than in some mammals.

3. Learning. Generally assumed that relative importance of learning increases from lower to higher animals. "The behavior of lower animals depends largely upon their structural characteristics and the immediate stimulating conditions, but that of mammals is largely conditioned by previous responses" (Maier and Schneirla, 1935, p. 265). Rate of simple learning does not increase phylogenetically, but "there is a fairly consistent rise in the limits of training and in the formation of complex habits with ascent in the phylogenetic scale" (Lashley, 1934, p. 468).

4. Abstraction, generalization, transfer, transposition. Transfer or transposition, as in brightness discriminations, "is present in all birds and mammals that have been studied," but "higher levels of generalization are limited to higher vertebrates" (Morgan, 1943, p. 110). Brightness transposition has been demonstrated also in fish (Perkins, 1931) and in bees (Hörmann, 1934).

5. Concepts and symbolic behavior. "What does undergo phylogenetic development, however, is the kind of capacity encompassed by the terms concept formation and symbolization. Most of the development, it may be noted, takes place in the mammalian scale between rats and man" (Morgan, 1943, p. 114). "Between the receptor system and the effector system, which are to be found in all animal species, we find in man a third link which we may describe as the *symbolic system*. This new acquisition transforms the whole of human life. . . . There is an unmistakable difference between organic reactions and human responses. In the first case a direct and immediate answer is given to an outward stimulus; in the second case the answer is delayed" (Cassirer, 1944, p. 24). In referring to experimental studies of monkeys and apes, Moore (1941) says, "But when we attempt to measure their power of abstract thought and their ability to see and form general principles in the logical order,

we obtain zero scores, for such abilities are simply not present."

6. Language. "The difference between *propositional language* and *emotional language* is the real landmark between the human and the animal world" (Cassirer, 1944, p. 30). "It is this faculty of language which seems to be the overt expression of a mental ability which is uniquely human" (Hooton, 1942, p. xxxvii). On the other hand, in referring to birds and fishes, Tinbergen (1942, p. 86) says that "many objective and experimental studies have revealed numerous relations between individuals worthy to be called 'language.'"

Motivational Aspects

1. Genetic and environmental determinism. The notion that the behavior of man is "free" whereas that of animals is strictly determined by inherited structures that react automatically and in set ways to the forces of the environment was given its most extreme expression by Descartes. The reaction against this position has taken two forms, emphasizing (1) the indeterminism of animal behavior, or (2) the determinism of human behavior. The question has been formulated frequently in terms of instinct versus intelligence. The current trend is towards a breakdown of the dichotomy; many writers suggest that the *relative* importance of structurally determined behavior decreases phylogenetically, whereas that of individual experience increases.

2. Viscerogenic (biogenic) versus psychogenic motivation. Behavior of the lower organisms is said to be motivated entirely by nutritional, eliminative, and reproductive "needs" or drives. Among the mammals independent or derived motives of curiosity or exploration and of play are sometimes admitted. Altruistic, ethical, esthetic, and religious motives are usually ascribed only to man, although their beginnings are sometimes reported as manifest in the behavior of infra-human primates and even lower animals.

3. Purpose. A controversial concept in comparative psychology, owing in part to its mentalistic implications. The recent trend is to ascribe some degree or kind of purpose, at least to the higher animals, as indicated by the use of such terms as anticipation, expectancy, and goal orientation.

4. Scope of needs. Needs of the organism increase in number and complexity. There is greater temporal persistence of emotions, attitudes, sentiments, greater complexity of goal and subgoal hierarchies, and increasing indication of conflict, frustration, conscience, or guilt.

General Adaptive Characteristics

1. Increasing diversity, richness, and complexity of behavior. Adaptivity to variable and complex environmental conditions versus uniform and simple ones.

2. Increasing plasticity or docility versus rigidly fixed, stereotyped response. Adaptation of the environment by the organism to its uses versus adaptation of the organism to the environment. Action versus reaction.

3. Increasing socialization, specialization and division of labor, and cooperation. Genetic versus psychological basis of social organization (e.g. Schneirla, 1946).

4. Cultural accretions (almost exclusively human).

5. Increasing degrees of awareness or consciousness. Self-consciousness is usually ascribed only to man (e.g. Verworn, 1889; Yerkes, 1905; Washburn, 1936).

6. Increasing incidence and complexity of behavioral aberrations: neuroses, psychoses, perversions (cf. Hebb, 1947).

7. Increasing value and importance of the individual as opposed to the race. Greater proportion of individuals born survive. (But intraspecies mass conflict is most prominent in ants and man.)

This fragmentary résumé indicates, if nothing else, how vaguely phylogenetic differences of behavior are formulated. The terms overlap, refer indiscriminately to

physiological processes, end products, or postulated intervening variables. They are often mentalistic and lack analytic precision, this being especially true for the so-called higher mental processes. The dimensions or axes of behavioral evolution along which phylogenetic differences may be measured quantitatively, or even in terms of more or less, have not been identified; we have, at best, approximations to usable definitions.

The recurring theme in the outline above is increasing *complexity*. In this or that detail, complexity may actually decrease with ascent in the phyletic scale, but in general it certainly increases. The term is, of course, too broad to be useful, unless the complexity is further specified: phylogenetically, behavior determination involves an increasingly larger number of factors. In the lowest organisms the most intense stimulus of the moment tends to govern the reaction. Later the reaction is increasingly determined by a number of concomitant stimuli that influence each other by summation, inhibition, or otherwise. The effects of previous experience become major factors in governing response to present stimulation, and this influence extends to more remote time.

As regards temporal integration, we are here considering the individual rather than the race. Man's designation as "the space- and time-binding animal" probably derived more from a recognition of his cultural achievements than from an analysis of his capacities as an individual. The cultural realm of development, perhaps even more than his individual capacities, sets man apart from the rest of the animal kingdom. Culture itself is the cumulative effect of individual capacity; it accelerates the biological advantage of man as an individual.

MOTIVATIONAL ASPECTS OF BEHAVIOR

One of the more obvious distinctions between animate and inanimate structures is that the former contain within themselves

mechanisms for maintaining the integrity of their organization under diverse environmental conditions. In our present state of ignorance about the physicochemical-neural mechanisms involved, the student of animal behavior is justified in accepting the capacity of organisms for self-regulation or homeostasis as an ultimate concept or principle. This does not mean, however, that it may be exploited as an overall explanation of behavior, as was done in the post-Darwinian treatment of instinct.

Homeostasis and the Biogenic Drives

Homeostasis depends on the preservation of an organism-environment balance within certain limits, and behavior serves to hold that relation close to the optimum. The life processes are continuous; nutrients are used up, wastes accumulate, internal secretions build up to threshold concentrations. The bodily mechanisms are such that these alterations of intraorganic states often lead to periodic or rhythmic outbursts of activity rather than to a gradually increasing intensity of motor expression. Variations in the temporal span of such rhythms are illustrated by respiration, feeding, and sex behavior.

The effectiveness of internal disequilibria in arousing activity in an organism may be designated the *sensitizing component* in behavior determination. It corresponds, roughly, to what Morgan (1943) has termed "the central motive state." When the situation is such that internal equilibrium is not restored promptly, the sensitizing factor persists over a period of time as a drive. The *directive components** of behavior determination specify the precise nature of the behavior and include that object or environmental condition—the goal or incentive—

* This use of the term "directive" should not be confused with that of Lorenz (1937). For Lorenz (following Heinroth and Uexküll), the sensitizing factor is the *Stimmung*, and our directive components are subdivided by him into "releasive" and "directive" factors in the external stimulating situation.

that elicits the final (consummatory) response leading to restoration of physiological balance.

When the consummatory response can occur without delay, the behavior is spoken of as a reflex or taxis. In such cases the directive factor is immediately present or is, in effect, unessential. When carbon dioxide is added to the water of their aquarium, *Daphnia* ordinarily rise to the surface. But, if the aquarium is lighted from below, the addition of carbon dioxide results in movement to the bottom of the tank. Without the added carbon dioxide there is no orientation with respect to light. Carbon dioxide supplies the sensitizing factor, light the directive component. Extreme intensities of any sensory modality may disturb homeostasis and thus may both initiate and direct behavior.

The behavior manifested when a drive is operative depends on the directive elements in the external situation. If the situation is a restricted and confining one, it will consist of whatever activity is possible: "general" or "spontaneous" activity. If the situation is a relatively open one and provides opportunity for varied activities, the behavior may be called "random" or "trial-and-error." It is, of course, never truly random, since the environmental features, and the animal's perceptions of them, delimit the possibilities. Finally, the animal may find itself in a situation providing a series of specifically directive elements, in which case the behavior will be termed "habit" or "instinct," depending on whether the directiveness is a function of experience or of inherited structure. In either case there is a fairly definite sequence of acts, which is repeated on subsequent occurrences of like circumstances. The final directive element, the goal or incentive, may be the same, whether the preceding behavior sequence has been trial-and-error, instinctive, or habitual.

Most of the situations provided by the natural habitats of animals are mixtures of

the extreme types suggested above. The hungry bird stays in the trees, soars high up in the air, goes to the ground, or wades along the shore, in accordance with characteristics of its species. The particular direction it takes may be quite haphazard, a matter of trial and error, or it may be determined by the individual's previous success or failure in obtaining food in a certain area. In either case the details of its progress are guided by the exigencies of the moment: air currents, spatial arrangement of trees and their parts, nature of the terrain.

Although details of the bodily mechanisms involved are mostly unknown, the relation between homeostasis and the sensitizing components of behavior determination dealt with thus far is reasonably direct and obvious. There are other cases in which the relation is not nearly so clear. The bee constructs a hive and fills it with honey; the spider weaves an elaborate web; the beaver fells trees and builds a dam. All three activities serve the nutritional needs of the animal in question. But the bee is presumably not hungry all the time that it is storing honey (and, if it is, this particular activity does not satisfy the present hunger). Furthermore many activities do not even indirectly serve the present or future needs of the individual in the ordinary sense of the term. At the proper season the bird builds a nest, mates, lays its eggs, broods, for weeks brings food to the young. The carnivore goes through an elaborate and stereotyped ritual in selecting a site for evacuation and in covering over its excrements.

The relevance of homeostasis in connection with such behavior is not obvious and certainly not direct. Much behavior must be ascribed to built-in sensitizing mechanisms that have either an extremely indirect and devious bearing, or possibly none at all, on the maintenance of *general* physiological equilibrium. However, homeostasis presumably applies to the nervous system, as a part of the organism, and the "normal" functioning of nerve tissue may be thought of

as a *specific* requirement of its physiological equilibrium. The inherited nervous structure contains within itself the "need" for functional expression, just as the inherited muscular structure requires exercise. The unique status of the nervous system in this respect is that it mediates its own sensitization as well as that of the other bodily tissues.

The Motivation of Perception and Play

A form of behavior seen so often that it has been taken for granted is the almost constant activity concerned with keeping informed about the environment. Much of the daily activity of the rodent, the dog, the monkey, or the chimpanzee consists in movements of the body and of the sense organs designed to keep the animal in touch with what is going on. Even in a familiar environment, and at times when there seems to be no external stimulation, the animal takes a look around, pricks up its ears, or sniffs the air.

When the motivational aspect of the behavior becomes too obvious to be ignored, we speak of an exploratory drive or instinct of curiosity. McDougall (1923, pp. 59-61) includes curiosity as one of the principal instincts of man and believes that it is "displayed by many of the higher animals, although its impulse remains relatively feeble in most of them. . . . In the animals nearest to ourselves, namely, the monkeys, curiosity is notoriously strong, and then it impels not merely to approach its object and to direct the senses attentively upon it, but also to active manipulation of it." Exploratory behavior may also be thought of (1) as reflecting a primary tendency of all tissues, including the sense organs and their central nervous connections, towards functional expression, or (2) as a secondary tendency derived ontogenetically from the primary drives. The latter interpretation is the more widely accepted one. Tolman (1932), for instance, classifies curiosity with gregariousness, self-assertion, and imitativeness as sec-

ond-order drives. Pavlov (1927), on the other hand, speaks of the "investigatory reflex."

Always accompanying gross exploratory behavior and often occurring independently of locomotion are adjustments of the sense organs and their accessory apparatus. The eyes (and/or the head) are turned and focused; the tongue, the lips or the fingers explore the object tactually; other activities are suspended. Gross exploration has no meaning except as it "exposes" the environment to the sense organs, making perception possible.

The fact that perceptual activity begins very early in life suggests that its motivation is primary rather than derived. Locomotor and manipulative exploration, being extensions of perception, would then be counted among the primary drives. The sensitizing component determining this behavior, it would appear, is almost constantly active; its directing incentive comprises all incoming sensory data, and its consummatory response is to make sense of those data—to identify them with inborn or previously established patterns, to relate their parts into an organized whole, and to analyze the whole into its constituent parts. The subheading of Woodworth's (1921) chapter on perception reads: "Mental life consists largely in the discovery of facts new to the individual, and in the re-discovery of facts previously observed." Woodworth (1947) has since elaborated this notion:

The present thesis . . . is that perception is always driven by a direct, inherent motive which might be called the will to perceive. . . . To see, to hear—to see clearly, to hear distinctly—to make out what it is one is seeing or hearing—moment by moment, such concrete, immediate motives dominate the life of relation with the environment.

In those animals whose repertory of perceptions is more or less limited to the relatively small number determined by innate organization, we find correspondingly little

perceptual investigation of the environment. In those animals, on the other hand, whose perceptual organizations are primarily acquired, the potential number of perceptual organizations provided by environmental stimulation is enormously increased, and to realize them all requires incessant perceptual investigation. The process of forming *new* perceptions is continuous, never finished.

Birds are, on the whole, very active creatures, and in them (as well as in the lower vertebrates and insects) an appreciable share of activity evidently goes into informing themselves about the environment. Most of their behavior, however, is a matter of executing, repetitiously and energetically, certain motor coordinations in accordance with environmental stimulus patterns corresponding to inborn perceptual organizations. In the mammal, and especially in the primate, the level of activity may be lower, but a proportionately greater share goes into keeping track of what's what in the world about. Almost nothing is thrown into the discard as irrelevant, and this appears to be especially true of younger individuals. The lesser distractibility of the adult primate (including man) as compared to young individuals is probably in part a function of (1) quicker, more efficient perception in experienced individuals and (2) a decrease in the number of new and unfamiliar stimulus patterns that motivate the animal to perceptual exploration and organization.

The motivational aspect of play behavior has been interpreted in various ways, none of which, as Beach (1945) points out, are very satisfactory. Schlosberg (1947) concludes that "the category 'playful activity' is so loose that it is almost useless for modern psychology." His criteria of uselessness and incompleteness, however, are not discriminative, since they would admit all instances of unsuccessful behavior, no matter how serious the situation. A second objection is that these criteria suggest that play behavior is essentially a "mistake" — the dis-

tortion, the thwarting, or the miscarriage of a more adequate course of events. Play behavior seems objectively and introspectively neither incomplete nor useless; the game has as much a beginning, a middle, and an end as most activities and seems to have its own motivating force. It is not merely an aberration of some other activity.

A theory of play must account for both its motivational and its formal aspects. This twofold requirement is met by the theory of Groos (1915), namely, that play represents a ripening and activation of the instincts before they are needed for serious use. The concept of "instinct," as used by Groos and many other writers, comprehends both the motivational factor and the specific, innately determined patterning of behavior. The similarity of youthful play behavior to serious adult activities is thereby accounted for. The "surplus energy" theory of play accounts for certain facts about play, such as that it occurs mostly in the young whose energies are not yet needed for serious activities, but it leaves the formal side of play behavior unexplained.

Whether or not it is a matter of using surplus energy, it does seem that a certain amount of muscular exercise is a primary need of the organism. If to this muscular activity drive we add the "direct, inherent motive" of perception, the dynamic aspect of play behavior, independent of other drives, would be adequately accounted for. Human play behavior is typically of a kind that gives much opportunity for perceptual activity. The same predilection for play involving perceptual factors may be seen also in chimpanzees, although here there is already a lesser variety, a greater tendency to repeat the same actions over and over again. In lower animals (with certain notable exceptions among the birds) play tends to duplicate serious, "biologically adequate" behavior. In animals whose inherited structure makes possible the acquisition of perceptions through experience, play behavior is correspondingly more variable, and there

is more of it because the environment provides these animals with more stimulation to perceptual activity.* In biological-teleological terms, play serves the purpose of developing an equipment of perceptual and motor patterns in the higher mammals, whereas animals with an inherited repertory of perceptions and motor coordinations do not need this opportunity, being already provided with such neural organizations.

Innate Determination of Directive Factors

The sensitizing component of behavior determination, it has been suggested above, is provided by the functioning of inherited structures. With respect to most sensitizing components, individuals and species are rather alike, although they may differ considerably in the relative importance of one or another kind of sensitization. It is with respect to the *directive* components of behavior that animals may be classified as being guided primarily either by instinct or by experience. The final, consummatory response is almost always structurally determined. But the stimulus-response sequence that precedes the final act may be primarily a function of experience in man and primarily a function of structurally determined responses to environmental stimuli in the insect or bird.

Much of our progress in the observation and analysis of instinctive behavior has been made by European investigators: Uexküll, Heinroth, Lorenz, Tinbergen, Brock, and others, together with their students and colleagues. Uexküll's (1921) concept of the *Umwelt*, the circumscribed portion of the environment that is meaningful and effective for a given species and that changes its significance in accordance with the *Stimmung* (Heinroth) or mood operative at a given moment, is of fundamental importance. The sequential chaining of stimuli and responses

* In laying stress on the role of perception, I do not intend to deny the possible importance of other primary or second-order drives, such as rivalry, mastery, or submission in play behavior.

subserving a given biological function, regardless of their innate or experiential determination, he designates as a *Funktionskreis* or functional cycle. Lorenz (1935) points out that in many "instinctive acts" the motor coordination involved may be completely determined by inherited structure (*Erbkoordination*), whereas the "releasing pattern," the stimulus concatenation that elicits it, may be innate or acquired. The chaining of behavior elements of diverse etiology he terms an "instinct-training interlacement." If the external releasing pattern is not forthcoming, the threshold of the reaction decreases until the latter may occur in the absence of the usual precipitating stimulus: a *Leerlaufreaktion* or "reaction in a vacuum." Thus, if it is sufficiently hungry, the very young bird may hold open its beak even when the usually necessary stimuli are not present.

The directive components of behavior determination are analyzed further by Lorenz and Tinbergen (1938) into externally "releasive" and "directive" factors. When an egg of the gray lag goose has rolled outside the nest, the goose stretches its neck out towards it, brings the bill behind the egg, and then rolls the egg towards the nest. During this maneuver the coordination is constantly adjusted to the tendency of the egg to roll sideways. These variable movements depend on the present stimulating situation, but the retraction of the bill and neck is invariable, an *Erbkoordination*. Once released, the latter is carried through in typical, stereotyped fashion even if the egg is removed as soon as the reaction has started. Tinbergen and Kuenen (1939) have shown that the "gaping reaction" of young thrushes is released by jarring of the nest and is directed or oriented (upwards) by gravitational stimuli.

The releasing pattern for an instinctive act, Lorenz (1935) points out, is usually a simple one, composed of only a few elements, but those elements are in a combination that is unusual or improbable in nature. Improb-

ability of the pattern is a safeguard against release of the act at the biologically wrong time or place. Particularly in social behavior, the releasing pattern may be the form and/or color of a structure (an ornament) or a certain act (movement pattern) of another animal. The simplicity of the releasing pattern is a "biological economy" and also insures that its effectiveness is not restricted to highly specific, possibly irrelevant details. Thus the inborn pattern of "child" or "parent" includes enough characteristics to designate the species, but not so many that only a particular individual of the species elicits the response.

Lorenz lays great stress on the phenomenon, apparently first described by Heinroth (1910), of *Prägung* or "imprinting." In autophagous birds, which are able to run about and obtain their own food right after hatching, only the adult of the species is effective in eliciting responses directed to the parent, such as trailing, food begging, and food acceptance. In many other birds the "object" of the parent-directed activities is not determined innately but is fixed, permanently and irreversibly, during a short period (often a matter of minutes or a few hours) following hatching. Goslings of the gray goose, hatched in an incubator, attach themselves permanently to whatever kind of animal, including man, the gosling sees during the first few hours after hatching. The object of possible imprinting is delimited, more or less in various species, by schematic inborn patterns to which the object must correspond, and the period in the life cycle during which imprinting may occur varies with different functional cycles in the same species.

Bierens de Haan (1937) expresses doubt that imprinting is basically different from conditioning or learning. Lorenz (1935) emphasizes the facts that (1) unlike learned behavior, which is subject to forgetting and relearning, the effects of imprinting are permanent and irreversible; (2) imprinting can

occur only during a narrowly delimited period of the life span, whereas the process of learning is not similarly restricted.

Furthermore, in all animals there are innate predispositions for particular motor coordinations, perceptions, and sensory or perceptual motor sequences. Certain neural organizations are more likely to occur as a result of experience than others. To a certain extent this readiness may be attributed to the effector equipment of the organism, but to a large extent it is a matter of inherited neural organization. The higher up we go in the animal scale, the fewer instances of purely instinctive behavior do we find. Even the eye-muscle coordinations of pecking in the chick are improved by practice, as well as by maturation (Cruze, 1935). Here we have a core of structural patterning that is refined or improved through learning. This seems to be the rule for *motor skills* in all animals, although even here the relative importance of the learning factor increases phylogenetically. The phenomenon of imprinting, as contrasted to the inborn releasing pattern, is one rather special instance of the increasing importance of experience in perception.

It is important to distinguish between the effects of variability and of experience. One source of *apparent* variability may be the simplicity of the inborn schema, which means that a large class of objects or stimulus patterns may release a given response. Another source of behavioral plasticity is a multiplicity of inborn stimulus-response connections, which may be activated by different stimulus patterns. The righting reaction of the sea star shows more plasticity than the combbuilding reactions of a bee. Uexküll has said that the horse is more of a machine than is an ameba, the behavior of the former being more predictable.

Modification of Motivation by Experience

For purposes of description and comparison we shall discuss instances of behavior

modification under the six categories indicated by the encircled numbers in Fig. 1. The first three categories represent modifications traditionally referred to in connection with motivation, whereas the last three are usually included in the discussion of learning

one, perhaps, conforming fully to the criteria of an unconditioned reflex. (3) The dotted line from C_f to S.C.S. and P.E.R., the vertical alignment of P.E.R. and S.C.S., and the two impartial arrows are in recognition of our ignorance concerning the mechanism of

FIG. 1. Schema of drive behavior, indicating six proposed categories or types of behavior modification.

- Left to right: temporal succession of events.
 Horizontal levels: arbitrary units of description.
 P.D.: physiological disequilibrium, persisting (dashed line) until
 P.E.R.: physiological equilibrium is restored (in whole or in part).
 S.C.: neural representation of sensitizing component, persisting until
 S.C.S.: the sensitizing component of behavior determination subsides.
 S_a and S_b : external directive components or stimuli.
 S_i : external directive component; the incentive or goal-object.
 S_a : a conditioned stimulus.
 R_a and R_b : innate or acquired responses to (S_a , S.C.) and (S_b , S.C.).
 R_c : innate consummatory response to (S_i , S.C.).
 C_a and C_b : consequents (on environment-organism relations) of
 R_a and R_b , and "leading to" the occurrence of S_b and S_i , respectively.
 C_f : final consequent of R_c , and (dotted line) resulting in P.E.R. and S.C.S.
 Encircled figures: proposed categories of behavior modification:
1. Modification of the sensitizing component.
 2. Externalization of drive.
 3. "Transformation of mechanisms into drives" (Woodworth).
 4. Classical or respondent conditioning.
 5. Instrumental learning.
 6. Experiential organization of perceptions and motor coordinations.

and the higher mental processes. In the present section we shall be concerned only with Nos. 1, 2, 3, and 4; Nos. 5 and 6 will be taken up in later sections on learning and on the genesis and scope of perceptions.

Supplementing the legend of the diagram, several further points should be noted. (1) S_a — $R_a C_a$ and S_b — $R_b C_b$ are intended as representative of a *much* longer series of such units usually comprising a drive sequence. (2) S_i — R_c may be considered representative of several "goal responses," only the final

reinforcement. The effect may occur before physiological equilibrium has been restored and perhaps even without any restoration of such balance. (4) Each S and each R in the diagram (e.g. S_a and R_a) may be conceived of as representing an organization of subordinate s-r's, such a patterning constituting the higher-unit S or R in which the psychologist dealing with molar behavior happens to be interested. (5) The numbering of the following paragraphs corresponds to the numbering in the diagram.

1. *Sensitizing component of behavior determination.** It seems doubtful that primary sensitizing factors, not provided by inherited structure, are ever developed through experience. The *details* of physiological need are determined to some extent by previous environment. Similar to this phenomenon, known as acclimation, are the specific needs associated with disease, pregnancy, and other special physiological conditions; drug "habits" and addictions are extreme examples of need specificity determined by earlier organism-environment relations. Spragg (1940) has presented convincing evidence of morphine addiction in chimpanzees, and other workers have shown somewhat similar phenomena in monkeys and dogs. (As Lindesmith, 1946, points out, the addiction syndrome is more elaborate in man than in chimpanzee, and this difference may be ascribed to man's linguistic symbols and/or the thought processes associated with them.)

The innate sensitizing component may be altered by interference or control of the relevant physiological mechanisms. Beach (1947), in his review of the work on endocrine and nervous control of mating behavior in mammals, concludes that "susceptibility to sexual arousal . . . in lower mammals depends heavily upon hormones from the re-

productive glands, and that in higher species, particularly apes and humans, the rigidity of such hormonal control is relaxed sufficiently to permit a considerable amount of sexual responsiveness and potency in the complete absence of sexual secretions." That is to say, in the higher primates the central nervous system mediates the sensitizing component somewhat independently of the gonadal secretions. The directive factors, as Beach points out, are often experientially modified and cortically controlled even in lower mammals. There is some indication that the sensitizing component of hoarding behavior in rats (Wolfe, 1939; Hunt, 1941; Morgan, 1947) is affected by food deprivation during early life; whether this is a result of physiological acclimation or of behavioral experience still needs to be worked out.

2. *Externalization of drive.* There are some drives (e.g. for rest, or for exercise) that can express themselves under most environmental conditions. Other drives, such as hunger and sex, require a highly specific external object for the consummatory response. Sometimes there are almost no behavioral indications of the presence of such a drive in the absence of the goal object. Even "general activity" may be absent. An adult male chimpanzee may be resting quietly, even sleeping, when food, or a receptive female, is introduced into the cage. At once there are unmistakable signs of the hunger or sex drive, and eating or copulation occurs, if the situation permits. This phenomenon Anderson (1941) has termed "the externalization of drive." Two interpretations seem possible: (a) Stimulation from the goal object is an essential part of the *sensitizing component*; the neural pattern is ineffective unless the external stimulation is added to the internal physiological condition. (b) The sensitizing component has become associated with the incentive, so that the latter sets off the former; the central nervous mechanisms originally activated only by certain hormones, for instance, may later be

* Just how a physiological need affects behavior is not known. That it does so is obvious. The hungry animal "looks for" food, makes an "effort" to obtain it, eats when food is available. The satiated animal does none of this. Somewhere the nutritive deficit acts upon the nervous system. This action is describable as a selective sensitization: the organism becomes sensitive and responsive to stimuli that innately or through experience are related to need-reduction activities. Whether responsiveness to stimuli not so related becomes inhibited, or merely relatively less, we do not know. Nor need we ask here *how* the physiological disequilibrium "works on" the central nervous system. The objective fact is a change in relative threshold of response to stimuli that do and do not have meaning for the need—for instance, whether food will be approached or disregarded. The directive components of behavior determination specify details of the response—whether the milk is lapped up or the meat is chewed.

aroused by other stimuli previously associated with the functioning of those mechanisms. This second interpretation does not preclude the need for specific internal conditions that permit the conditioned response to occur. Summation may be necessary. Anderson (1941), however, believes that when externalization has gone far enough "the drive becomes aroused in the absence of the original internal conditions." Obviously there are limits to this process, since the sight of the drinking fountain is less likely to arouse the behavior associated with thirst in the water-satiated than in the water-deprived animal. The implications of the theory of externalization have not been consistently verified in experiment (e.g. Koch and Daniel, 1945; Siegel, 1943).*

There has been no systematic work on drive externalization in animals below the mammals. Various observations suggest that it is more frequent among the higher than among the lower mammals and, as regards

* Inactivity or sleep during the absence of the incentive may have biological utility; in the case of hunger, for instance, it would conserve energy and so keep the animal from getting even hungrier. The conception of sleep as an instinct (Claparède, 1928) or independent drive, providing escape from other motives (Willey and Rice, 1924), is a possible substitute for "externalization" in accounting for the observed behavior.

It should be noted that the theory (see Chapter 13) that an acquired fear drive motivates avoidance learning implies a rather special form of drive externalization. Two sensitizing factors are involved. An external stimulus, occurring in association with a noxious situation (e.g. electric shock), becomes conditioned (1) to the adequate (shock-reducing) overt response to shock, and (2) to the emotional response that is innately elicited by shock. The emotional response has physiological effects or sensory consequences that provide a second sensitizing component, namely fear. Any response that removes the external fear-arousing stimulus reduces the fear, and therefore becomes conditioned to that stimulus. According to this explanation the original drive, whose sensitizing component derives from the electric shock, is not externalized. The fear drive, on the other hand, is usually if not always externalized, fear being typically aroused by a danger signal rather than by actual injury or other physiological disequilibrium.

the sex drive in particular, more so in the male than in the female.

3. "*Transformation of mechanisms into drives*" (Woodworth), or "*functional autonomy of motives*" (Allport). In discussions of these phenomena it is usually assumed that some portion of a drive behavior sequence becomes detached, motivationally, from the usual end unit (consummatory response) of the chain. Whether this part becomes completely divorced also from the original sensitizing component is not always so explicitly stated. The concept of functional autonomy derives particularly from the observation of human subjects; its applicability to lower organisms is rarely unambiguous. First, it is necessary to rule out the possibility that the behavior in question, which may resemble an intermediate portion of a longer sequence, is not motivated independently by its own drive mechanism, such as that of muscular exercise, perception, or play. The hoarding behavior of rodents would readily fit the interpretation of an autonomous motive derived from the nutritional drive, but Morgan (1947) champions the independent status of a hoarding instinct. Second, the various part behaviors of a prolonged drive sequence involve sub-goals — approaches, avoidances, manipulations — that may temporarily manifest a quasi-independence, but that disintegrate (extinguish) if their relation to the sensitizing component or to the final response of the drive is lost. The acquisition of money by the human miser *may* represent a functionally autonomous motive, but the accumulation of tokens by the chimpanzee (Wolfe, 1936; Cowles, 1937) continues only as long as the tokens remain a means for satisfying a primary drive — i.e. as long as they operate as a secondary reinforcement. Williams (1924) showed that an unbaited white-black discrimination box (in which correct choice previously had been rewarded with food), placed at the end of a maze, was, for some time, about as effective in promoting maze learning as was a food reward.

4. *Classical or respondent conditioning.* In any reflex or taxis, where the sensitizing and directive components occur together, or where the latter is absent, the S-R connection is rigidly fixed by inherited structure. This is usually true also of the S_i - R_e sequence (see diagram) of drive behavior. Any stimulus concurrent with S_i or the unconditioned stimulus will, after a number of pairings, independently elicit the response. Such substitution may be carried along for several steps (higher order conditioning). Summarizing the experimental literature on classical conditioning in animals from the protozoa to the primates, Razran (1933) concluded that there was no convincing evidence for consistent phylogenetic trends in any of the investigated aspects of conditioning.

The specificity of the stimulus eliciting R_e in accordance with the particular need of the organism has been demonstrated especially by the work of Richter (1942-43, 1947) and Young (1941) with rats. When the requirement for a given type of food, mineral, or vitamin was raised by inanition or gland extirpation, the animal's preference for that item greatly increased. After sectioning of the gustatory nerves, adrenalectomized rats lost their selective preference for salt and died of salt deficiency.

COGNITIVE ASPECTS OF BEHAVIOR

Most problem-solving situations are extremely complex, in the sense that many behavior mechanisms are involved. Although the situation may be psychologically uncomplicated for the animal, the particular mechanisms functional in this or that individual or species and the specific sources of difficulty for the subject may be quite obscure. We are baffled, for instance, when the difficulty of discrimination learning by chimpanzees is enormously increased by moving the cue object just a few centimeters back from the place against which the animal must push

in making its choice response (Jenkins, 1942).

The present discussion proceeds from the convictions (1) that the process of connecting perceptions to overt responses—probably seen in its purest form in simple “conditioning” experiments—differentiates the lower from the higher invertebrates but is not highly discriminative among the several vertebrate levels; (2) that animals differ greatly with respect to the innate versus experiential basis of their perceptions and that this difference constitutes the most important axis of behavioral evolution within the vertebrate series from fish to the anthropoid apes; (3) that, in so far as perception is organized by experience, variations among individuals and species in perceptual and conceptual development are functions of several behavior mechanisms that must be postulated as determinants of perceptual-conceptual organization; (4) that a sudden increase in the efficacy of one of these mechanisms, symbolization, has made possible the great range of concepts used by man.

The repertory of inborn perceptions, plus the functioning of organizing mechanisms, determines the perceptual-conceptual scope of the organism. Perceptual-conceptual scope represents the organism's information about (cognition of) its environment. The gamut of innate and learned connections between its percepts-concepts and its various overt responses constitutes the organism's adjustment to the environment.

Before proceeding to a discussion of this formulation of the principal axes of behavioral evolution in the higher animals, we may consider briefly some basic integrative processes to be seen in the behavior of the most primitive forms of animal life.*

* This division of the chapter, being organized around supposedly primary or fundamental cognitive mechanisms and their evolutionary development, does *not* present a comparative survey of adaptive or intelligent behavior. Only the main trends of development are illustrated by representative instances from the appropriate phyla. Examples of basic integrative processes are taken exclusively from the behavior of

Integrative Processes in Protista

No unambiguous instances of learning among protista are reported in the literature. The behavior of these one-celled organisms does manifest alteration with continued stimulation, however, and such alterations are often analogous to the modifications seen in higher animals. The effects of continued or repeated stimulation in protista are most conveniently described in terms that apply also to certain aspects of metazoan behavior, especially the behavior observed in artificially simplified situations (see, for instance, Skinner, 1938).

Variability. Some degree of response variability is obviously a prerequisite for learning, although most learning experiments make very limited use of the animal's motor versatility. The direction of locomotor responses in amebas is notably variable. Strong stimulation usually results in withdrawal of all pseudopods and temporary immobility; resumed locomotion tends to be in the direction opposite to the original one. With weaker and nonlocalized stimulation locomotion may be changed to almost any direction. The response of paramecia is relatively stereotyped, varying in magnitude with intensity of the stimulus.* The nature of the locomotor response is such, however, that change of direction increases automatically with increasing intensity of the response. The ciliate *Stentor*, by contrast, has a variety of distinct responses that may be given to the same stimulus.

Spatial and temporal summation. When two or more stimuli, each of subthreshold

protista; those of learning, from the behavior of invertebrates and lower vertebrates. The section on the genesis of perception gives specific illustrations for only the more common perceptions that are found even among the lower animals. In the section dealing with factors of perceptual-conceptual organization few specific illustrations are presented, but the discussion concerns itself increasingly with the determinants of behavior seen only in the mammals and especially in the primates.

* The beating of cilia of the oral groove, however, may be quite independent of that of the body cilia (Mast and Lashley, 1916).

intensity, are applied simultaneously or within a short interval, a response may be elicited. The stimuli whose effects are thus combined need not belong to the same modality. Often it is not known whether the two modalities are differentiable by the organism or whether both are mediated by the same sensory surface. It seems probable that in some instances, at least, distinct receptor mechanisms are involved and that the summation or facilitation is intersensory. Folger (1927) demonstrated with amebas that a mechanical stimulus and a light stimulus, each of intensity insufficient to elicit a response by itself, would produce responses in a high percentage of cases when one of these stimuli followed the other (in either order) within about three seconds. If "summation" is defined as an algebraic process, we may include here those cases in which a second stimulus minimizes response to the first. General activity, as well as responsiveness to light, mechanical jarring, and other stimuli, may be greatly reduced in paramecia by contact with a solid.

Acclimation and adaptation. There are many observations of the intensification, reversal, inhibition, or other alteration of response to one stimulus by the action of a second stimulus modality (particularly chemical and thermal) which probably are not instances of summation in the usual sense. At one temperature the organism may react strongly to light, whereas at a lower temperature it remains indifferent to light changes; orientation to an electric current may be reversed by changing the chemical composition of the medium. In these cases the environmental agent is more important in its effect on the physiological state of the organism (compare the role of anoxia, nutrition, drugs) than as a stimulus in the usual sense of the word.

Adaptation to continuous (versus repeated) stimulation is usually termed acclimation (or acclimatization) and, with respect to thermal and chemical modalities at least, often involves alterations in the organism's

physiological processes as well as in its response to the stimulus. The range of environmental conditions to which many protista can adjust themselves is quite remarkable, provided the changes are gradual rather than sudden. Several species of flagellates successfully acclimated themselves, over a period of seven years, from an initial temperature of 16 degrees C to a final temperature of 70 degrees C.

The effects of continued stimulation on behavior are often obscured by concurrent influences on the organism's physiological condition. When exposed to continuing illumination, dark-adapted colonies of *Volvox* are at first indifferent, then positive, then negative, and finally positive again. In general it is the onset of external stimulation that elicits response (onset being defined as including the total period necessary to bring the product of intensity \times time to threshold value), whereas continuation of the environmental energy merely provides a new base line for determining the direction and amount—and thus the stimulating value—of further changes in the stimulus. Increase of illumination produces temporary immobility in an ameba, the duration of which varies with stimulus intensity; subsequently the organism sends out pseudopods and moves about as before.

Cessation of response, when a stimulus of mild intensity is repeated frequently, has been observed in all protistan forms studied. *Stentor*, for instance, contracts on its stalk when stimulated by a weak mechanical stimulus, but it omits this response after the stimulation has been repeated a few times at intervals of a minute or so. If the stimulus is of sufficiently high intensity or is applied at widely spaced intervals, adaptation does not occur. A strong mechanical shock still elicited contraction in *Vorticella* after a series of 420 stimulations.

Refractory phase. It is often difficult to distinguish between the effects of sensory and motor fatigue, adaptation, and acclimation in the behavior of protista. A distinc-

tion may be made, however, between the effects of stimuli repeated at very short intervals and those more widely spaced. In the former case the second stimulus may fail to elicit a response at all, or the response may have a longer latency and be of reduced magnitude. As Warden, Jenkins, and Warner (1940, p. 72) have pointed out, this phenomenon bears a marked resemblance to that of refractory phase as seen in vertebrate nerves.

Sensitization. Repetition of a stimulus-response sequence sometimes results in increased sensitivity—an effect exactly the opposite of that just considered. A *Nostoc hormogonium*, which at first stimulation failed to react to illumination lasting 340 seconds, on the nineteenth trial responded to a stimulus duration of only 45 seconds. Amebas, moving into a lighted area, continue to send out pseudopods in the same general direction until, after a number of repetitions of the stimulus, they reverse the direction of locomotion. On subsequent trials the number of repetitive responses in the original direction decreased to zero (in 6 to 27 trials). Effects such as these, which are concerned with successive stimulus-response sequences, are not to be confused with the summation of stimuli to produce a single response.

Interactions. The several processes outlined above, some producing effects opposite to those of others, interact in complex ways. The following tabulation may be helpful in organizing the main factors under consideration:

- I. Algebraic summation of total effective stimulation eliciting one response. Time span relatively short.
 - A. Positive (additive).
 1. Intrasensory temporal summation.
 2. Intersensory spatial (simultaneous) and/or temporal summation.
 - B. Negative (subtractive).
 1. Intrasensory. "Refractory phase" phenomenon.
 2. Intersensory. Interference or inhibitory effects by stimuli of one mo-

dality on response to those of a different modality.

- a. "Sensory" or "central" inhibition.
- b. Interference by prepotency of secondary, incompatible response.

II. Effects of previous stimulation or S-R experience on subsequent behavior. Time span relatively longer.

A. Positive. Intrasensory or intersensory.

1. Acclimation.
2. Sensitization; increased sensitivity, augmented speed, and/or magnitude of response.

B. Negative.

1. Acclimation.
2. Sensory or motor fatigue.
3. Adaptation. A gradient of decreasing responsiveness to the intensity or quality of continued or repeated stimulation.

Stimulated by particles of carmine dropped from above, *Stentor roeselii* exhibits a sequence of responses (described by Jennings, 1906) conforming closely to the usual picture of trial-and-error learning: (1) The head end bends towards the aboral side; (2) the oral cilia reverse the direction of their beat, so that the water stream is carried away from the body cavity; (3) the stalk contracts into its tube of mucus; (4) the organism breaks off its attachment to the substratum and swims away. If the stimulation is then repeated sufficiently soon and often, the earlier phases of the sequence may be omitted in accordance with what Jennings has called the "readier resolution of physiological states." These various events may involve (1) the anterior-posterior physiological gradient, making the anterior parts more sensitive and responsive; (2) fatigue and/or adaptation of the anterior sensory-motor elements; (3) temporal (and spatial) summation of stimuli until thresholds of the later responses are reached; (4) sensitization of the later phases of the sequence.

Learning

The term learning refers to a relatively enduring change in the response to a con-

stant external stimulating situation under fairly constant physiological conditions—a change that is a function primarily of intervening experience, i.e. of stimulus-response sequences and their consequences. Variability of response as such, and changes produced by growth or maturation, by variations in drive, state of health, drugs, hormones, fatigue, sensory adaptation, and so on, are not instances of learning. By specifying "a constant, external stimulating situation" the definition seeks to avoid confusion between learning and other phenomena, such as transfer or abstraction generalization.

Most learning experiments produce evidence falling into one of two classes: a uniform response is given to a constant stimulating situation that previously elicited either a different response or variable, and generally unpredictable, responses. Thus the two-object discrimination situation may elicit, initially, chance response to white (positive) and to black (negative), or consistent response, by pre-established preference, to black. Later the animal responds consistently to white.* Sometimes the original behavior, prior to experience, is not observed, but the improbability of the observed response occurring by chance, i.e. without experience, may be acceptable evidence for learning. This would be the case, for instance, when the wasp returns to its nest on its initial excursion into new territory, or when the monkey responds consistently to the "correct" container (which changes from trial to trial) in a series of delayed response trials.

* In classical conditioning the S_c often precedes the S_u , so that development of conditioning may be followed by noting the onset of the conditioned response before S_u occurs; in that case the recurring external stimulating situation is constant in the same way as it is in instrumental conditioning. Where the S_c and S_u are actually simultaneous, the stimulating situation during training includes S_c and S_u , whereas the initial and final testing situations include only S_c . Since the external stimulating situation eliciting the critical response is not constant, simultaneous conditioning does not conform to our operational definition of learning: within the framework of the present

The total training time required by an animal for mastery of a given problem *may* include (1) a period devoted to organizing the critical perception; (2) time consumed in discovering the critical stimulus pattern in the context of the present situation, in discarding possibly prepotent but here irrelevant perceptions, and in responding to the less obtrusive but differential pattern; (3) time used in the S-R connecting process itself (including, often, the formation of wrong connections before or in addition to the right connection). Usually it is impossible to determine the relative importance of these three phases, although in any given case extraneous evidence may indicate the presence or absence of the first one listed.

Given the effectiveness of the S, there are certain factors that influence formation of the S-R connection and that presumably are common to all learning situations; they include the strength of the principal drive, the kind and amount of incentive, the time relations in the stimulus-response-consequence succession, the effectiveness of subsidiary facilitating and interfering drives, the spacing of trials, and so on. As far as the writer is aware, there is no evidence indicating consistent phylogenetic differences with respect to the direct effectiveness of these factors,

formulation, failure of conditioning could be ascribed either (1) to a failure of S_c to elicit an independent perception during training, or (2) to a failure of the connecting process (S_c -R) itself. Positive results, on the other hand, would indicate that there was a perceptual response to S_c during training *and* that this became connected to R.

The status of backward conditioning is, in this connection, somewhat ambiguous. If the stimulating situation were described as starting with and including only S_c , backward conditioning would be an instance of learning as here defined. Exclusion of the brief aftereffects of S_u or of S_u -R_u, however, seems arbitrary and unjustifiable; these aftereffects would be part of the stimulating situation during training but not in the critical test of behavior modification. It may be noted in this connection that Spooner and Kellogg (1947) concluded, on the basis of an experiment with human subjects, that "backward conditioning is apparently an entirely different phenomenon from forward conditioning."

with the possible exception of an increasing time limit, in the higher animals, on the maximum interval between successive trials.

There is a second group of determining factors that are specific to the particular learning situation and to the phylogenetic position and ontogenetic history of the subject. As may be seen in the following incomplete listing of such factors, they are responsible for many of the most important differences in the relative difficulty of various learning situations, and they refer, not to the S-R connecting process, but rather to conditions relating to the prerequisite of that process: perceptual responsiveness to "the stimulus" (i.e. phases 1 and 2 as given above).

1. Stimulus and response option. Difficulty increases with the number of stimuli to which the subject may respond and with the number of overt responses that can be made to each. The objective details contributing to the enhancement or attenuation of stimulus obtrusiveness are, of course, not the same for all animals.

2. Stimulus and response prepotency. Difficulty decreases as the critical stimulus and the correct response become increasingly prepotent over other stimuli and responses.

3. Differential reinforcement of irrelevant cues. In almost all learning situations numerous irrelevant stimuli impinge on the animal's sensorium at the moment of reinforcement or nonreinforcement. The differential rewarding of an irrelevant stimulus, especially if it is a prepotent one, retards the learning.

4. Perceptual-conceptual repertory and span. Species differ radically in their capacity to organize sensory complexes into stable recognized patterns or perceptions. Some perceptions are ubiquitous; others, as of number, middleness, or triangularity, are rare. Some are already fully organized when the learning experiment begins; others are formed in the course of training.

Recognition of the primary role of perception in behavior determination serves to focus attention on a pervasive difficulty in the analysis of learning. The usual learning experiment yields a single, overall score. If behavior modification may be a function of two or three processes (i.e. phases 1, 2, and 3, as postulated above), to which of these, or in what proportion to each, shall the single index of change be ascribed? An experimental design that would yield separate, independent indices for the several variables would be the ideal solution.*

Before discussing perception and its determinants, we may briefly examine some instances of learning among those animal groups whose perceptual organization is relatively simple and, to a major extent, inately determined.

All the modes of integration observed in protista are seen even more clearly in coelenterates, echinoderms, worms, and mollusks. (The sessile sponges are behaviorally more primitive, and therefore psychologically less interesting, than are many unicellular organisms.) Instances of adaptation and sensitization are especially numerous, and in these metazoan forms the mechanisms involved are more often attributable to "central" than to peripheral factors.

Echinoderms. Although in certain structural features the Echinodermata most

* One type of solution, by Hull (1943), may be stated in three parts: (1) Phases 1 and 2 are minimized by the assumption that any "sensory aggregate" impinging on the sensorium when a reinforced response occurs becomes connected to that response. (2) It is assumed that the performance indices deriving from learning experiments pertain to the connecting process, and that therefore the laws of this process are quite accurately known. (3) Any differences between performance scores and the results predicted from the laws of connection are attributed to primary stimulus generalization and/or the principle of afferent interaction. This conceptualization has the advantage of including the facts of perception within a highly integrated, formalized, and partly quantified system of psychology. Against this must be weighed the danger of treating perception as a subsidiary adjunct of the total learning process rather than as its most important component.

closely resemble the vertebrates, they are not far advanced behaviorally and there is no convincing evidence of learning capacity in this phylum. Much experimental work on the righting reaction of the starfish leaves unanswered the question whether local tissue change or learning is to be credited for the shift, produced in the course of training, from the use of the preferred to use of the nonpreferred arms in the reaction.

Coelenterates. Pieces of filter paper were placed on certain tentacles of sea anemones at 24-hour intervals. At first the tentacles grasped the paper and brought it to the mouth where it was swallowed, later to be rejected. After several experiences the paper was not swallowed. Finally the particular tentacles being trained failed to grasp the paper at all. At this time the untrained tentacles still accepted the paper, but they reached the stage of rejection in many fewer trials than had been required initially. Apparently the learning involved central as well as local modification.

Worms. Flatworms, which are stimulated to locomotion by light, were repeatedly exposed to cycles of 5 minutes of illumination, followed by 30 minutes of darkness. Each time they started creeping forward, a tactual stimulus was applied to the head end, which stopped the movement. By the end of twenty-five such cycles no movements were occurring during the periods of illumination. Extirpation of the cephalic ganglion abolished this suppression (conditioned inhibition) of the crawling response to light. The annelid, *Nereis virens*, was conditioned in a few trials to come out of an open glass tube in response to sudden changes in light intensity when this light stimulus was regularly followed, after about 20 seconds, by chemical stimulation from a piece of clam placed at the entrance of the tube.

Earthworms have been trained successfully to make consistent left or right turns in T- and Y-shaped mazes. Peculiarly enough, reversal of the habit required fewer

trials than had the original habit; one possible interpretation of this result is that mastery of the maze involved both (1) development of prepotent responsiveness to the effective cue, and (2) the association of that perception with a particular overt motor response.

Mollusks. Somewhat faster learning of a T-maze has been reported for land snails. In a conditioning experiment the pond snail *Physa* was given double stimulations with (1) lettuce touching the mouth region (eliciting mouth opening) and (2) pressure on the foot (inhibiting mouth opening). Originally (2) was prepotent over (1). After some 250 double stimulations however, the mechanical stimulus on the foot resulted in mouth opening even when the unconditioned stimulus (lettuce) was omitted. In this experiment the conditioned stimulus, instead of being neutral in regard to the required response, was one that originally inhibited the response. Retention of the habit for 96 hours was demonstrated. Experimental extinction occurred within about twelve trials, but reconditioning required fewer trials than had the original training. Differential conditioning has been observed in the mollusk, *Eledones moschatae*. The unconditioned stimulus was tactile, and the conditioned stimuli were flashing lights of various wavelengths (which probably varied also in brightness value).

Arthropods and lower vertebrates. Some of the insects, ants in particular, are capable of learning the shortest path through long mazes with many culs. Their performances in this situation are in most respects not inferior to those of mammals and are superior to those of the lower vertebrates. Among the latter, reptiles appear to be somewhat better than fishes and amphibians. Instances of response substitution have been observed in representatives of the arthropods and lower vertebrates. Cockroaches, which are strongly negative to light, were trained to stay in the lighted part of a long box by giving them electric shocks in the

darkened end of the box. A glass partition in an aquarium separated specimens of pike or perch from their natural prey, small minnows. After numerous experiences of bumping against the partition, the larger fish learned to suppress their attacks on the minnows even after the glass partition was removed. Electric shock or other noxious stimulation, concomitant with the response of snapping at food, effectively inhibited eating behavior in amphibians and reptiles. Differential conditioning, and mastery of visual discrimination problems involving approach-avoidance responses, have been demonstrated in arthropods, fish, amphibians, and reptiles.

The Genesis of Perception

The lower organisms begin life as more or less finished products, then or soon thereafter possessing all the behavioral tools that they will ever have. By contrast the higher animals and especially the primates go through a long period of maturation and growth. Bones grow, bodily proportions change, muscles get stronger, motor skills develop. This rather spectacular emancipation from physical inferiority has tended to obscure the more important cumulative development of permanent acquisitions that serve as instruments of behavioral adjustment in all later life. The most striking example of this is the child's acquisition of language—a stupendously complicated symbolic system, not even approximately achieved by any other organism. (Consideration of the magnitude of this achievement makes questionable the notion that "intelligence," in the sense of capacity or power, increases from birth to maturity; exactly the opposite seems at least as probable.)

The importance of experience in the development of perception among the higher primates is suggested by the work of Riesen (1947) with chimpanzees raised in darkness. These animals were first brought out into the light when about 18 months old. With respect to visual perceptive abilities they

were then roughly equivalent to newborn animals. Even after 6 months in a normal environment visual perception was still greatly retarded in comparison with other animals of like age. The importance of experience in the development of human vision is indicated in the data from cases of congenital blindness compiled by Senden (1932): children and adults required months and years to attain or approximate normal visual perception after the operation that first brought them vision.

Data on the course of ontogenetic perceptual development in lower animals is fragmentary (see Cruikshank, 1946; Munn, 1938). The general trend, however, is clear: the difference between initial and ultimate perceptual ability increases as we go from the earlier to the more recent stages of phylogeny; the time, both absolute and relative to life span, during which perception is improved becomes progressively longer. It is less in carnivores and rodents than in primates, still less in birds. The butterfly, having emerged from its cocoon and dried its wings, is then about as well equipped to respond to the significant objects and energies of its environment as it ever will be.

In the following paragraphs a brief comparative survey is made of some of the more common or universal perceptions. Where the inherited structure provides a capacity for organizing sensory elements into these fundamental patterns, the potential number of perceptions is much greater than where the structure provides those basic organizations ready-made. It is very much like being supplied with a large stock of raw materials and tools or, instead, with a fixed number of finished products.

Locus of stimulation. Responses that depend on the particular point of the body being stimulated are seen in the lowest animals. The spatial relations of the pseudopods forming the food cup of the ameba are adjusted precisely to the position of the food particle. With increasing intensity of a noxious stimulus, the altered direction of

locomotion approaches a deviation of 180 degrees from the point of stimulation. In the paramecium, on the other hand, the stereotyped "shock reaction"—a reversal of ciliary beat which sends the organism backwards in a spiral path—is variable in magnitude according to the intensity of the stimulus but apparently bears no relation to the locus of stimulation. A strong chemical diffusing from the rear of the organism may produce a shock reaction that brings the animal into higher concentrations of the poisonous substance. This maladaptive reaction may be in part a function of the paramecium's sensitivity gradient, the chemical stimulus being relatively ineffective on the posterior parts. A mechanical stimulus applied to the posterior end, on the other hand, results in forward movement, whereas a similar stimulus applied to the anterior part produces the shock reaction. The differential reactions of coelenterates to locus of stimulation are clearly a function of the "conduction with decrement" characteristic of their nerve-net system. Localized mechanical stimulation of the jellyfish produces strongest contraction of those parts of the bell nearest the point of stimulation, and the result is locomotion away from that point. In feeding, the tip of the stimulated tentacle contracts so as to grasp the food, then bends as a whole towards the center; the manubrium, in the meantime, bends quite precisely towards the stimulated tentacle. Similar locus-determined responses are seen in the echinoderms.

The relative importance in the adaptive behavior of the lower organisms of reactions based on body locus of stimulation is largely replaced, in higher animals, by perceptions based on the distance receptors (which depend in part on location within the sense organ). Among mammals, however, response to body locus is still seen in such activities as scratching, cleaning, grooming, and in many manipulations. It is clear that in the lower organisms the effect of locus of stimulation is structurally determined;

the question of nativism-empiricism as regards "local sign" becomes a problem only in the higher forms.

Movement. Although a few exceptions have been reported, it is generally true that animals are more responsive to a moving stimulus than to a still one (see reviews by Kennedy, 1936, and Schiller, 1937). A moving stimulus avoids sensory adaptation and multiplies the on-off effects of stimulation many times. Reaction to *apparent movement* has been demonstrated in fish, but it was not found in crabs, dragonfly larvae, and houseflies (Gaffron, 1934; Schiller, 1934).

Direction, distance, depth. Ample evidence is available to show that most animals, including many unicellular forms, adjust their responses (particularly of locomotion) in accordance with the direction of the stimulating source relative to the body. Concerning the mechanisms mediating such adjustment, interpretations have varied widely. The highly mechanical and rigid determination postulated by Loeb (1918) has proved to be inadequate in many cases, especially where bilateral symmetry has been artificially destroyed; the more "psychological" trial-and-error theory of Jennings (1906), involving comparison or temporal integration of moment-to-moment differences in stimulation, also fails to account for all the facts. The problem of orientation in the lower animals has been reviewed by Crozier and Hoagland (1934) and by Fraenkel and Gunn (1940). Light, thermal, vibrational, static (gravity), and chemical stimuli may provide the cues for directional perception in lower organisms; in higher animals these are augmented by the development of special sense organs such as the lateral-line system and auditory apparatus. The greatest advance in this direction arises from improvements in the organ of vision.

The most primitive basis of distance perception is intensity of stimulation, and in some modalities (e.g. olfaction, audition) it remains the principal cue. In animals like

the bat, having a "radar apparatus" (Hartridge, 1945), the intensity and temporal lag of the reflected vibration are presumably responsible for distance perception. In general, however, the principal improvements in distance and depth perception are again associated with the visual mechanism (Walls, 1942).

Size and form. Tactual size perception is manifested in the feeding behavior of many unicellular organisms, coelenterates, mollusks, and higher forms: acceptance or rejection depends on size as well as on chemical composition. There is evidence of crude visual size perception among mollusks, but that for visual form perception, even in the octopods which have a well-developed camera eye, is not convincing (Ten Cate and Ten Cate-Kazeewa, 1938). Among arthropods the evidence seems to indicate visual size and form perception in those groups having eidoscopic eyes. Warden, Jenkins, and Warner (1940, p. 698), however, consider it likely "that insects, such as the honeybee, *distinguish patterns, not on the basis of form but primarily through the relative stimulating efficiency of intermittent illumination.*" Hertz (1934) has presented evidence in support of her interpretation that form perception in bees is not (in all cases, at least) merely a matter of flicker rate produced by the degree of articulation of the figure, as suggested by Zerrahn (1933) and later writers. Even spiders, having the ocellar type of euthoscopic eye, have been reported to be able to detect and capture prey visually. Forel (1904) suggested that insects that can move their antennae, bearing the organs of smell, over objects, may have olfactory size and form perceptions. Among fish, amphibians, and reptiles, visual size and form perception varies considerably, according to the habitat and mode of life of different species within each class. All three groups are excelled in this respect by the birds, whose visual acuity is probably equaled only by the higher primates.

Perceptual and Conceptual Scope

A given stimulus patterning may, in one animal, correspond to an innate perceptual organization and elicit a definite, species-constant reaction. In another animal this pattern may gradually be organized into a perception that comes to elicit one or another overt response. In a third species this particular concatenation never, under any circumstances, becomes integrated and cannot, therefore, serve to evoke a response. There are innate differences in the potentiality of certain patternings to be organized into perceptions. If the potentiality is not there, no amount of training will be effective in bringing about a response to the pattern.

The following four sections will be concerned with the factors that determine what is a "stimulus" for a given animal. The basic factors determining stimulus organizations will be discussed under the headings of *pattern specificity* (identification of specific stimulating patterns or concatenations in successive experiences); *the selective process of attention* (the separation or abstraction of an identified pattern from other elements in the total stimulating situation); *concept formation* (the interaction and balance of pattern specificity and the selective process); and *symbolization* (an instrumental aid to the integration of temporally separated experiences).*

A preliminary question pertaining to the definition of what may constitute a stimulus

* The theoretical and experimental significance of these terms in reference to the behavior of organisms with innately determined perceptions is quite different from their significance for the behavior of animals whose perceptual organization is developed in and by experience. In the former the concepts are of value in describing certain constancies of relations manifested in the limited repertory of species-uniform behavior; they may therefore help in classifying the observed phenomena. In the latter, on the other hand, these concepts are postulated as mechanisms or functional principles and so imply the possibility of predicting and experimentally controlling behavior; the mechanisms provide a basis for explaining behavior but must themselves be accounted for in terms of the inherited structure.

concerns perceptual responsiveness to relations—the problem of whether such responsiveness is elementary and "primitive," or whether it is instead a later development, deriving perhaps from the mechanism of symbolization. To this question we now turn our attention.

Perception of relations. The bearing of stimulus intensity on response, as seen in the behavior of the lower organisms and often in the unconditioned reflexes of higher animals, has been noted above: with increasing intensity the response increases in magnitude (decreases in latency, etc.) or may change to a different kind of response. In conditioned or learned behavior a different relation seems to obtain, at least in some cases: the specific intensity used in conditioning evokes the maximum response, whereas greater and lesser intensities elicit responses of a magnitude that decreases with the "distance," in either direction, of the test intensity from the original conditioning intensity. This relation has been reported also for "distance" on continua of wavelength of sound and (within limits) of light, as well as for spatial distance of a tactual stimulus on the skin. The phenomenon has been termed irradiation (Pavlov), primary stimulus generalization (Hull), and induction (Skinner); the evidence has been reviewed by Hull (1947).

Lashley and Wade (1946) deny that the available data support the concept of a primary stimulus gradient. The phenomenon of so-called stimulus generalization, they say, represents "a failure of association." Generalization indicates that the perception that determines the response (e.g. approach) includes in its pattern only those elements that are common to both the training and test stimulus; elements representing, for instance, "a tone" or "a white surface." The specificity of the pattern is not such as to represent "a tone of this pitch and of that intensity," or "a white square of such and such a size." In differential conditioning

the perception comes to include these specifying elements.

Perhaps the strongest argument in favor of the "absolute" theory is that it postulates a single mechanism to account for both absolute and relational response (Spence, 1937, 1941). Its most serious drawback is that as yet no one has been able to suggest a plausible neurological basis for the assumed process of irradiation (e.g. Hovland, 1937). The neurological speculations advanced by Lashley (1929 and 1942), Köhler (1940), and Householder (1947) in explanation of relational response are, in various respects, inadequate, but they are at least a beginning. The relational theory does not deny that absolute properties become effective under proper training conditions; it holds only that animals often respond to ratios of excitation and that in many cases the perception of a relation is more primitive or elementary than, and prepotent over, the perception of specific magnitudes.

If the assumption is accepted that when an animal is responding "relationally" its behavior is in fact determined by the perception of a relation (and not by the net effect of excitatory and inhibitory strengths of the specific magnitudes of the stimuli presented), the available comparative data indicate that relational response appears earlier, phylogenetically, than does response to absolute properties. Moreover there is no indication of any reduction in the prepotency of the perception of relations with ascent in the animal scale.

Pattern Specificity

When we say that an organism is responding to a "stimulus," what is usually meant is that the response has been elicited by a simple change in the environmental energies impinging on the sensorium — an increase of light intensity, for instance, or a change of tonal pitch. Being a *change*, a stimulus involves a spatial and/or temporal *pattern* of stimulation; the nature of the stimulus depends as much on the preceding or adjacent

light intensity as on the intensity of the so-called stimulus. When the patterning becomes more obvious or more complicated, as in a melodic sequence or in the spatial light distribution of a picture, the term, perception, is commonly used. Insofar as it is determined by external stimulation of the moment, every response is elicited by a perception. And every perception depends on a certain minimum of sensory patterning.

Visual size perception, as mediated by the primate eye, illustrates the need for a high degree of pattern *specificity*. A given combination of sensory data deriving from retinal-image size, accommodation, and convergence (disregarding other, supplementary cues) gives a certain size perception; the same perception is given by proper concomitant variation of all three constituents, whereas variation of the first one alone gives a different size perception. To this fundamental process of perception — the response to unique concatenations of interdependent sensory elements — we apply here the behaviorally descriptive phrase: *identification of specific patterns*.

The pattern may consist of just a few determining elements. In other cases it involves a large number of necessary elements, and any deficit or deviation from this complex pattern means that the perceptual response will not be elicited. Such instances are the basis of the Gestaltist argument (e.g. Volkelt, 1914; Buytendijk, 1924) that animals react to the total situation and are unable to analyze the whole into its component parts.

The Selective Process of Attention

Since pattern specificity usually pertains to only a part of the total environmental situation, perception involves not only an associative synthesizing process but also an analysis or dissociation whereby the essential pertinent elements are separated out from the rest of the concomitant stimulation. It will be convenient to discuss this separative insulating process under three subheadings

for which we use the arbitrary designations: (1) contextual isolation, (2) cue reduction or reintegration (Hollingsworth, 1928), and (3) abstraction-generalization.

1. One may imagine an experiment in which an animal, say a chimpanzee, is raised under controlled conditions such that every rectilinear form it ever sees is green, whereas no curvilinear figure is ever green. That animal's perception of a rectangle would presumably include green as one of the necessary items constituting the perceptual pattern. Under the more usual conditions such aspects as color, size, and so on, are quite irrelevant to rectangles; they, together with features of the background and perhaps some visceral distress of the moment, are context. Normally the essential elements, $A_1B_1C_1$ are more or less independent of the items $D_1E_1F_1 \dots$ in forming the perception. If $A_1B_1C_1$ are the necessary components of the pattern X_1 for "rectangle," and D represents color, then $A_1B_1C_1D_1 = A_1B_1C_1D_2 = X_1$. For our hypothetical chimpanzee, on the other hand, $A_1B_1C_1D_1 = X_1$, but $A_1B_1C_1D_2 \neq X_1$ (where D_1 represents green, and D_2 any other color). To the degree that a perception is independent of irrelevant elements in the total situation we may say that it has been isolated from its context.

2. In learned perceptions involving many sensory elements, the presence of just a few of these elements elicits the response appropriate to the much larger pattern. A particular individual is perceived in darkness by his voice, or by his odor. Schematically, in the perception $A_1B_1C_1 = X_1$, the discrimination of A_1 from A_2, A_3, \dots , plus the previously established association of A_1 with B_1 and C_1 results in $A_1 - - = X_1$. The phenomenon is presumably a function of the frequency and invariability of the concomitant occurrences of A_1, B_1 , and C_1 , and of other A 's (A_2, A_3, \dots) with other B 's and C 's. On the other hand, inborn perceptual organizations appear to require always the full complement of sensory elements constituting the pattern.

All available evidence is consistent in indicating that the perceptual response is a central rather than a peripheral process. The struc-

tural basis of a perceptual response being at least one step removed from the primary sensory fibers, it is possible for one or a few of the latter to activate the response as a whole, thereby providing a conceivable mechanism for cue reduction.*

3. Two or more total stimulating situations may have one or several elements in common. When an acquired response evoked by one situation is elicited also by others, we say that the common elements have been abstracted; it is the perception of the pattern appearing within each of these complexes that determines the response. Any nonspatial, two-choice discrimination problem calls for some degree of abstraction. The second part of the hyphenated term, abstraction-generalization, has been included in order to emphasize that in infrahuman animals abstraction (as also "contextual isolation" and "cue reduction") can be inferred only from generalization tests. That is, whether the animal has been responding to the perception $A_1B_1C_1$ in the training context $D_1E_1F_1$ may be tested by determining whether the response is generalized to $A_1B_1C_1D_2E_2F_2$, and so on. And conversely, generalization (or transfer) from one situation to another means that something has been abstracted from the context of the first and is now operative in that of the second. In animal behavior, abstraction and generalization are inseparable, each implying the other.†

The three divisions of the separative process serve mainly to locate an approximate region within a broad range of behavioral phenomena. These regions may be schematically illustrated in terms of a simple discrimination situation. Assuming that the

* For an excellent discussion and fertile theory of the neurological correlates of perception and thinking, see D. O. Hebb (1949). I am indebted to Dr. Hebb for the privilege of reading the manuscript of his book and also for many stimulating discussions related to various problems considered in this chapter.

† The inseparability of abstraction, generalization, and classification in human perception and thinking was recognized on rational and introspective grounds by the English associationists. For a particularly lucid discussion, see Charles A. Mercier's *Psychology, normal and morbid*. New York: Macmillan, 1901.

subject has learned to choose a plaque bearing a green square and to avoid a similar plaque bearing an erect red triangle of similar size, (1) continued response to the former when a new experimenter presents the plaques in a different room indicates contextual isolation; (2) differential response to plaques on which the figures were both yellow or were represented only by black dots at the corners illustrates cue reduction; (3) response to a plaque bearing many small red squares versus one bearing a very large inverted red triangle indicates abstraction of squareness from triangularity. The choice of terms is arbitrary. Finally it should be pointed out that the separative process involved in innate perceptions reduces to a question of pattern specificity and the potency of that pattern in relation to the total stimulating situation.

Concept Formation

Smoke (1946) defines concept formation as "the process whereby an organism develops a symbolic response—usually, but not necessarily, linguistic—which is made to the members of a class of stimulus patterns, or to an aspect of such a class, but not to other stimuli." A common (symbolic) response to the members of a class is termed a "class concept"; to an aspect of a class, an "abstract concept." A third type of concept might be called a "thing concept" (often termed "perception of things"). It is the sum total of the subject's knowledge or perceptions of a discrete object. In the present section we consider whether there is any evidence for concept formation below the human level, regardless of whether it is necessary to postulate a mediating symbolic process.

One implication of these definitions is that a high degree of abstraction and prepotency of a specific pattern is involved. Thus if the animal gives a consistent response to red, regardless of its shade or the variety of contexts in which red appears (Weinstein, 1945), it may be said to have an ab-

stract concept of redness. Or, if a variety of suitable objects are used interchangeably to reach a suspended lure, the animal may be said to have a concept of the class of objects that may serve as a platform.

A second characteristic implied in discussions of concept formation is that it requires the integration of multiple, temporally discrete events. Diverse experiences must be brought together in order that the concept may emerge or be educated. (In this respect the difference between concepts and percepts is one of degree.) In Hamilton's quadruple choice, Yerkes' multiple choice, and Hunter's single or double alternation problems, the effective cue cannot be discovered in a single trial, but only on the basis of repeated experience. Sometimes the animal is said to be responding on the basis of a principle of alternation, of oddity, of matching, and so on. In each case a temporal integration of experiences is involved. It seems reasonable, therefore, that this conceptual organizing may take up most of the time used in "learning" a problem involving the concept, and that its connection to a given overt response may then occur very rapidly, as Guthrie (1935), Lashley (1929), Krechewsky (1932), and others have suggested for relatively simpler learning situations.

A third characteristic of concept formation is implied in its definition as "response to an aspect of a class." Response to "a class" involves specificity of a larger pattern; response to "an aspect" involves a separative abstracting process. Responsiveness to both identities and differences, and a necessary balance between the two, is implied.* Consistent response to red (versus other colors) requires identification (of red) and differ-

* The importance of this balance for "intelligent" behavior was recognized by William James (1890, Chapter 22) under the term, "sagacity," but the problem has received almost no experimental attention. Hollingworth (1928, p. 412) describes the sagacious individual as occupying a position between the extremes represented by the "obsessed" and the "scatterbrained."

entiation (from yellow, green, blue); but in the consistent response to color (versus visual form, size, texture) the identification itself requires an abstraction or differentiation (e.g. of what is common to various colors) and the differentiation involves identification (of that common element). "Color" qualifies without much question as a concept; "red" is more often considered a percept.

The conditional matching problem furnishes one of the best illustrations of the balanced responsiveness to identity and difference involved in conceptual behavior. The subject must choose that one of two objects that matches a third object (sample) in either color *or* form, in accordance with an independent (background) cue. This problem has been mastered by monkeys (Harlow, 1943a) and by a chimpanzee (Nissen, Blum, and Blum, 1949). In further tests with monkeys generalization of the response to *new* colors and forms was demonstrated (Harlow, 1943b; Young and Harlow, 1943). This achievement of infrahuman primates approximates conceptualization as it is known in man.

The thing concept (or perception) also involves a balance of the specifying and separative processes, as well as an integration of temporally discrete experiences. In animal behavior, a thing concept is indicated when the response is based not on one or another of the constituent perceptions, but on an integration of all of them. Behavior completely dominated by one *or* another aspect of a larger situation is characteristic of the lower animals but is labeled regressive or disintegrated when it occurs in man. The behavior of the mother bird that responds to the genus-constant distress call of the young and rescues it, only later to kill the young bird because it does not show the species-characteristic markings or behavior (Lorenz, 1935), illustrates an almost complete absence of thing perception. The male chimpanzee who defers to a physically weaker but sexually receptive female in a

food situation (Yerkes, 1943) is perhaps responding to the female not only as a competitor for food, but also, simultaneously, as a partner in the sexual relation.

Symbolization and Language

The necessity of postulating a symbolizing process to explain human thinking has long been recognized, and the process has been investigated by introspective and objective techniques. The anecdotal school of comparative psychology was uncritically generous in postulating ideational and imaginal processes to explain the behavior of animals, especially of the higher forms. Since Lloyd Morgan (1894) first formulated his famous canon regarding parsimony, the pendulum has swung from one extreme to the other. Most writers now invoke symbolic processes only when simpler mechanisms, such as conditioning, seem inadequate, or when their faith in a reduction to these principles breaks down under the fantastic complexity of animal behavior. It is not easy to decide whether it is more parsimonious to make the established principles do by elaborating their interrelations, or instead to bring in a new concept that, at one stroke, "solves" a whole array of perplexing problems.

A criterion for the justified invocation of symbolism is expressed by C. T. Morgan as follows: "Only when the response of an organism must be determined by conditions not present at the time of adjustment can it be supposed that a symbolic process is operating. . . . a symbolic process is indicated when the signal or cue for adjustment made is not present at the time of response" (1943, p. 543). Among the infrahuman animals there are two types of behavior that have persistently demanded a symbolic process for their interpretation: (1) trace conditioning, double alternation, delayed-reaction learning, and delayed-reward learning, and (2) the prompt solution of novel problem situations apparently involving reflection, implicit trial-and-error, insight, foresight, or inferential reasoning.

Delayed reaction to spatial cues appears to be a relatively simple task for primates. With sufficiently favorable motivating conditions, the complexity of the problem (number of alternatives) and the length of the delay interval may be extended almost indefinitely. The capacity for delayed response has been demonstrated also in lower mammals, in birds, and (with 4-second delays) in fish (Schiller, 1948). The performances of insects in returning to the nest after the initial excursion into new territory, and the relocation of a food source, seem often to involve this same ability. Nonspatial delayed reaction is apparently much more difficult, although only monkeys and apes have been adequately tested in this problem. Various observations such as those of Baerends (1941) suggest that, when certain biologically vital cues are involved, nonspatial delayed response may occur in lower animals, even in insects. (In these cases it is of course necessary to rule out the possibility that the performance reflects merely the activation of a particular motivation plus innately determined response to immediate external stimulation.) Finally, it has been shown that even rats can learn spatial discriminations if the reward or punishment is delayed for some time after the critical response (Wolfe, 1934), whereas differentiation of nonpositional cues with delayed reward is very difficult even for chimpanzees (Riesen, 1940).

The facts lend themselves to the interpretation (Nissen, Riesen, and Nowlis, 1938) that the learning of delayed-reaction and delayed-reward discrimination requires the mediation of ready-made differential responses to the cues involved. (The operation of a symbolic process or "representative factor" in delayed reaction was originally suggested by Hunter, 1913.) Because of the ubiquitousness of spatial relations, symbolic responses (whether in the form of implicit iconic movements or purely "central responses") to spatial factors were developed earlier, phylogenetically, than those repre-

senting other stimulus characteristics. Several lines of evidence accord with this interpretation: (1) Rats can learn a nonspatial discrimination with delayed reward when forced to make differential movements at the time of choice (Grice, 1948). (2) Nonpositional delayed response is aided by a "forced" movement to the correct stimulus (Forster, 1934; Finan, 1942; Cowles, 1940). (3) Chimpanzees improve their performance in nonspatial delayed response (Riesen and Nissen, 1942) and delayed-reward learning (Riesen, 1940) after being trained to make certain arbitrary movements that are differential with respect to the pertinent visual cues.

The second type of problem for which it has often been considered necessary to postulate a symbolic process is that in which the animal effects a prompt solution without having had experience with all elements of the situation in their present concatenation. Many such apparently insightful solutions may be ascribed to the prepotency of a perception, abstracted from the new context, to which a response (appropriate in the new context) has previously been learned. The immediate use of a string to draw in food may be a direct transfer from experiences in the wild where branches or twigs were grasped at their tips to bring fruit within reach. In some instances the seemingly insightful solution may even be ascribed to the prepotency of a perception for which there is an innately determined response.

The prompt solution of detour problems is frequently interpreted as evidence of insight or reasoning ability. Tolman and Honzik (1930), for instance, gave rats opportunity to become acquainted with three routes, *A*, *B*, and *C*, of progressively increasing lengths, from the starting place to the goal. Given free choice, the rats chose the shortest route, *A*, or, if this was prevented, the next-to-shortest route, *B*. If, now, a block was placed in that final part of the pathway common to both *A* and *B*, the rats, finding their favorite route blocked, tended

to take the longest but unblocked route, *C*, rather than *B*. (When the block was placed in the nearer portion of *A*, which did *not* form a part of route *B*, the rats tended to choose *B* rather *C*.) Such insight *may* involve a spatial perception elicited by a reduced cue: the initial parts of *B* evoke a perception of the complete route *B*, and this now includes the block that was experienced on that part of *B* common to *A* and *B*. This interpretation assumes (1) the abstraction (from the total perceptions of *A* and *B*) and identification of the element that is common to *A* and *B*, (2) a prompt (one-trial) learning similar to that displayed in the delayed reaction, and (3) a temporal integration of successive events into a perception. The latter assumption, as Woodworth points out, may be used also in explaining the elimination of blind alleys in ordinary maze learning: the stimuli received at the end of the cul are not the same as those received at its entrance. How, then, is response to the entrance stimuli modified by the temporally distinct stimuli of the end of the alley? "If the rat first perceives an alley as an alley and proceeds to explore it, the alley remains the same for him and the dead end, when discovered, is registered as pertaining to the same alley that was perceived at the entrance. . . . The conditioning experiment is really concerned with the establishing of a new perception" (Woodworth, 1947). Experiments similar in principle to that of Tolman and Honzik have been performed by Maier (1929) with rats and by Bingham (1929) with chimpanzees.

In the multiple-stick test (e.g. Köhler, 1925; Jackson, 1942; Birch, 1945) the monkey or ape uses a short stick to rake in a long stick. The long stick is then used to rake in the food. The short stick and the food (which cannot be reached with it) may be together on one platform, the long stick on a second platform. The animal takes the short stick to the second platform, uses the short stick to get the long one, returns to the first platform and rakes in the food.

Let us now assume that the second platform is moved farther and farther away from the first one until, finally, one platform cannot be seen from the position of the other. The subject is brought to the first platform. The available short stick does not suffice to reach the food. But the present situation re-integrates a perception of the long stick and of the route to the second platform on which it previously has appeared. Let us suppose, further, that *this* subject has had experience only with one stick, on the same platform with the food, and that a week earlier it had merely seen a long stick, out of reach behind bars, in another room. Now (a week later) our hypothetical subject is confronted with the platform on which there is food and a stick too short to reach the food. The subject looks at the situation, goes to the other room, taking along the short stick, rakes in the long stick, returns to the first platform, and rakes in the food.

The question now is whether we must assume the mediation of symbolic processes, of memory images, or something of the sort, in order to explain this hypothetical behavior. The series of detour situations outlined above was chosen deliberately to indicate (1) the impossibility of defining with any precision the kind of animal behavior that does or does not require the postulation of symbolic processes, and (2) a basic continuity in the transition from perceptually to symbolically mediated behavior. Specificity of identifiable patterns and abstraction, i.e. association, are always involved, but in varying degree. To what extent we describe the behavior of our subject in the two-stick experiment as being ideational or symbolic depends on such factors as how much stick experience he has had, how far apart the platforms are, how long ago he saw the second stick, how well he knows the pathway from the food platform to the other room — all subject to quantitative variation. The more attenuated the basis of association, the more compelled do we feel to postulate a

symbolizing process, an instrumental aid to problem solving, such as language.

Brief consideration of certain characteristics and uses of linguistic responses (words) may give some clues to the function of symbolic processes in concept formation and problem solving: (1) A word response is a concise and discrete central representation of a thing, a class, or an aspect of a class; it isolates what is pertinent, excludes what is irrelevant. (2) In itself (i.e. in its problem-solving noncommunicative function) it has no effect on the organism-environment relation; it does not commit or implicate the organism as does, for instance, an overt response of locomotion. (3) Word responses are not mutually incompatible, interfering, inhibiting; many words can occur together or in rapid sequence. Words, therefore, may effect temporal integration; they summarize many past experiences into a manageable unit. Concepts that derive from a diversity of experience can occur — can be organized or educed — only when symbol or word units are available to assemble and incorporate a large body of experience. Many relational concepts (e.g. causality) are a function of diverse experiences, and these concepts could hardly be formed without the aid of words (or other symbols) to compress those experiences into the compass of a functional moment. Now, in the narrower sense, at least, linguistic responses are unknown among animals other than man. However, if we think of language as a symptom or indicator of symbolism, rather than as its necessary condition, the possibility of symbolic processes occurring in animals is not excluded. But our conclusion that occasional instances of infrahuman behavior reflect early and fragmentary stages in the phylogenetic development of symbolization must be considered quite tentative.

RECAPITULATION

The present section, being, so to speak, a summary of summaries, must be presented

in condensed and dogmatic form, without the development of implications or the consideration of alternative points of view.

Motivational versus Cognitive Differences in Evolution

For psychology, differences among animals with respect to what they want are trifling by comparison with differences in the means by which they satisfy their wants. The fact that one organism feeds itself by ingesting algae, others by eating crabs, insects, grass, or eggs, is of only incidental interest in contrast to the various behaviors by which algae or crabs, insects, grass, or eggs are obtained. It is in the cognitive rather than in the motivational aspects of behavior that we find the significant axes of behavioral evolution. Differences in motivation consist largely in an increasing complexity or degree of indirection of drive sequences terminating in goal attainment. These motivational differences are derivative, depending on the cognitive equipment of the animal. Differences in forms of social interaction, including those aspects we call culture, also derive from cognitive factors. In an earlier section we found only one type of behavior modification, namely, "transformation of mechanisms into drives," for which there is any convincing evidence of phylogenetic difference, and this distinction applies mainly to man as contrasted with other animals. This emphasis on cognitive factors does *not* mean, of course, that the student of comparative behavior may disregard its motivational aspects. Such neglect would be as inexcusable as disregarding the animal's sensory equipment or mode of locomotion, as if its receptor capacities and whether it walks, crawls, flies, or swims were irrelevant to the problem.

Axes of Cognitive Development

Sensory elements and response units may be thought of as the raw materials of behavior. The range and differentiation of environmental energies to which the organism is sensitive depend on the sense organs

and their central connections. With increasing sensory differentiation, the possibilities of central (perceptual) organization into unique patterns are rapidly multiplied. Sensory differentiation is, therefore, a necessary, but not a sufficient, condition for breadth of perceptual scope. Behavioral complexity is likewise increased as the organism is able to make discrete and independent movements of all parts of its body. Phylogenetically the locomotor coordinations develop earlier than those involved in manipulation. Variety and precision of motor patterning culminates in the manual dexterities and speech of man.

Perceptual organization (sensory correlation) in evolutionary development proceeds along two axes: (1) inherited perceptual patterns and (2) individual acquisition of perceptions. Acquired perceptions are organized in the course of experience by the postulated mechanisms of pattern identification, the selective process, and symbolization. As regards (1), an initial peak, phylogenetically, is seen in the insects, and a second one in the birds. In the higher primates this trend takes a pronounced drop. Experiential perceptual organization (2), on the other hand, seems to play only a minor part until we come to some of the birds and especially the mammals. Among the monkeys and apes (2) rapidly displaces (1) and leads to a wider perceptual scope than is found among any of the lower organisms. Somewhere among the higher mammals, perhaps not before the primate level, there emerges a new instrumentality for perceptual and conceptual organization, namely, symbolization. Although we have suggested a gradual development of the symbolic process, the evidence is overwhelming that the curve representing this dimension of behavioral evolution rises sharply upwards with the appearance of man.

The effectiveness of the S-R connecting process rises from the lower to the higher invertebrates; and no further rise is apparent until we come to the higher primates. It is probable that symbolization helps not

only in perceptual organization but also in making possible prompt and efficient connection of percepts and concepts to specific responses. One-trial learning becomes the rule rather than the exception among the highest primates. There the connecting of the central symbolic processes with one another, and with overt responses, seems to occur with unique facility.

A Phylogenetic Comparison of Intelligence

Behavioral evolution is characterized by increasing complexity. With ascent in the phyletic scale, the effective environment expands spatially and temporally and provides an ever-wider range of behavior determinants. This expansion follows upon the organism's ability to integrate and organize. It is only with the advent of "culture" that the effective environment itself expands rapidly from generation to generation.

We have now discussed and summarized what appear to be important axes along which phylogenetic changes in behavioral complexity may be traced. We have also seen, usually rather vaguely, the points of the phyletic scale at which inflections or origins of the curves representing these several axes occur. The accompanying figure is a rash venture, presenting a tentative estimate of the composite of those curves.

The ordinate of Fig. 2, it will be noted, is labeled "Intelligence level." It could as well have been called "Behavioral complexity" or "Spatio-temporal span of behavior determination." Or it may be taken to represent the sum total of the organism's cognitions and adjustments.*

* By thus including those behavior integrations strictly determined by the inherited structure, as well as those whose development is contingent upon individual interaction with the environment, we depart from the traditional instinct-intelligence dichotomy. The distinction between the innate and the acquired is certainly an important one. But the usual connotation of "intelligence" is a measurable, or at least describable, performance. Intelligence that does not express itself in behavior is a contradiction of terms. Performance reflects neural organization, and this comprises structurally determined pat-

The particular divisions of the animal kingdom indicated in Fig. 2, where one division contains a single species and another includes several phyla, represent a compromise between conventional classification and present behavioral evidence. (A single continuous curve could have been drawn by reordering the usual taxonomic sequence.) Within the division of protista the Rhizo-

tion of lower mammals behavioral data are inadequate to permit an estimate of the relative positions of the various orders.

It is quite possible that the continuous curves drawn for each division should be broken up into numerous discrete curves, each representing a subgroup. Further refinements in behavioral measurement might indicate, for instance, that the higher am-

FIG. 2. A tentative estimate of comparative intelligence in the animal kingdom.

poda, Mastigophora, and Infusoria are represented by the upper (right-hand) portion of the curve; among the lower invertebrates the Echinodermata are displaced to the left of their usual taxonomic position; within the lower vertebrates and the primates the conventional order is maintained; for the divi-

terms as well as patterns formed in the course of experience. The fact that there *will be* organizing activity is determined structurally as much as is the fact that there *are* certain species-constant organizations. The variability of environmental factors that enter into individually acquired organizations provides for a greater degree of plasticity in behavior. There is little indication in the final test of survival, however, that nature is prejudiced in favor of one or the other mode of intelligence.

phibians are more advanced than the most primitive reptiles. Needless to say, distance along the abscissa is *not* proportional to the number of species or individuals included. The fact that the curve represents an average, a pooling of attainments along each of several dimensions, means that, with respect to one or another of these, a given species may stand considerably higher or lower than its position on the curve indicates. There are, obviously, no absolute units of measurement for the ordinate; a given distance on one curve cannot be presumed to be equal to the same distance on another curve or at another level of the same curve. The vertical axis thus represents only order, or direc-

tion of difference. The top of the final curve suggests the debatable position of modern natural man. Because we know so little about the behavior of earlier forms of *Homo sapiens*, this curve is dotted.

Instinctive Behavior: Reproductive Activities

FRANK A. BEACH
Yale University

Certain patterns of behavior are commonly referred to as "instinctive." They are thought to differ in various ways from other reactions that are called "learned." We shall not be concerned with the validity of this distinction. As Stone (1942*a*) has stated, the experimentalist is less interested in classifying behavior than in determining the factors that control its development and organization.

The experimental analysis of instinctive activities does not differ significantly from one response pattern to another. In fact methods of investigating the dynamics of an instinctive reaction are equally applicable to the study of learned behavior. The same questions have to be answered, and very often the same techniques can be applied.

Very few of the responses relegated to the instinct category have been experimentally analyzed. It is conceivable that this is why they are regarded as qualitatively different from other forms of behavior that have been systematically examined in the psychological laboratory. Only after a bit of behavior has been studied exhaustively can it be meaningfully compared and contrasted with other reactions.

The following material has been selected to illustrate the methods that have proved useful, the kinds of information currently available, and the types of interpretation customarily advanced in connection with the

experimental analysis of instinctive activities. Reproductive behavior has been studied more intensively than most instinctive patterns. This chapter deals therefore with observations and experiments on sexual, parental, and filial behavior.

SEXUAL BEHAVIOR

The central features of reproductive behavior are the responses involved in courtship and mating. Analysis of these reactions includes identification of their external correlates—the environmental factors responsible for their occurrence, or, in a narrower sense, the stimuli that elicit them.

Functions of Sensory Stimulation

The environmental stimuli that influence sexual behavior can be divided arbitrarily into three categories.

Stimuli affecting physiological readiness. These are the external conditions that produce within the organism a physiological state necessary for the occurrence of sexual reactions. These may include general climatological factors such as length of day, temperature cycles, or seasonal rainfall. Or they may be more directly associated with the presence and activity of other animals of the same species. The distinguishing characteristic of the events, processes, and objects placed in this category is that they do not

elicit behavioral responses, but instead they prepare the organism for reaction to more specific types of sensory cues.

ILLUMINATION. Annual and diurnal cycles of illumination affect sexual activity in many vertebrate species. Seasonal occurrence of courtship and mating in some fishes, birds, and mammals is closely related to the progressive increase or decrease in the amount of daylight per 24 hours. The correlation is dependent upon functional changes in the anterior pituitary gland and in several other endocrine organs controlled by the pituitary. Marshall (1942) and Beach (1948) have summarized the evidence.

Brook trout ordinarily spawn during December when the days are growing shorter, but Hoover and Hubbard (1937) induced fertile reproduction in this species during August by artificially decreasing the duration of light per 24-hour period. Rowan's (1932) early work on the American crow and other studies by Bissonnette (1932*a*), Cole (1933), Witschi (1935), and Wolfson (1940) prove that a gradual increase in the amount of daily illumination induces recrudescence of the sex glands and concomitant appearance of mating behavior in several avian species. Burger (1943) found that the starling testis is activated by wavelengths falling between 580 and 680 millimicrons. Longer or shorter wavelengths that are plainly visible to the bird do not influence reproductive condition.

Some seasonally breeding mammals are affected by changes in the length of day. Sheep, goats, deer, cats, and ferrets can be brought into full breeding condition during months in which this would not normally occur, provided the lighting conditions are appropriately manipulated (Hammond, 1944; Dawson, 1941; Bissonnette, 1932*b*, 1941; Rice, 1942). Marshall and Bowden (1934) showed that the sexual cycle of the ferret is influenced by all wavelengths from 365 to 650 millimicrons.

Some animals that breed throughout most of the year display cycles of reproductive activity that are correlated with the diurnal

rhythm of illumination. The Japanese med-aka fish ovulates just before dawn; but artificial reversal of the day-night cycle is accompanied by egg laying at the time of the artificial dawn (Robinson and Rugh, 1943). Norway rats are most active during the night, and females come into heat in late evening or early morning (Ball, 1937). Females maintained under reversed light-dark rhythm display a 12-hour shift in their mating behavior and are sexually active during the solar day (Beach, 1938). Beach and Levinson (1949) found that the sexual responses of male rats are more intense and frequent during the night than in daytime.

TEMPERATURE. Environmental temperature influences sexual behavior in many invertebrates. Fertile mating awaits the attainment of reproductive maturity, and this is affected by temperature in some cases. Hogben (1940) described two species of moths, the larvae of which feed upon plants that bloom at different seasons. If larvae of the earlier emerging species are artificially cooled, their metamorphosis is delayed and they reach maturity simultaneously with the second species. Under such conditions males and females of the two types can be crossed and fertile hybrids are produced. The continued separation of the two species is thus dependent upon differential reactivity to environmental temperatures.

The seasonal occurrence of breeding behavior in several vertebrate species is a function of changes in external temperature. The testes of the killifish involute at the end of the spring spawning season when the weather is growing warmer; but gonadal regression can be markedly retarded by artificially reducing the water temperature (Burger, 1939). Kendeigh (1934) believes that seasonal temperature cycles are as important in controlling avian reproduction as are changes in the amount of daily illumination.

The thirteen-lined ground squirrel breeds in April and May, before and after which time the sex glands are relatively inactive. Wells (1935) analyzed the anterior pituitary

glands of these animals and found a seasonal increase in the concentration of gonadotrophic hormones which stimulate the testis and ovary. The rise in hormone level just before breeding season cannot be attributed to changes in illumination, for it begins while the animals are hibernating in subterranean burrows. Temperature may play a role in the gonadal cycle. Wells (1936) showed that testicular regression at the close of the season can be delayed for as long as 5 months if the males are kept in temperatures of 4 degrees C.

Daily cycles of environmental temperature also influence sexual activity. Browman (1943) noted that female rats maintained in constant light or constant dark tended to

excavate nests and lay infertile eggs. Control tests showed that chemical and tactile stimuli have little or no effect upon the female's performance.

Matthews (1939) observed that visually isolated hen pigeons do not lay eggs. Installation of mirrors in the cage induces occasional egg laying; and the frequency of ovulation is further increased if the females can see other pigeons. Field observations show that the presence of other individuals is biologically important to the reproduction of wild birds that form large breeding colonies. Comparison of the reproductive success of four colonies of herring gulls as recorded by Darling (1938) gave the results summarized in Table 1.

TABLE 1

REPRODUCTIVE SUCCESS IN HERRING GULLS AS A FUNCTION OF THE SIZE OF THE BREEDING COLONY

Number of Birds in Colony	Date of First Egg	Total Days of Egg Laying	Nests Built and Occupied	Eggs Laid	Fledglings	Reproductive Success *
84-90	May 7	17	40	84	35	42%
30-34	May 12	23	12	26	8	31%
20	May 18	26	7	16	3	19%
4	0 †	0	0	0%

* Percentage of eggs incubated and hatched.

† Some nest building began 19 days after egg laying started in the largest colony (May 26), but since no nests were occupied and no eggs laid the structures were classified as "nonfunctional."

come into heat during the cooler portion of the 24-hour period.

PRESENCE OF OTHER ANIMALS. Stimulation afforded by other individuals of their own species contributes to the attainment of reproductive condition in some fishes, birds, and mammals. Ripening of eggs in the ovary, secretion of sex hormones, and the resultant execution of mating reactions may be partly or completely dependent upon the presence and behavior of associates.

The female African mouthbreeder fish rarely digs a nest, lays eggs, or exhibits any other sexual activity if she is visually isolated from others of her kind. But Aronson (1945) demonstrated that when females can see another mouthbreeder they periodically

The large colonies were more effective reproductive units. In them oviposition began earlier, was better synchronized within the colony, and resulted in a higher proportion of mated pairs. More birds laid eggs and a larger percentage of eggs was hatched in the large than in the small colonies. Smith's (1943) studies of the Eastern redwing indicate that reproductive success in the second brood is greater for large than for small colonies.

R. K. Enders (personal communication) has shown that seasonal ovarian development and the accompanying behavioral changes in some mammals are influenced by association with other individuals. Female minks were isolated at some distance from others of their

species, and other females were subjected to daily vaginal smears and kept in individual wire cages near the rest of the herd. Examination of the gonads early in the breeding season showed that ovarian follicles were significantly smaller in visually isolated individuals than in minks that lived near others of their kind.

Ovarian function in the human female can be altered by so-called "psychic" factors. Menstruation is appreciably delayed in some women suffering from homesickness, fear of pregnancy, or chronic anxiety (Dunbar, 1938; Gill, 1943; Klinefelter, Albright, and Griswold, 1943; Loeser, 1943; Fuerstner, 1944).

Critical features of the immediate surroundings. The second type of stimulation involved in sexual performance is derived from external factors that do not directly evoke behavioral reactions but predispose the sexually ready individual to respond appropriately and completely to stimuli afforded by the potential mate. Fertile males and females of some species are capable of sexual behavior only in a particular environmental setting.

ESSENTIAL CHARACTERISTICS OF THE HABITAT. Many adult amphibians that live a terrestrial existence can mate only in the water. Various species of toads come into full breeding condition in the spring or summer but show no sexual activity if the weather has been exceptionally dry. A sudden rainfall that creates temporary ponds and puddles is followed by the prompt appearance of courtship and mating (Noble, 1931).

Aquatic birds usually mate and nest near a body of water, and Schoolland (1942) observed that proximity to water stimulates sexual behavior in domestic ducks. Ducklings were hatched and reared under conditions in which the only water encountered was contained in a small drinking saucer. When the birds were 5 months old they were permitted to approach but not to enter a large washtub sunk in the ground and

filled with water. Mating behavior appeared while the ducks walked around the tub, although it had never been observed before.

Failure of wild animals to reproduce in captivity is sometimes due to the absence of one critical environmental condition. The common catfish rarely spawns in aquaria, but Breder (1935) induced fertile mating by placing rocks and plants in the aquarium to pro-

FIG. 1. Mating in the Siamese fighting fish. The male "embraces" the female and fertilizes the eggs as she extrudes them. Mating takes place directly beneath the bubble nest that the male has built on the surface of the water. When mating is completed, the male retrieves the fertilized eggs and puts them in the bubble nest where they remain until hatching. (Reproduced through the courtesy of the American Museum of Natural History.)

vide a natural shelter where courtship and nesting could occur. An appropriate spawning site proved to be an essential prerequisite to sexual behavior.

The presence of a nest or some other structure created by one or both partners is necessary for successful courtship and mating in some species. Some male fish and birds prepare a nest before engaging a female in courtship. The Siamese fighting fish that is ready to spawn builds a "bubble nest" on the surface of the water. The passing female is lured beneath the nest by the male's courtship behavior, and there mating takes place (Fig. 1). A closely related species of fish (*Betta picta*) has a mating pattern that is very much like that of the fighting fish, save for the fact that the male builds no nest.

Female fighting fish will enter into preliminary courtship with males of the second species, but the pattern is broken off before copulation can occur, apparently because the presence of a nest is essential to complete receptivity on the part of the female (C. M. Breder, personal communication).

TERRITORY POSSESSION. Males or females of some species establish a breeding territory and restrict their mating behavior to this geographical area. Potential mates evoke a sexual response only when they are encountered within the territory of the reacting individual.

Nice (1941) has assembled numerous examples of sexual territory in birds. Males of some species gather together in "leks" where they perform their courtship displays and are visited by females. Each male has a small territory that he defends against other males. Once a female has entered the territory of one individual she is no longer courted by other males. Fertilized females depart, and each male serves a number of females in succession. Birds that form more permanent mateships may show sexual behavior only within the boundaries of the male's territory, although they go elsewhere to feed.

Comparable behavior is characteristic of mammals (Burt, 1943). Some of the most dramatic examples are seen in the sexual behavior of the fur seal and elephant seal (Osgood, Preble, and Parker, 1914; Matthews, 1929). Bulls arrive at the rookery several weeks in advance of the cows, and with a great deal of fighting each male chooses and protects his particular area on the beach. Old and large individuals claim locations near the water's edge, and younger bulls are forced to settle down in less desirable regions. When a cow arrives and climbs out on the beach, she enters the territory of some male and he forcefully prevents her departure.

By permitting females to join his harem and then holding them there, the bull accumulates from three or four to as many as 50

or 75 cows. Pups conceived the previous year are born shortly after the female's arrival, and then copulation takes place. Cows are not allowed to leave the territory of their mate until they have been impregnated. Thereafter they are free to enter the ocean and feed, later returning to suckle the pups. In these cetaceans sexual and territorial behavior are interdependent.

Stimuli afforded by the sexual partner. The third class of stimuli involved in courtship and mating comprises the sensory qualities of the male or female that influence the reactions of the opposite sex. The majority of studies on sensory functions in sexual behavior have dealt exclusively with stimuli belonging in this category. Different conclusions have been reached according to the species observed, the methods of investigation, and the general point of view held by the experimenter (Lashley, 1938; Tinbergen, 1942).

INSECTS. Courtship and mating in insects involve a sequence of reactions, each of which may occur in response to a different sensory cue. In some species, for example, the male's approach to a female depends exclusively upon chemical stimuli.

Male June beetles fly from distances of 15 yards to join a female whose genitalia and adjacent scent glands are extruded. The same orientation response is made to a freshly killed and crushed female, but a crushed male is not approached. The chemical compound isoamyline attracts males as effectively as does a receptive female (Travis, 1939). Male wireworm beetles exposed to the odor of lactic, butyric, or caproic acid crawl upon other males in the vicinity, extrude their genitalia, and execute abortive copulatory responses (Lehman, 1932).

Collins and Potts (1932) observed individually marked gypsy moths in the field and found that the male's approach to the female consists of a zigzag, upwind flight over distances up to half a mile. The effective stimulus is a glandular secretion that can be extracted with benzene. Concentrated

extracts of this material are species-specific. They have no stimulative value for other kinds of moths (Haller, Acree, and Potts, 1944) but will attract male gypsy moths from distances of more than 2 miles (Collins and Potts, 1932).

Grosch (1947, 1948) found that male wasps display characteristic signs of sexual excitement when exposed to paper upon which females have been crushed but from which all body fragments have been removed. Males attempt to mate with amputated female abdomens but not with the severed thorax and head. A chemical substance produced by the abdominal glands of the female attracts males over a distance of 15 centimeters. Blind males readily approach and mate with females, but wasps deprived of the antennae that bear the chemoreceptors show no excitement in the presence of females and no tendency to approach them.

In some insects auditory stimulation is responsible for preliminary orientation to a sexual partner. Sexually active male field crickets produce a chirping sound by rubbing the wing covers together, and females that are ready to mate tend to move toward the source of this sound. Baier (1930) placed a number of females in one cage and males in another. The two cages were connected by a sound system, and the females clustered around the loudspeaker from which the males' chirping issued. Males in glass containers were placed in the females' cage, but the visual stimulus did not produce orientation responses on the part of the females.

Although a single sensory cue may suffice to bring males and females together, other stimuli influence subsequent phases of the mating pattern. Kellogg (1907) found that the male silkworm moth is attracted to the female exclusively by chemical stimuli. Males approach and attempt to copulate with scent glands that have been dissected out of the female, but they pay no attention to females from which these glands have been removed. When a female is touched by the male, her

scent glands are drawn into the body and the source of chemical stimulation is removed. The subsequent copulatory activities of the male are guided entirely by tactile cues.

It has been stated that male wasps deprived of the antennal chemoreceptors show no sexual excitement in the presence of females and do not approach them. However, Grosch (1947) observed that when antennaless males accidentally bump into a female they sometimes mount in sexual fashion. This suggests that tactile stimuli evoke the mounting reaction in normal mating.

FISHES. Vision contributes to piscine courtship and mating. In certain species visual perception of form and movement is important. Breder and Coates (1935) showed that male guppies attempt to mate with the projected shadow of a swimming female, approaching the silhouette with normal orientation and moving the gonopodium (male sex organ) directly toward the location of the female's genital opening. Noble (1934) examined the response of male sunfish to models moved through the water on a wire. Crude cardboard replicas elicited courting behavior when they were made to move in the manner of a female sunfish. The same stimulus object evoked aggressive responses when a different motion was imparted to it.

Morphological differences between males and females provide visual cues that affect sexual behavior in the three-spined stickleback. Males that have built their nests drive other males away and court any gravid females. The ventral body surface of the male stickleback is red. Females lack this characteristic, but those that contain eggs have a markedly swollen abdomen. Tinbergen (1942) discovered that nest-guarding males display courtship reactions when confronted with a rough model in which the abdominal region is enlarged. Very accurate models of the female stickleback do not evoke sexual responses if the abdominal area is slim (Fig. 2). Models painted red on the

underside elicit an attack by the experimental males; but when the same model is inverted it calls forth a much less intense response.

According to Noble and Curtis (1939) the female jewel fish in spawning condition discriminates between males and females on the basis of visual cues. The essential masculine characteristics include bright-red body colors

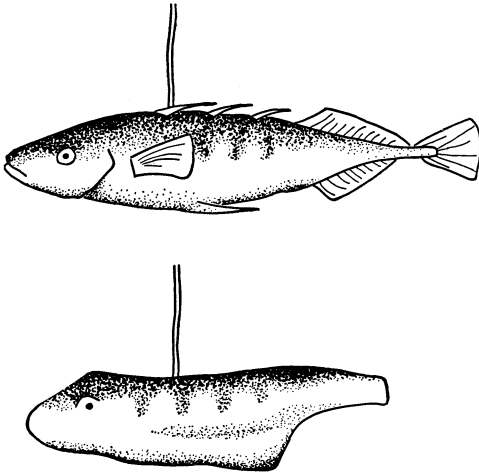

FIG. 2. Models of the three-spined stickleback presented as stimulus objects to the male. The crude model with a swollen abdomen evokes courtship, whereas the more accurate model lacking this essential characteristic is not sexually stimulating to the male. (Redrawn from Tinbergen, 1942.)

and special swimming movements. Gravid females were placed in large aquaria with smaller tanks on each of three sides. Stimulus animals in the small aquaria were clearly visible to the experimental female through two panes of glass and an air space of 1 centimeter. Two of the small tanks contained female jewel fish, and one contained a male. All experimental females with previous spawning experience laid their eggs as close as possible to the male's tank.

In the same testing situation two males were offered as stimulus animals. One was injected with yohimbine hydrochloride, and one with adrenalin chloride. Yohimbine expands the melanophores, intensifying the fish's coloration, whereas adrenalin contracts

these structures and renders the animal pale. By spawning at a point adjacent to the tank containing the yohimbine-treated male, the female indicated her preference for a brightly colored mate. Both males were then transferred to the female's tank, and she drove the adrenalin-treated fish away from her eggs but permitted the other male to assist in caring for them.

Internal fertilization occurs in several fishes, and it is probable that tactile stimuli control certain phases of the copulatory act. Descriptions of mating in the Mexican sword-tail and the platyfish (Schlosberg, Duncan, and Daitch, 1949) strongly suggest that insertion of the male's sexual organ and maintenance of body contact between the pair during sperm transfer involves considerable cutaneous stimulation.

AMPHIBIANS. Male frogs and toads that are ready to breed utter a characteristic "sex call," and in some tree frogs this auditory stimulus is known to attract gravid females (Noble and Noble, 1923). Calling male toads attract others of their own sex and large breeding congresses are built up as a result (Bragg, 1940). Male cricket frogs are sexually excited by the calling of other males and respond by clasping and attempting to mate with the nearest individual, regardless of its sex (Greenberg, 1942).

The experiments of Noble and Aronson (1942) revealed that several different kinds of stimuli are involved in the mating behavior of male and female leopard frogs. Males approach and try to clasp any other frog, regardless of its sex or reproductive condition. The initial orientation depends upon vision. Blinded males do not approach a second individual although they mate normally with the female once contact has been established. Auditory and tactile stimuli control the male's tendency to retain his hold or to release the clasped object. Males, and females that have laid their eggs, utter a "warning croak" when clasped by another frog. In addition they are much slimmer than the female containing eggs. Males

promptly release any frog that is not fat and that emits the "warning croak," and maintain their hold on any fat and silent partner.

The gravid female leopard frog clasped by a male releases several batches of eggs at fairly regular intervals. Synchronized with the female's spawning movements are the "ejaculatory pumps" of the male. These consist in sliding forward and then backward on the female's back and are accompanied by the emission of sperm. The ejaculatory pumps depend upon tactile sensations arising as a result of the female's muscular contractions when she expels each cluster of eggs.

The female's spawning reactions depend upon tactile stimuli derived from the male's clasp. Throughout the mating the male's forelimbs are locked tightly about the female's chest just behind the axilla. Normal egg-laying behavior is shown by isolated females if a rubber band is stretched tightly around the body at this point.

Many salamanders mate on land, and Noble (1929) showed that in some of these species chemical stimulation contributes to effective reproduction. The male two-lined salamander bears special scent glands in the skin of the head and at the base of the tail. During courtship the male first presses his temporal region against the female's snout and then walks away. The female follows the male closely, keeping her chin pressed against his tailbase. Spermatophores deposited by the male are promptly taken into the cloaca of the female, and fertilization is thereby achieved.

REPTILES. The courtship and mating of lizards depends heavily upon vision. The male American chameleon extends his dewlap and bobs his head up and down when another lizard comes in sight. Other males respond to this display by withdrawing or by executing the same behavior, and in the latter case the two animals usually fight. Female chameleons approach the challenging male and show a characteristic flexing of the

neck, which indicates sexual receptivity (Fig. 3). This visual stimulus evokes courtship on the part of the male (Greenberg and Noble, 1944).

Male fence lizards react to the approach of a second individual by rising high on all four legs, displaying the brilliant colors of the lateral and ventral body surfaces. If the newcomer is a male he adopts the same posture. An aggressive encounter follows and one or the other male is driven from the scene. Females are dull in color and respond to the male's display with the execution of receptive behavior. Noble and Bradley (1933) painted female fence lizards with colors like those of the male and found that these individuals were treated as rivals rather than as potential mates. The receptive behavioral reactions of experimentally altered females were not sufficient to evoke courtship when combined with masculine coloration. Male lizards attempted to mate with other males whose legs were tied together to prevent the assumption of the fully erect posture and the display of masculine body colors.

Contact stimuli are important in the copulation of all lizards. At the beginning of mating the male holds the female's neck in his jaws, and later he may bite other portions of her body. Breeding males of some species bear hypertrophied "combs" on the inner surfaces of the thighs. During courtship these are rubbed against the female's flank and the resulting stimulation induces her to cooperate in copulation (Noble and Bradley, 1933).

The gecko and a few other lizards react sexually to certain auditory stimuli. Receptive females utter a sex call or chirp that attracts the male (Evans, 1935a). Greenberg (1943) found that male geckos are able to discriminate between the sexes on the basis of a chemical stimulus emanating from the skin of the female's tail. Bodily adjustments of the pair during coition consist in reflexive responses to stimulation of specialized tactile receptors. In this species,

therefore, auditory, chemical, and touch sensations are all involved in sexual performance.

Male brown snakes and garter snakes are attracted by moving objects during the breeding season, and vision thus contributes

BIRDS. The importance of visual and auditory cues to sexual behavior in birds is attested by numerous experiments. Peripherally blinded male pigeons court the female, but their behavior is so poorly oriented that copulation does not occur (Schrader, 1889).

FIG. 3. Sexual display by the American chameleon. Males react to the sight of another lizard by extending the fan or dewlap and by bobbing the head up and down. Other males retreat or respond by performing the same actions. In the latter instance a fight may occur. Estrous females, such as the one shown in front of and below the male, remain quiet, flex the neck laterally in a receptive gesture, and as a result are courted and fertilized. (Reproduced through the courtesy of the American Museum of Natural History.)

to encounters between potential mates. The subsequent discrimination between males and females depends to a large extent upon chemical sensitivity. Skin from a receptive female exerts a stimulating effect upon breeding males. During coition bodily movements of the partner provide essential tactile cues, and males do not attempt to copulate with anesthetized estrous females. Tactile receptors in the male's chin mediate cues that assist in orientation; covering this region of the head prevents successful mating (Noble, 1937).

Noble (1936) showed that female flickers invite the male to copulate by uttering a specific call and assuming the coital position. Under normal conditions male flickers court any other individual of their species that shows these reactions. They attack a second male, apparently recognizing sex on the basis of the black "moustache" that is worn by all males but not by females. Females to which an artificial "moustache" is attached are attacked by their mates in spite of uttering the sex call and adopting the copulatory pose.

Male golden pheasants make copulatory responses to the stuffed skin of a female pheasant, but male skins are promptly attacked (Noble and Vogt, 1935). The stimulus object need not be posed in the coital position, because the male's discrimination is based upon differences in color pattern. Male robins rely heavily upon color vision in discriminating between the sexes. Mounted birds with a red breast are attacked, and those lacking this characteristic are often courted (Lack, 1939).

MAMMALS. It is often assumed that olfactory stimuli play a primary role in the sexual activity of lower animals. Under laboratory conditions, however, anosmic male rats and rabbits will mate with receptive females (Stone, 1923; Brooks, 1937; Beach, 1942a). Several sources of tactile stimulation can be eliminated without abolishing copulation. Anesthetizing the skin of the ventral body surfaces does not prevent such activity (Stone, 1923), and clipping the vibrissae or desensitizing the skin of the snout and lips permits the survival of effective sexual performance (Beach, 1942a). Partial deafening is without apparent effect (Stone, 1923). The combination of blindness and anosmia, or the elimination of olfaction and touch in the snout and lips, lowers the probability of copulation but does not insure its elimination (Beach, 1942a). Removal of the eyes and olfactory bulbs and destruction of the cochlea do not prevent the female rabbit from receiving the buck (Brooks, 1937).

It can be concluded that sexual arousal and coital reactions in rats and rabbits do not depend exclusively upon vision, olfaction, audition, or touch. However, survival of mating behavior after interference with one afferent pathway does not prove that the same system made no contribution when it was functional. Furthermore the methods of testing behavior have not been designed to measure the animal's capacity to court and mate under natural conditions. Males and females confined in small observation cages are forced into physical proximity.

Bodily contact occurs frequently, and the possible role of distance receptors is not revealed. Finally, desensitized animals have always been tested with normal mates, and under these conditions a deficiency in the responsiveness of the operated individual is frequently compensated when the intact partner intensifies its sexual behavior.

The normal mating performance of male and female rodents almost certainly is facilitated by several kinds of sensory stimulation, including those eliminated in the experiments described above. Olfaction undoubtedly contributes to sexual arousal in some male carnivores. Beach and Gilmore (1949) showed that urine from the estrous bitch has a stimulative value for sexually active male dogs. Urine collected from females in heat was compared with that of nonestrous bitches. Males spent a significantly greater amount of time investigating the urine collected from receptive females.

Female cats that are blind, deaf, and anosmic will mate with the male (Bard, 1939), but a normal male will approach and grip the female and she need only respond appropriately to touch and pressure sensations arising from contact initiated by the partner. The importance of vision in feline reproduction is indicated by the fact that cortically blind male cats do not approach or follow the receptive queen although they copulate normally if the female rubs against them in the course of her spontaneous courtship (Beach, 1949).

Observational evidence indicates that sexual arousal and orientation to the potential mate in male and female primates rests upon visual and auditory cues. When the pair comes together, chemical and contact stimuli also contribute to mating (Yerkes and Elder, 1936).

In mammals, as in all animals that reproduce by copulation, the behavior of males and females just prior to and during coitus appears to be governed primarily by tactile and pressure stimuli. The estrous rat sometimes displays mating responses when the

experimenter strokes or palpates her back and sides with his fingers (Ball, 1937). Stroking the rump of the receptive guinea pig evokes assumption of the copulatory posture (Young et al., 1938), and comparable reactions can be elicited in the golden hamster (Beach, 1950). By pressing heavily on the back and sides of the sow in heat and moving the tail to one side, it is possible to induce the female to present the genitalia and grunt as in copulation (Altmann, 1941). Estrous female cats adopt the mating position if the experimenter grips the loose skin of the animal's neck in his fingers and presses upon its back (Bard, 1939). In each case the stimuli described mimic those normally provided by the sexually active male.

Genital sensation contributes heavily to effective mating in male and female mammals. Female hamsters, skunks, porcupines, and dogs adopt the mating position when the male licks, nibbles, or scratches at the vaginal region (Beach, 1947). The blood pressure of the estrous bitch rises abruptly in response to this form of contact (Pussep, 1922), and females that resist the male's initial attempts to mount often become fully receptive after a period of genital stimulation. Male primates stimulate the feminine genitalia manually and orally prior to coition, and the reactions of the female plainly indicate the sexually exciting quality of the resulting sensations (Bingham, 1928).

Females in which genital sensations are lacking may nevertheless show some mating behavior. This is the case in rats (Beach, 1945) and mice (Raynaud, 1938) with congenital absence of uterus and vagina. Deafferentation of the genitalia does not eliminate copulatory reactions in female rabbits (Brooks, 1937) or cats (Bard, 1935). Under normal conditions sensations from the genitals contribute to sexual behavior in female mammals, but it is evident that in at least some species this source of stimulation is not essential to mating.

Sexual arousal and the execution of copulatory responses occur in male cats after

surgical anesthetization of the genitals and surrounding regions (Root and Bard, 1947). However, ejaculation has not been demonstrated in these animals, and other findings prove the importance of penile sensitivity to normal copulatory performance in several mammalian species. Male dogs show erection, ejaculation, and coital movements in response to manual stimulation of the phallus (Bard, 1939). Male rats rendered incapable of intromission by transection of the os penis continue to pursue and mount females. But intromission is rarely achieved, and the ejaculatory response is lacking. The results suggest that the attainment of the sexual climax is prevented by the absence of normal genital stimulation (Beach and Holz, 1946).

Sexual arousal and mating behavior in all or nearly all animals appear to involve the activation of several different afferent systems. Orientation to and movement toward a potential mate may occur in response to visual, auditory, or chemical cues. Any or all of these modalities may continue to influence the degree of excitement and to guide the bodily reactions of male and female during precoital courtship. The final stages of the copulatory relation are almost universally dependent upon somatic sensations of touch and pressure.

As far as the sensory basis for sexual arousal is concerned, there is no clear evidence of any progressive evolutionary change from invertebrates to mammals. Some classes include species that rely heavily if not exclusively on visual or chemical or auditory cues for the initiation of erotic excitement. But other species in the same classes depend upon multisensory stimulation for the same effect. The specificity of the adequate stimulus varies from species to species, and intraclass variability is as great as that between major phyletic divisions.

Studies of the Nervous System

A complete analysis of any type of behavior includes examination of its internal

correlates. It is necessary to understand the contributions of the nervous system, the muscles, and the various chemical factors in the blood to the occurrence of the responses under examination. Some evidence concerning internal correlates of sexual behavior has been presented in the discussion of sensory functions. Studies of external and internal correlates are often complementary. Investigation of the role of various receptor systems frequently helps the experimentalist to delimit the range of external factors that might be essential.

Insects. Male wasps and silkworm moths do not approach the receptive female after removal of the antennae on which the olfactory organs are located. But these operated males mount a female if they come into contact with her, and in such circumstances fertile mating is possible. Grosch (1947) amputated the posterior body segments containing the reproductive organs. Male wasps prepared in this fashion displayed typical courtship reactions and repeatedly tried to mount the female. The sensory and motor mechanisms of the anterior body parts are, therefore, capable of carrying out their part of the sexual pattern even though large segments of the total response system are missing.

Kellogg (1907) found that, although antennaless male silkworm moths mate when placed in contact with the female, this behavior cannot be induced after the entire head has been removed. In the absence of the dominant cephalic ganglia the segmental nervous centers lose their excitability and are incapable of mediating even fragments of the total sexual pattern. The same operation does not eliminate sexual responses in the female of this species. Males mate with headless females and the latter display normal oviposition reflexes and lay eggs. Female bodies deprived of the head, thorax, and part of the abdomen continue to attract the male. This fractional part of the female lays a few eggs during mating and some of the eggs develop.

Fishes. The primary importance of the visual system to sexual behavior in some fishes is revealed by descriptions of courtship and mating in peripherally blinded jewel fish (Noble and Curtis, 1939). Eyeless females of this species will lay eggs in the presence of a normal mate. But the eggs are scattered over an area about three times as large as usual, and the female does not synchronize her behavior with that of the male. Blind males may fertilize a small portion of the eggs laid by their normal partners, but they are unable to time the spawning responses appropriately, and they fail to integrate their behavior with that of the female.

Unilateral destruction of the cerebrum, or the placement of small bilateral lesions in this area, does not prevent normal reproduction in the jewel fish, according to the preliminary findings of Noble and Borne (1941). But more extensive forebrain loss disorganizes courtship and spawning. There is no indication of localized function in any part of the forebrain. Different elements in the pattern drop out as a result of large brain lesions, but the same reaction may disappear after destruction of different portions of the forebrain, and the number of elements eliminated appears to be a function of the extent of the lesion. Complete decerebration abolishes sexual activity.

Aronson (1948) studied the effects of partial and total removal of the forebrain upon sexual behavior in the male African mouthbreeder fish. He found that subtotal decerebration has little or no effect upon courtship and mating. Completely decerebrate males display no change in the early phases of courtship, but the reactions immediately before and during spawning are seriously affected.

Nest building, which usually precedes spawning, is appreciably reduced by this operation. Normal males always fertilize the eggs promptly after the female has laid them, but decerebrate fishes did so in only 8 per cent of the cases. Forebrainless males

rarely carry the fertilized eggs in the mouth in the manner of normal individuals. Control lesions in the cerebellum had no effect upon sexual activities, and Aronson concluded that changes noted in decerebrate males could be referred specifically to disturbance of forebrain function rather than general shock following injury to any part of the nervous system.

Amphibians. We have seen that the visual system contributes to effective mating in

lesions do not orient themselves normally on the female after the clasp has been achieved.

The "warning croak" which the male emits when clasped by another frog depends upon the presence of the inferior colliculi and is independent of higher centers. Males that are ready to breed produce a characteristic sex call which is mediated primarily by the midbrain although it may survive extensive invasion of this area. The spawning move-

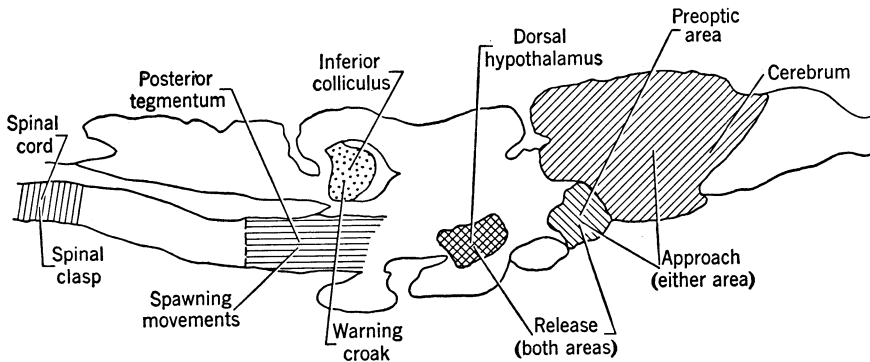

FIG. 4. Diagrammatic sagittal section through the brain of the leopard frog, showing some of the regions that mediate different elements in the male's mating pattern. (Redrawn from Aronson and Noble, 1945.)

some amphibians. Peripherally blinded male leopard frogs fail to swim toward the waiting female, although they are capable of fertile spawning if they come into physical contact with a mate. The South African clawed toad is less dependent upon visual cues, according to the report of Berk, Cheetham, and Shapiro (1936). Blind males of this species approach and clasp females, and, although the clasping position is often abnormal, it is usually corrected without delay.

Aronson and Noble's (1945) careful studies of mating in brain-operated leopard frogs show that different parts of the nervous system exert special control over particular elements in the total pattern (Fig. 4). The male's tendency to clasp a second frog in sexual fashion depends in large measure upon spinal mechanisms. Clasping occurs despite complete transection through the caudal end of the medulla, although animals with such

elements shown by the clasping male each time the female expels a cluster of eggs are not affected by removal of the forebrain. They survive as long as the posterior tegmentum is intact.

After spawning is completed, the normal male relaxes his mating clasp. Frogs with large lesions in the preoptic region of the forebrain and the pars dorsalis of the hypothalamus fail to release the female, but injury to more anterior brain parts does not produce this effect. The male's tendency to swim toward another frog survives removal of most of the forebrain, provided the preoptic area is spared. It is not eliminated by operations that destroy only the preoptic region. Apparently both the preoptic nucleus and the remainder of the forebrain normally contribute to this response although either area is capable of mediating it independently.

Reptiles. There is very little evidence concerning neural correlates of sexual behavior in reptiles. Diebschlag (1938) reported that unilateral decerebration does not prevent mating in the male emerald lizard, but bilateral removal of the forebrain abolishes courtship and copulation.

Birds. It was stated above that peripherally blind male pigeons are incapable of coordinated courtship and mating. Schrader's (1889) observations on brain-operated pigeons showed that total decerebration eliminates mating. Forebrainless males may display some courtship responses, but they do not orient their behavior to the receptive female. Rogers (1922) also noted the absence of effective reproductive behavior in pigeons deprived of the hyperstriatum, which constitutes a large part of the complex avian forebrain. He concluded that the hyperstriatum "ties together" the discrete responses involved in courtship and copulation.

Unpublished studies conducted in the writer's laboratory indicate that the partial destruction of the forebrain reduces the probability that male pigeons will copulate with females, but it does not always affect preliminary courtship behavior. Total decerebration (confirmed by examination of the sectioned brains) eliminates courtship as well as copulation. Different elements in the sexual pattern do not appear to be controlled by separate parts of the corpus striatum. Forebrain injury reduces the male's responsiveness to the female without rendering him physically incapable of sexual performance. Some males sustaining extensive brain injury resume copulating after the injection of androgen.

Mammals. The neural correlates of sexual behavior have been studied more extensively in mammals than in lower vertebrates. Progressive encephalization of nervous function in the course of mammalian evolution has been accompanied by several changes in the control of courtship and mating, but there

are many basic similarities between mammals and other animals.

SPINAL MECHANISMS. Erection and ejaculation occur in male rodents (Bacq and Brouha, 1933), rabbits (Durfee, Lerner, and Kaplan, 1940), and dogs (Schafer, 1900) in response to electrical stimulation of the sacral cord. These genital reflexes survive in male mammals despite complete transection of the spinal cord in the lumbar region.

Abdominal sympathectomy eliminates ejaculation but does not prevent erection or active copulatory responses in male rats, rabbits, guinea pigs, or cats (Bacq, 1931; Bacq and Brouha, 1933; Root and Bard, 1947).

Male cats (Dusser de Barenne and Koskoff, 1934) and dogs (Schafer, 1900) in which the cord is sectioned above the lumbar region react to stimulation of the penis by executing gross movements suggestive of intercourse. Riddoch (1917) described the "coital reflex" which occurs in spinal man in response to genital stimulation. More recent observations by Munro, Horne, and Paull (1948) and Rosenquist (1949) reveal that complete spinal section does not necessarily prevent fertile copulation in the human male.

Certain elements of the female mammal's sexual pattern survive transection of the spinal cord. Some estrous reactions continue in the bitch after lumbar section (Golz, 1874), and female cats with the cord cut at the cervical level react to stimulation of the perineum by treading and moving the tail to one side as in copulation (Maes, 1939).

Description of the fragmentary sexual responses shown by the spinal animal should not obscure the fact that these are isolated segments of a pattern. In intact individuals the spinal mechanisms are subject to control by higher nervous centers. Nevertheless, in mammals as in insects and lower vertebrates the neural correlates of sexual behavior include segmental reflex mechanisms capable of a considerable degree of autonomous function.

BRAIN MECHANISMS. Coital behavior of female mammals depends in part upon certain diencephalic mechanisms. Guinea pigs, rats, and cats show marked reduction or complete elimination of sexual responsiveness following destruction of the anterior hypothalamus (Fisher, Magoun, and Ranson, 1938; Dempsey and Rioch, 1939; Bard, 1940). Male rats with hypothalamic lesions are reported to display less sexual behavior postoperatively, although no description of the changes has been published (Clark, 1942).

The importance of higher brain regions varies according to the sex of the individual and the species to which it belongs. Complete removal of the cerebral cortex, hippocampus, and corpus striatum does not abolish copulatory activity in female guinea pigs, rabbits, rats, or cats (Dempsey and Rioch, 1939; Brooks, 1937; Davis, 1939; Bard, 1936). Beach reported (1944) that decorticated female rats show increased sexual excitability accompanied by certain behavioral deficiencies. The tendency to direct the receptive reactions toward the male is lost; and separate elements in the sexual pattern are not normally synchronized.

Male rabbits deprived of all neocortical tissue continue to display grossly normal sexual reactions (Brooks, 1937). Davis (1939) found that extensive cortical injury did not always eliminate mating behavior in male rats, but investigations by the present writer (Beach, 1940, 1941) showed that sexual activity in males of this species is definitely affected by cortical lesions involving more than 20 per cent of the total neopallium. Destruction of 20 to 50 per cent of the cortex eliminates mating in some individuals but not in others, and the number of rats copulating after operation is inversely related to the amount of tissue removed (Fig. 5). Male rats with bilateral lesions exceeding 60 per cent of the cortex do not copulate postoperatively.

Smaller lesions that do not abolish coition may render it more difficult to elicit. The

proportion of tests in which the male shows mating reactions is reduced after operation. However, when the copulation does occur, the pattern of the response is normal. Some animals that fail to mate after relatively small lesions can be induced to do so when injected with large amounts of male hormone.

These findings suggest that the cortex is not directly involved in the organization of sexual

FIG. 5. Effects of cerebral injury on mating behavior in male rats. The proportion of different groups continuing to copulate after operation varies according to the amount of cortex removed. (Redrawn from Beach, 1940.)

responses in the male rat but serves to maintain the excitability of lower centers that are essential to the integration of mating behavior. In the absence of facilitative support from the cortex, these hypothetical executive mechanisms become relatively unresponsive to exteroceptive stimuli.

It has been pointed out that female rats continue to mate despite total decortication. Presumably this indicates that the neural circuits essential to feminine sexual performance are not so dependent upon cortical facilitation as are those for masculine reactions. Convincing proof of this assumption is provided by the results of another experiment (Beach, 1943). Many normal female rats display masculine mating

responses when placed with a second female that is in heat. Male behavior is eliminated in these females by large cortical lesions, but their feminine mating responses survive.

Unlike females of their species, male cats do not mate after extensive forebrain injury (Bard, 1940). This difference is due in part to the fact that the female's coital adjustments do not involve precise sensory-motor coordinations mediated at the cortical level. But, in addition, the decerebrate female displays spontaneous courtship, and no comparable behavior is seen in decorticate males. Sexual excitability in female carnivores, as in female rodents, appears to be much less dependent upon cortical facilitation than it does in males.

Removal of critical cortical areas produces specific deficiencies in the male cat's mating performance. Animals lacking the visual cortex have difficulty locating and following the female, but their coital behavior is normal if they are placed in contact with her. Removal of the frontal lobes renders the male incapable of coordinated sexual activity. Cats with such lesions show no reduction in sexual excitability, but they experience great difficulty in achieving intromission because their bodily adjustments to the female are awkward and uncoordinated (Langworthy, 1943). The completely decorticated male shows no signs of excitement in the presence of an estrous female and does not attempt to copulate when placed in the proper position (Beach, 1949).

Differences between male rats and male cats reflect the increased corticalization of sensory-motor functions in carnivores. Cats retain their sexual excitability but fail to copulate after the removal of particular cortical areas because these areas are essential for the integration and timing of successive stages in the coital pattern. Absence of responsiveness in complete decorticates suggests that the entire neopallium contributes to the male's capacity for sexual arousal in carnivores as well as in rodents.

The neurological evidence shows that the sexual behavior of all animals includes a number of reflexes controlled by primitive neural circuits. From frog to man we find proof that certain elements in the normal mating pattern can be mediated by spinal mechanisms lacking any connection with the brain. At the same time it is clear that the integration of the individual reactions into a biologically effective sequence becomes increasingly dependent upon the forebrain as encephalization of sensory-motor functions progresses. Finally, there are several indications that susceptibility to sexual arousal, and the ability to engage in fertile copulation, are less dependent upon the cerebrum in the female than in the male.

Studies of Blood Chemistry

Sexual behavior in vertebrates and invertebrates may be strongly affected by various alterations in blood chemistry such as those produced by drugs, special diets, or hormonal secretions.

Drugs. Several commercially available aphrodisiacs, widely used by animal husbandrymen, have been tested on laboratory animals. Cantharides, which is prepared from the dried body of a species of beetle, stimulates the mucous membranes of the urogenital tract and is given to domestic animals as a sex stimulant. However, the present writer administered different concentrations of this substance to castrated male rats without producing any change in mating behavior.

Another drug commonly used as an aphrodisiac is yohimbine, an alkaloid derived from the bark of the West African yohimbe tree. Fugo and Gross (1942) reported that female rats injected with yohimbine-HCl displayed abnormally long estrous cycles and exhibited masculine mating responses. Hypophysectomized animals were not affected by the drug, and the authors concluded that the drug affects the ovaries indirectly as a result of its influence upon the anterior pituitary. In contradiction to this report, Sulman and

Black (1945) state that they were unable to demonstrate any effect of yohimbine on the sex glands, the sexual organs, or the behavior of mice or rats of either sex. And we have already noted that masculine sexual behavior frequently occurs in untreated female rats.

Alcohol depresses genital reflexes in male dogs (Gantt, 1940).

Sexual activity decreases in monkeys addicted to heroin and reappears in exaggerated form when the drug is withdrawn (Seevers, 1936). Dogs maintained on a schedule of morphine injections become sexually hyperactive during periods of withdrawal (Tatum, Seevers, and Collins, 1929), and monkeys masturbate frequently under similar conditions (Kolb and DuMez, 1931). Morphine decreases sexual desire and potency in human beings, and prolonged withdrawal of the drug is accompanied by increased sexual reactions. Continued erections and frequent emissions occur in the deprived male addict, and "spontaneous" orgasms are reported by females (Terry and Pellens, 1928). Spragg (1940) found that morphine acts as a sex stimulant in male chimpanzees. Shortly after the daily shot of the drug males display frequent erections, masturbation, and eagerness to copulate with females. Sexual excitability and potency decrease progressively during the 24-hour period following an injection. No explanation is available for these species differences in the effects of morphine.

Diet. Stone (1924) showed that the onset of adult sexual behavior is delayed in rats maintained on a quantitatively reduced diet. The results cannot be referred to retardation in secretion of testicular hormone, for prolonged inanition does not affect the histological condition of the secretory cells (Siperstein, 1920-21). However, male rats raised on a quantitatively insufficient diet copulate as early as or earlier than control animals, provided they are treated with androgen (Stone, 1942a). The most likely explanation is that the hypernormal concentration

of male hormone compensates for the detrimental effects of semistarvation.

Miles (1919) described decreased interest in sexual matters on the part of young men whose normal caloric intake was reduced by one-third to one-half. Specific dietary deficiencies sometimes affect sexual reactions. Wiesner and Bacharach (1937) maintained rats on a diet lacking vitamin E but adequate with respect to A and D and containing yeast. After several months, mating responses disappeared in many animals and became less frequent and less complete in the remaining individuals.

Hormones. Much of the evidence concerning the effects of hormones upon behavior has been summarized elsewhere (Beach, 1948). The mating reactions of some insects appear to be independent of sex hormones, for removal of the reproductive glands in larvae or adults does not prevent copulatory behavior in the gypsy moth (Oudemans, 1899), the silkworm moth (Kellogg, 1904), or the cricket (Regen, 1909). In most vertebrates, however, sexual activities are strongly affected by glandular products. All endocrine secretions that contribute to metabolic processes of the organism are indirectly involved in sexual behavior. Sexual functions are likely to be depressed or eliminated by acute hypothyroidism, by deficiency of adrenocortical hormone, or by any other glandular disturbance having an adverse influence upon general health. More immediate and direct effects are exerted by the gonadal hormones.

FISHES. Sexual behavior can be induced before the normal breeding season by stimulating the gonads to produce sex hormones. This effect has been produced in goldfish by injections of pituitary hormones (Hasler and Meyer, 1942). Immature male guppies show adult mating reactions if treated with androgen (Eversole, 1941). Noble and Kumpf (1936-37) found that removal of the ovaries eliminated mating activity in female jewel fish and Siamese fighting fish, but adult castration did not influence the male's sexual

responses. Administration of ovarian hormones to spayed females was followed by the reappearance of breeding behavior.

AMPHIBIANS. Sexual behavior in amphibians occurs seasonally, and the sex glands are maximally active during the breeding period. The male leopard frog utters the sex call only when the secretory cells of the testis are functional. Administration of androgen to immature male toads elicits a precocious appearance of the adult mating call (Blair, 1946). Male and female frogs and toads become sexually active out of season if they are injected with a pituitary substance that brings the gonads into functional condition (Noble and Aronson, 1942). Castration of male amphibians before the beginning of the mating season prevents breeding behavior (Noble and Aronson, 1942), but gonadectomized frogs display normal sexual behavior following implantation of testicular tissue or injection of appropriate extracts (Edinger, 1913).

REPTILES. The seasonal appearance of sexual behavior in snakes and lizards is closely correlated with recrudescence of the sex glands and secretion of gonadal hormones (Blanchard and Blanchard, 1942; Reynolds, 1943; Cieslak, 1945). Administration of gonadotrophic hormones is followed by out-of-season mating in lizards (Evans, 1935*b*; Greenberg and Noble, 1944). Evans (1935*c*) treated immature female chameleons with pituitary hormones and obtained precocious sexual responses; and similar effects have been produced in males by the administration of androgen (Noble and Greenberg, 1941). Removal of the reproductive glands during the breeding season is followed by a rapid loss of sex responses in male and female lizards, and the injection of androgen into castrated males or of estrogen into spayed females restores copulatory behavior (Reynolds, 1943; Greenberg and Noble, 1944).

BIRDS. Annual breeding cycles in some birds are closely and positively related to the functional development of the sex glands

(Bullough, 1942*a*). Premature sexual responses appear in male and female domestic fowl treated with androgen and estrogen, respectively (Noble and Zitrin, 1942). Castration eliminates copulatory behavior in male pigeons, although some courtship responses survive indefinitely. The loss is gradual, extending over several months (Carpenter, 1933). Ovariectomized adult domestic and wild birds show no breeding behavior. But gonadectomized females are capable of normal sexual behavior under the influence of injected ovarian hormones, and the same is true of castrated males treated with androgen (Noble and Wurm, 1940; Davis and Domm, 1943).

SUBPRIMATE MAMMALS. A great many mammalian species are seasonal breeders, and the yearly occurrence of sexual activity depends upon the development of the secretory function in the gonads (Rice, 1942). Out-of-season breeding has been induced by the administration of pituitary hormones that stimulate the reproductive glands (Gaunt and Hays, 1938; Nelsen and Maxwell, 1941). Some domesticated mammals are fertile at all seasons, and the female comes into heat at regular intervals. The rhythms of sexual receptivity are closely associated with parallel cycles of hormone secretion by the ovaries (Hammond, 1944; Blandau, Boling, and Young, 1941). Immature female rats display no mating behavior, but they can be induced to do so by precocious stimulation of the ovaries (Smith and Engle, 1927), and males and females show adult behavior 2 to 4 weeks earlier than usual after treatment with the appropriate sex hormone (Beach, 1942*b*). Castration of either sex in infancy prevents the appearance of adult mating reactions at the time of puberty (Beach, 1942*c, d*; Hertz, Meyer, and Spielman, 1937). However, males and females gonadectomized in infancy show normal coital behavior if treated with gonadal hormones in adulthood (Moore and Price, 1938; Boling, Young, and Dempsey, 1938).

Female rodents and carnivores promptly cease to show sexual responsiveness and possess little stimulative value for the male after ovariectomy in adulthood, but normal mating occurs in these animals in response to the appropriate hormone treatment (Wiesner and Mirskaia, 1930; Ring, 1944). Male rats, rabbits, and hamsters react to adult castra-

studied systematically. Casual observation suggests that male sheep, pigs, horses, and cattle exhibit some sexual activity for long periods after castration in adulthood, but no details are available (Steinach, 1894; Rice, 1942). Experiments now being conducted in the writer's laboratory prove that some male dogs show normal sexual behavior at least as long as 2 years after castration in adulthood.

FIG. 6. One effect of androgen administration upon mating behavior in castrated male rats. "Latency" refers to the interval between the introduction of a receptive female and the occurrence of the first copulation. The speed with which coitus is initiated by castrated animals is seen to depend upon the amount of male hormone they are given. Other aspects of the coital pattern are similarly affected. (Redrawn from Beach and Holz-Tucker, 1949.)

tion with a gradual loss of sexual activity (Stone, 1927, 1932; Beach and Pauker, 1949). Ejaculatory responses disappear a week or two after the operation. The capacity for erection and intromission survives somewhat longer but is lost within approximately 1 month. Incomplete mating reactions tend to persist indefinitely. These postoperative changes can be prevented or reversed by supplying the castrated male with androgen, and the behavioral effect is quantitatively related to the amount of hormone administered (Fig. 6).

The behavioral consequences of castration in larger domestic mammals have not been

PRIMATES. The sexual behavior of lower primates is less dependent upon gonadal hormones than is that of some lower mammals. Monkeys have a clear-cut menstrual cycle which depends upon the periodic increase and decrease in the concentration of ovarian hormones, but the female's willingness to copulate is not entirely restricted to the estrous period (Carpenter, 1942). Captive and free-living females occasionally receive the male when they are not physiologically in heat. Furthermore, ovariectomized females are capable of some sexual activity without the support of exogenous hormones (Kluver and Bucy, 1939).

Yerkes and Elder (1936) observed that female chimpanzees often encourage copulation despite low levels of estrogen. Mating may continue after removal of the ovaries, although it occurs rarely and perhaps only in rather unusual situations (G. Clark, personal communication). It should be understood that reduction in dependence upon gonadal hormones is relative rather than complete. Monkeys and apes are most receptive and eager for intercourse at times when the estrogen level is high.

Many women experience cycles of sexual responsiveness that correlate with the menstrual rhythm (Davis, 1929; Stopes, 1931; Dickinson, 1931). In most instances, however, maximal desire occurs just before or just after menstruation. These are not fertile periods and do not correspond with the peak of estrogen secretion. The additional fact that erotic excitability survives ovariectomy or menopause, often without reduction (Filler and Drezner, 1944), suggests that the

trend observed in subhuman primates has been extended even further in our own species with the result that ovarian hormones are not necessary to full sexual behavior.

Very little is known concerning the sexual capacity of castrated monkeys or apes. One adult chimpanzee gonadectomized in infancy is reported to copulate readily and vigorously with receptive females. The ejaculatory response is lacking, but it appears under androgen therapy (Clark, 1945). Prepuberally castrated men are rarely if ever capable of complete sexual response. Removal of the testes in adult males sometimes causes marked reduction in sex drive and capacity for satisfactory intercourse. In other cases, however, no change is experienced for as long as 10 to 20 years after the operation (Feiner and Rothman, 1939; Tauber, 1940). Men whose sexual ability declines as a result of castration can sometimes be restored to normal by androgen therapy (Moehlig, 1940). Until more data are collected we can only point out the range of individual differences and observe that in some men testicular hormone is not necessary for normal sexual activity.

This review of the endocrine basis for sexual behavior indicates that ovarian hormones are essential to mating in females of many if not all vertebrate classes and orders with the specific exception of primates. Considering successively monkeys, apes, and human beings, we see evidence of a progressive relaxation of this hormonal control over sexual responsiveness. In male animals it is clear that testicular hormone is necessary to normal development of mating behavior, for prepuberal castration usually reduces the frequency of sexual reactions in adulthood, and the responses that occur are never complete. However, the effects of castration in adulthood may vary with the species and even with the individual involved. Some male fish, dogs, horses, cattle, and human beings are capable of normal sexual performance years after removal of the sex glands. It is possible that differ-

ences in the importance of gonadal hormones for masculine and feminine sexual behavior are related to differences in the extent to which the forebrain influences these two types of reaction.

Development in the Individual and Modification by Experience

Sexual behavior appears in many animals before they are reproductively mature, and a few elements in the adult mating pattern are present in infancy.

Behavior of immature individuals. Basic sexual reflexes mediated by spinal centers may be fully developed at the time of birth. Erection of the penis occurs in newborn boys and in neonatal primates of other species (Halverson, 1940; Hines, 1942). For a few hours after birth infant guinea pigs respond to tactile stimulation of the perineal region by adopting the mating posture of the adult female (Boling et al., 1939).

The play of juvenile mammals often includes portions of the adult mating pattern. Rats of most domestic strains become fertile at approximately 50 days of age, but young animals pursue, mount, and clasp other individuals as early as 21 days after birth. Pelvic thrusts sometimes occur, and the only element lacking is the ejaculatory reflex (Beach, 1942*b*). Comparable prepuberal sex play is common in guinea pigs, hamsters, and other rodents (Louttit, 1929; Bond, 1945). Scott (1945) noted that male lambs mount other sheep in sexual fashion as early as 3 days after birth though they do not become mature until the following year. According to Hooker (1944) copulatory behavior appears in male calves 3 months before fertile mating is possible. Male lion cubs exhibit incomplete mating reactions at 3 months of age and attain reproductive maturity at the end of the second year (Cooper, 1942).

Subprimate mammals rarely display any part of the female mating pattern before puberty. Absence of prepuberal feminine behavior in lower mammals is due to the rigid

dependence of such reactions upon gonadal hormones. The complete adult response can be elicited precociously if the appropriate ovarian hormones are administered, and this shows that the essential neuromuscular mechanisms are mature before they are normally called into play. In some species the testis secretes small amounts of hormone soon after birth (Oesting and Webster, 1938; Hooker, 1944), but the sex play of immature males is unchanged by castration at birth (Beach, 1942*d*). The difference in prepuberal behavior reflects differences in the extent to which the male and female patterns are controlled by gonadal secretions, and perhaps the unequal contribution of the forebrain to the two types of response.

Infantile sex play is more frequent and complete in primates than in lower mammals. Furthermore it appears in females as well as in males, and this probably reflects the partial independence of feminine sexual activity from strict hormonal control. Male macaque monkeys rub the erect penis against objects in the environment as early as 3 weeks after birth, and during the first year they exhibit rhythmic motions of the pelvis in response to stimulation of the penis. Use of rubber playthings and other small objects in sexual fashion is common (Hines, 1942). Male chimpanzees masturbate themselves and mount other individuals in sexual play several years before adolescence (Bingham, 1928).

Female rhesus monkeys display the sexual presentation pattern as early as 6 months after birth (Carpenter, 1942). Several years before puberty female chimpanzees engage in sexual play with young males, exhibiting invitational responses and permitting mounting with partial intromission (Bingham, 1928).

Behavior of inexperienced adults. Observations by naturalists and animal husbandrymen suggest that mature males without mating experience frequently attempt to copulate with biologically inadequate partners.

Cichlid fishes reared in isolation attempt to mate with other fish of either sex, but after some experience they restrict their courtship to females (Noble and Curtis, 1935). Young red-winged blackbirds attempt coition with the stuffed skins of either males or females; but older males mount only the dummy females (Noble and Vogt, 1935). Craig (1914) found that doves reared in isolation do not respond normally to receptive females but often try to mount the hand of the experimenter. Inexperienced bulls try to mount heifers that are in proestrus and are not yet receptive, whereas the experienced breeder mounts only those cows that are fully in heat. De Alba and Asdell (1946) state that adult males lose this discriminatory ability if they are isolated from females for a long time. According to Macirone and Walton (1938) sexually inexperienced male rabbits mount the doe in abnormal positions more frequently than do older bucks.

Heterosexual experience is not essential to effective mating in adult rats (Stone, 1922), and unpublished observations by the writer indicate that the same is true of dogs. Male and female rats reared in individual cages from the age of weaning display normal mating reactions when placed together after they mature. Inexperienced males given the opportunity to mate with young female guinea pigs, infant rabbits, male rats, nonestrous female rats, and female rats in heat rarely mount any animal save the receptive female (Beach, 1942*a*). This disagreement with impressions based upon field and farmyard observations may reflect species differences, but the observational evidence will have to be validated by systematic studies before any final conclusion can be reached.

Several observers have reported that inexperienced male primates are incapable of complete copulation (Bingham, 1928; Yerkes and Elder, 1936). Mature monkeys and apes that have never mated give evidence of sexual arousal in the presence of receptive partners, but their coital responses

are fragmentary and disorganized. Attempts to cover the female are poorly oriented, and intromission is not achieved. The capacity for prompt and effective copulation is developed gradually through practice.

Female primates are less dependent upon learning, and the naive monkey or ape usually responds adequately to an experienced male. When an inexperienced male and female are placed together, the sexual behavior of the latter is much more appropriate and effective than that of her partner. Female monkeys that have never copulated sometimes attempt to assist the consort in the performance of his role. It is possible that sex differences in the mating behavior of inexperienced primates is indicative of a parallel difference in the contribution of the cerebral cortex to masculine and feminine performance.

Alterations produced by experience. Practice is not essential for effective coitus in many animals, but susceptibility to sexual arousal and the kinds of behavior shown by the sexually excited individual can be altered by experience.

ELIMINATION OF INHIBITION. Male mammals often fail to respond to receptive females encountered in new and strange environments. In general the absence of arousal seems due to the distracting effects of nonsexual stimuli (Beach, 1947). Females are much less susceptible to this form of inhibition, and commercial animal breeders usually take receptive females to the male to be bred in surroundings with which he is familiar (Kokolsky, 1945). The sex difference may be due in part to the relative independence of feminine behavior from cerebral functions.

The sexually inhibiting effects of a strange environment may be dissipated gradually as the male becomes accustomed to his new surroundings, and some individuals that fail to mate at first contact succeed in doing so after they have been put with a receptive female in the same pen or cage several days in succession. The proportion of male rats

showing copulatory reactions increases in the course of the first three or four sex tests, and this presumably reflects individual variation in the readiness with which different males adapt to the testing situation (Beach, 1940).

Environmental interference may be suddenly and completely eliminated as the result of a successful copulation. Regardless of their term of residence in the laboratory very few male cats copulate the first time they are taken to the observation room and placed with a receptive female. The absence of sexual responsiveness may continue for months, but after one completed mating the male displays spontaneous courtship and copulation in all subsequent tests (Zitrin and Beach, 1945).

PRODUCTION OF INHIBITION. Male mammals often fail to copulate in an environmental setting previously associated with punishment. Dogs that have become "neurotic" as a result of experimental treatment are slow to respond to estrous females presented in the room where the experiments were conducted, but the same males mate readily in the kennel (Gantt, 1944). Male rats subjected to electric shock during or immediately after copulation with the receptive female usually fail to mate in subsequent tests (Wheeler, 1933).

Painful or frustrating experiences associated with initial heterosexual contacts often depress responsiveness to receptive females. Young male foxes that have been attacked or frightened by the female often avoid contact with other vixens in later tests, and consequently males are trained for breeding by placing them with gentle females that are fully receptive (Enders, 1945). If a severe fight occurs during initial matings, young male mink fail to develop the sexual aggressiveness necessary for effective breeding. But males that have copulated successfully several times are not repelled by temporary resistance on the part of the female and can be depended upon to

fertilize any animal that is in estrus (Kokolsky, 1945).

A male's readiness to mate may be conditioned by the presence and behavior of other males. In one experiment four roosters kept in a small pen with several hens developed a dominance hierarchy. One male was completely subordinate to the other three, and his attempts to mate with females were a signal for prompt attack by all other males. Eventually the sexual activity of this individual was completely suppressed. Even when the three dominant cocks were removed from the pen, the subordinate rooster made no attempt to court or tread the females (Guhl, Collias, and Allee, 1945).

Schneirla (1946) has called attention to the fact that the behavior of confined animals may bear little resemblance to what would appear in a natural environment. However, the importance of social dominance to sexual activities has been revealed by field studies of free-living birds. J. W. Scott (1944) noted that dominant male sage grouse have free access to receptive females whereas socially subordinate cocks rarely have an opportunity to mate.

POSITIVE RESPONSES TO NONSEXUAL STIMULI. Sexual arousal and mating behavior are most likely to occur in a setting that offers few distracting stimuli. Furthermore a specific environment previously associated with sexual activity tends to acquire a stimulating value that increases the probability of mating. Male rats that have copulated with receptive females in a particular cage often attempt to mate with males or nonreceptive females encountered in the original testing situation (Beach, 1942a). Male rabbits accustomed to receiving estrous does in the living cage will mount small animals of several species or even inanimate objects that are offered in similar fashion (Brooks, 1937).

Breder and Coates (1935) established in male guppies conditioned sexual responses

to a glass beaker. In preliminary tests the empty beaker was investigated by the male fish but no mating behavior occurred. Next a receptive female was placed in the beaker, and some of the males became sexually active, attempting to copulate with the female through the glass. Successive presentations of the beaker containing a female were made at hourly intervals and produced an increase in the percentage of males responding. After this the empty beaker was lowered into the males' tank and evoked sexual attempts on the part of many individuals. The empty beaker introduced 24 hours after it had been paired with the visual stimulus of a female called forth mating responses in 16 per cent of the tests. One hour later the female was offered inside the beaker, and 83 per cent of the tests were positive. A single presentation of the empty beaker extinguished the response.

Certain behavioral characteristics of the estrous female appear to become sexually exciting to the male as a result of experience. Female howler monkeys display a sporadic arm reflex when they are approaching or copulating with a male. Carpenter's (1942) field observations of this species led him to suggest that through associative learning the female's arm movements come to exert a stimulating effect upon the male before physical contact is established.

CONDITIONING TO SPECIFIC PARTNERS. Experience is responsible for the specific preferences shown by some animals in their selection of sexual partners. Guhl, Collias, and Allee (1945) found that in chicken flocks roosters court and mate with hens of low social rank more frequently than with those whose dominance status in the flock is high. High-ranking females are less likely to show the sex invitation and less likely to respond receptively when approached by the male. Guhl and Warren (1946) reported that individual hens show a preference for mating with particular roosters, and a female that is

entirely receptive to one cock may avoid copulation by another male.

Male mammals of several species do not attempt to mate with strange females even though they are fully receptive. Comparable discrimination is not always shown by females. The estrous porcupine accepts any sexually aggressive male without delay, but males do not copulate with a female until the two animals have inhabited adjacent cages for several days (Shadle, 1946). Domesticated male ungulates sometimes refuse to serve a particular type of female. A stallion bred exclusively to dark mares may show no inclination to mount a white one; and jacks that have been allowed to mate with jennets often fail to copulate with mares (Marshall and Hammond, 1945).

Tinklepaugh's (1928) description of sexual behavior in a male rhesus monkey reveals a very complex sort of conditioning. After two years of cohabitation with one female monkey of a different species, the male was caged with a mate of his own kind. Although she was sexually receptive, the male's reactions consisted solely of violent aggression. Eventually his aversion was reduced to the point of permitting coition, but immediately after copulating the male inflicted severe wounds on his own body. Self-mutilation occurred whenever the original mate came into sight.

This brief survey of the development of sexual behavior in the individual indicates the dangers of broad generalizations concerning the role of learning in courtship and mating. Although, under laboratory conditions, some animals are capable of mating without previous heterosexual experience, there are many species for which this is not true. And even within the same species the two sexes may differ in the completeness of their initial coital performance. Finally, although fertile copulation is possible in some inexperienced animals, it is abundantly clear that the individual's subsequent sexual reactions may be profoundly modified by experience.

PARENTAL AND FILIAL BEHAVIOR

In the following discussion all responses involved in care of the eggs and young are classified as parental behavior. Preparation for egg laying and provision for the welfare of the offspring are arbitrarily treated as parental activities even if the eggs or young are subsequently left to develop without incubation, protection, or feeding. All responses of young animals to the parents or to other adults acting in a parental capacity are listed as filial behavior. Methods of analyzing parental and filial reactions are the same as those employed in the study of courtship and mating. In fact it is worth repeating that this general type of analysis is applicable to any form of behavior.

Functions of Sensory Stimulation

In parental as in sexual behavior we find that certain forms of stimulation lead to relatively long-term physiological changes that in turn make possible adaptive reactions to more specific external correlates.

Stimuli affecting physiological readiness. The crop sacs of pigeons and doves are thin membranous structures at all stages of the life cycle except during the last 8 to 10 days of the incubation period. At this time the two lateral pouches of the crop in both sexes increase as much as twenty times in thickness; and during the succeeding 3 weeks, while the young are being fed, the thickened mucosa is desquamated intermittently in thick layers of caseous "crop milk." Formation of "crop milk" is influenced by exteroceptive stimuli. The cock pigeon with no squabs to feed produces "milk" if he is able to see other adults caring for their young (Witschi, 1935).

In a number of birds and mammals parental reactions appear after a period of exposure to young animals of the same species. It is not unlikely that stimuli afforded by the young evoke physiological changes in the adult that predispose the latter to be-

have in a parental manner. It should be understood, however, that this interpretation is speculative and alternative ones are not lacking. Exteroceptive stimulation may create the physiological conditions necessary to parental behavior in colonial nesting birds that have no young of their own. Newly hatched Adelie penguins are herded into groups and guarded by one or two "nurses" while the rest of the adults search for food which is brought back to the young. Adults that have no offspring of their own are nonetheless stimulated to participate in the communal feeding of fledglings (Bullough, 1942*b*). The eggs of the emperor penguin are laid on the sea ice in the depth of the antarctic winter. Owing to the rigorous climate many eggs fail to hatch, and incubation and care of the surviving eggs and chicks are shared by all adults. A dozen or more birds stand about each egg, taking turns at incubation, and later all adults cooperate in feeding the young (Wilson, 1907).

Virgin rats or mice rarely display parental reactions toward newborn young of their species. However, Leblond and Nelson (1937) found that retrieving and hovering over young can be induced in animals of either sex by exposing the inexperienced individuals to fresh litters for 3 or 4 days. The maternal responsiveness of laboratory rats ordinarily is coextensive with lactation. Milk is produced for approximately 3 weeks, and nest building, retrieving, and protection of young rats tend to die out at the end of this period. Wiesner and Sheard (1933) showed that the female rat's tendency to care for young can be extended long after lactation ceases if she is regularly provided with newborn foster litters. Some rats subjected to this treatment remained "maternal" for 5 months. Apparently an underlying physiological state favorable to maternity can be maintained by appropriate exteroceptive stimulation.

Stimuli controlling oviposition. Females of some species lay their eggs while mating is in progress, and this type of oviposition has

been discussed in connection with sexual behavior. In other oviparous species fertilization is internal, and the eggs are not deposited for some time after copulation. Oviposition reactions of this sort are here classified as parental responses. The distinction is merely one of convenience.

The gravid female's choice of a site for egg laying is obviously influenced by exteroceptive cues. In some cases the stimulus involves only one sensory modality, but more often the behavior pattern is controlled by a series of stimuli mediated by several receptor systems. Flies that normally deposit their eggs in overripe fruit exhibit oviposition movements in response to the chemical stimulus provided by 20 per cent alcohol mixed with 5 per cent acetic acid (Barrows, 1907). These are the concentrations of the two compounds in fermented apple juice.

Some parasitic wasps inject their eggs into the caterpillar of the flour moth, and the first phases of the pattern appear to be evoked exclusively by chemical stimuli. Living caterpillars sealed in glass capsules are not approached, but wasps placed upon a glass plate that has been rubbed with the skin of the caterpillar flex the abdomen and extend the ovipositor in preparation for egg extrusion. Caterpillar models made of clay or wood are disregarded unless smeared with the juice of the normal host, in which case they stimulate preliminary oviposition responses. Larvae of beetles that differ in shape and color from the flour moth caterpillar evoke the same behavior when they have been covered with body fluids from caterpillars. Neither the models nor the beetle larvae are actually parasitized, however, and it is probable that the final act of inserting the ovipositor depends upon tactile cues (Murr, 1930).

Other wasps lay their eggs in the larva of the sawfly while it is still enclosed in a compact cocoon. Chemical stimuli associated with the larva induce orientation responses in the gravid wasp; but after contact is established the female mounts the cocoon

and explores it with her antennae, and tactile stimuli assume primary importance (Russell, 1941). Artificial cocoons with rough edges are rejected in favor of others with more rounded contours. Models that are texturally similar to the sawfly cocoon are selected in preference to others lacking this resemblance. Still another type of stimulus is involved in the first stage of the normal oviposition pattern of this insect. Although it is chemically attractive and possesses appropriate tactile characteristics, a cocoon is not parasitized if it contains advanced wasp grubs from a previous parasitization.

These few examples show that oviposition in insects is not controlled by one simple stimulus or by a single receptor system. Instead it resembles sexual behavior in being a concatenated sequence of reactions, each depending upon different external cues.

The parental reactions of some vertebrates are restricted to depositing the eggs in an appropriate environment. Loggerhead turtles leave their eggs in deep sand nests several yards above the high-tide line. Daniel and Smith (1947) observed that females always select nest sites from which the ocean is clearly visible, even though the choice of a location involves extended detours and wanderings from the point of approach to the beach. Visual stimuli are particularly important at one stage in the life history of the species. Newly hatched turtles emerge from the nest at night and proceed directly to the ocean and out to the deep sea which is their natural habitat. The going to sea depends exclusively upon movement toward the most brightly illuminated region of the horizon. Because the water reflects light from the sky, the seaward segment of the horizon is brighter than any other. But the young turtle's positively phototropic tendencies are brought into play only if the nest site offers a direct view of the ocean.

Effects of the immediate surroundings upon response to the eggs or young. The parental reactions of animals are influenced by many factors in addition to the stimulus pattern

afforded by the eggs or young. The behavior elicited by a given stimulus often depends upon the setting in which it is encountered. The male three-spined stickleback fish builds a nest in which the female deposits her eggs. The spawn is guarded by the male, and if eggs fall out of the nest he replaces them. However, any eggs that the female may deposit outside the nest are not retrieved (Russell, 1944).

Black-headed gulls will retrieve eggs that roll out of the nest. The normal clutch in this species consists of two, but birds roll as many as seven additional eggs into the nest if they are placed only an inch or so away. The strength of the retrieving tendency is inversely related to the distance involved and the number of eggs left in the nest (Kirkman, 1937). Eggs placed 9 to 12 inches away usually are not retrieved as long as some eggs remain in the nest. But if the nest is empty all birds will roll in at least one egg from this distance. Eggs offered at distances of 3 to 4 feet are never retrieved; but if the nest is empty some gulls build a new nest around the displaced eggs. Noble and Lehrman's (1940) field experiments with laughing gulls showed that in this species also the tendency to retrieve displaced eggs is a function of the distance from the nest, the number of eggs displaced, and the number remaining in the nest.

If the nest and eggs of the sooty tern are moved as much as a yard during the bird's absence, the returning parent usually spends some time hovering over the original nest site. It may even alight at the place where the nest was built and execute the customary movements of rearranging the clutch. Appropriate responses eventually are made to the nest and eggs in the new position, but the adjustment takes some time (Watson, 1908).

For the broody laughing gull the eggs, the nest, and the nest site all have stimulus value. Normally these three factors occupy the same position in space, but it is possible to separate them experimentally. According

to Noble and Lehrman (1940) gulls that are given a choice settle upon the eggs in preference to the old nest site or to the empty nest in a new position. When offered the empty nest versus the original nest site, the birds react positively to the site and ignore the displaced nest. Simple field tests of this sort make it clear that under normal circumstances the bird's parental responses are conditioned not only by the sensory qualities of the eggs but by a complex combination of cues associated with the nest and its immediate surroundings. This generalization also applies to reactions toward the young after hatching.

Young cuckoos that are hatched by birds of another species frequently eject the normal young of their foster parents from the nest. The adults do not protect or feed the displaced nestlings even though they fall only an inch or so away from the nest's edge (Russell, 1944). Many songbirds continue to feed their offspring as long as they remain in the nest, and spontaneous departure from the nest does not occur until the young bird is capable of an independent existence. Occasionally, however, an immature fledgling may topple out of the nest, and under such conditions the youngster is ignored and left to die. Only in the nest setting does the young bird possess stimulus value as an object to be fed.

Birds of colonial breeding species such as the arctic tern establish a small territory around the nest, and for several days after the young have hatched the parents will protect and feed them only within the territorial boundaries. Later the parents are able to recognize their own offspring and will feed them wherever they are encountered (Bullough, 1942b). Some birds including the sooty tern viciously attack one of their own young that has wandered out of the nest territory and attempts to return (Watson, 1908).

In all species of doves and pigeons the male and female share responsibility for incubating the clutch. The female sits on the

eggs from late afternoon until the following morning and the male takes her place during the day. If the female dies or disappears the male incubates through the day and spends the night near the eggs, but does not sit on them (Lorenz, 1935). The stimulus value of the nest and eggs varies with time of day and is not simply a function of their sensory qualities. The male will feed his young despite the loss of the female, and in such circumstances the behavior of the nestlings presumably affords a more intense and compelling stimulus to parental behavior.

Stimuli afforded by the eggs, the young, or the parent. The parental responses of animals that feed and protect their offspring depends heavily upon the behavior of the young themselves. It is, therefore, appropriate to examine simultaneously the sensory bases for filial and parental reactions.

FISHES. Mated pairs of jewel fish cooperate in protecting and "fanning" the eggs, and both parents continue to guard the fry after hatching. The young remain close to the adults for a week or more, and Noble and Curtis (1939) showed that this tendency is dependent upon the reddish color and general movement of the parents.

Young jewel fish were placed in the central tank of the apparatus illustrated in Fig. 7. Circular metal disks in the adjacent aquaria could be moved back and forth mechanically. Colored disks 1 inch in diameter had no effect upon behavior. A bright-red 2-inch disk was promptly approached by the young fish, whereas black or blue disks of the same size were avoided or ignored. Regardless of its shape any moving red object within a certain size range served as a positive stimulus. Motionless disks and those without red coloration were ineffective.

Recently hatched young of some species of African mouthbreeders swim into the mouth of the parent in response to sudden and intense stimulation. Peters (1937) found that this reaction is guided by relatively simple visual cues. Young mouthbreeders

readily approach crude models of an adult, orienting to the position of the dummy's eyes and attempting to swim into it at the normal location of the mouth.

REPTILES. Female lizards of some species incubate their eggs and retrieve any that are

The female's initial response to a displaced egg is to touch it lightly with the tip of the tongue. Lizards and some other reptiles possess a chemoreceptor known as Jacobsen's organ. It is situated in the roof of the mouth, and odoriferous particles are depos-

FIG. 7. Apparatus used to test responses of young jewel fish to moving objects of different colors. The experimental animals are placed in the center tank, and metal disks suspended in the smaller aquaria move back and forth mechanically. The offspring of red parents swim toward moving red disks and avoid blue or black ones. Young of black species approach black or dark blue disks but not those painted red. The strength of these tendencies is altered in young fish that are reared by foster parents of a foreign species. (Redrawn from Noble and Curtis, 1939.)

displaced from the nest. The blue-tailed skink reacts differentially toward her own eggs as compared with similar stimulus objects. She does not retrieve or incubate eggs of closely related genera that closely resemble her own in size and shape (Noble and Mason, 1933). Paraffin models of eggs are rejected as are the female's own eggs that have been covered with shellac. Egg identification does not depend upon vision, for blindfolded lizards readily retrieve their own eggs and discriminate against models or eggs of other species.

ited upon this organ by the tip of the tongue as it flicks in and out of the mouth. The lizard's reaction to different kinds of eggs apparently depends upon chemical stimulation of Jacobsen's organ, for removal of the tip of the tongue eliminates retrieving.

BIRDS. In most avian species the retrieving and brooding of eggs depend primarily upon visual and tactile stimuli. Some birds are influenced chiefly by one form of stimulation, and some by another. Kirkman (1937) observed that black-headed gulls continued to sit upon their own eggs painted a

variety of bright colors. Eggs of other species, wooden models, or balls were incubated as readily as normal eggs. Artificial eggs with sharp contours were not brooded. The effective stimulus to incubation in this species can be of any color, or any material, and can possess any odor. The shape is immaterial as long as the contours are rounded. Any suitably shaped object will be brooded if it is small enough to sit on and large enough so that it does not sink into the material of the nest. Other birds such as the graylag goose are so sensitive to irregularities in the shape of the egg that they will not roll into the nest their own eggs that have a small lump of putty on one side (Lorenz and Tinbergen, 1938).

Certain visual characteristics of the eggs may be especially important in controlling parental reactions. Ringed plovers will accept and brood spotted eggs of a variety of colors, but unspotted ones are deserted or ejected from the nest (Koehler and Zagarus, 1937). Color rather than pattern is the essential visual stimulus in other species. Marples and Marples (1934) noted that sea swallows were slow to brood their own eggs that had been painted red or blue. Some females eventually sat on the eggs, but many never resumed incubation.

Broody female laughing gulls will sit upon their own eggs that have been dotted with spots of blue, red, or yellow, but there is usually a long delay before the bird accepts the altered eggs (Noble and Lehrman, 1940). Blue and yellow are less disturbing than red, and some females push red-spotted eggs out of the nest. These negative responses are not due to alteration in the visual pattern of the egg, for females readily incubate eggs of another gull even though the spatial distribution of chromatic material on the shell is highly variable from one clutch to another. Eggs that are entirely covered with paint are not accepted by the gull even if the painted pattern is identical to the normal one. Chemical cues may be involved in this discrimination.

According to Noble and Lehrman (1940), when the eggs of the laughing gull are colored artificially it interferes with retrieving more than with brooding, and displaced eggs marked with spots of color are frequently left outside the nest. This observation agrees with our earlier conclusion that the bird's parental responses are conditioned in part by the immediate surroundings of the stimulus object. Colored eggs outside the nest are inadequate stimuli, whereas the same eggs in the nest may evoke parental behavior. The general setting of the nest adds to the stimulus value of the abnormal eggs and renders them acceptable as objects to be brooded.

The importance of tactile stimuli in the gull's brooding behavior is revealed by the fact that eggs to which bits of grass are attached by rubber cement are incubated briefly and then deserted.

Interaction between parent birds and recently hatched young usually consists of a sequence in which a particular activity on the part of the adult calls forth a specific response by the young which in turn elicits the next reaction by the parent. Young birds that remain in the nest after hatching exhibit a gaping response which stimulates the parent to place food in the nestling's mouth. Very young blackbirds gape in response to tactile stimulation produced by jarring the nest. Normally this stimulus occurs when the returning parent alights on a nearby branch or on the edge of the nest. About 10 days after hatching, the blackbird's eyes open, and thenceforth the gaping response is elicited by visual rather than tactile stimuli. Crude silhouettes of a bird head evoke gaping when they are raised above the edge of the nest (Tinbergen and Kuenen, 1939).

Flickers nest in holes in trees or posts, and in the young of this species gaping is stimulated by a sudden darkening of the nest, which normally occurs when the adult blocks the opening of the nest hole. Artificial closure of the opening evokes gaping even though no vibratory or auditory stimuli ac-

company the visual change (Lehrman and Stephenson, 1940).

Feeding behavior shown by the parent in response to gaping and begging young is controlled in some instances by visual stimuli. In nestlings of many species the roof of the mouth is marked with special structures or bright colors, and Tinbergen (1942) has suggested that these visual signs elicit the adult's feeding reaction. In other cases auditory cues provided by the vocalizations of the young birds are important. Young flickers utter a special note while they are gaping, and it seems probable that this facilitates the parent's attempts to deliver food in the relatively dim surroundings of the nest hole.

Precocial birds like the duck or chicken are not fed by the mother, but they often find edible objects by following her or coming when she utters the special call associated with the discovery of food. Females of the same species respond to young ones on the basis of visual or auditory stimulation. Audition is of major importance for chickens. Katz (1937) tied chicks to stakes in locations outside the hen's visual field. When the little birds uttered the "fright chirp," the female became very active and continued to run about until she located the young ones. The hens frequently attacked the string and the stake as they would a living enemy. Chicks confined in glass containers struggled against the vessels but were ignored by hens that could see but not hear them.

Audition and vision are jointly involved in the maternal behavior of some precocial birds. Muscovy and mallard ducklings are quite different in physical appearance, but they utter similar "fright calls" when attacked. The muscovy female with a brood of her own will run toward any mallard duckling that gives this call, but when she comes close enough to see the typical mallard head markings the female attacks the strange individual (Lorenz, 1935).

MAMMALS. Naturalistic observations suggest that the parental and filial behavior of mammals is controlled by a combination of

sensory cues, that various modalities may be dominant in different species, and that different kinds of stimulation influence separate elements in the total pattern. Experimental investigations of this problem are meager and incomplete.

It is clear that lactating females of many mammalian species discriminate between their own offspring and other young ones of the same age, but the sensory basis for this selective responsiveness is known in only a few instances. Just before parturition the ewe tends to react in maternal fashion to any newborn lamb in her vicinity, but after giving birth she restricts her attentions to the individual she has delivered and rejects others of the same age group (Fraser, 1937). Auditory stimulation is one of the factors involved in this discrimination, for the lactating sheep reacts specifically to the bleating of her own offspring and disregards the vocalizations of other lambs (Scott, 1945).

Comparable maternal behavior is displayed by fur seals and elephant seals according to the reports of Preble (1923), Bonnot (1929), and Hamilton (1934). Cows leave the rookery to enter the ocean and feed, and upon returning the female hesitates on the periphery of the herd and bellows loudly. After a short delay she rushes directly to her own young one, paying no attention to the hundreds or thousands of pups belonging to other cows. If any pup except her own attempts to suckle the female, she vigorously repels it and may toss the strange young one several feet away. Not all species of seals are equally discriminating, for lactating African cape seals readily nurse an orphan pup (Shortridge, 1934).

Young mammals of many species are able to identify their own mothers. Scott (1945) believes that the necessary learning occurs very rapidly in domestic sheep, since the lamb's discriminatory reactions appear within a few days after birth. The wild lamb remains very close to its mother for 2 weeks after birth. Later it may wander about, but it runs to the ewe when she utters a

special call. Among the Dall sheep of Alaska, lambs are herded into groups and guarded by one or two ewes while the remainder of the adults graze. Murie (1944) noted that returning ewes begin to bleat when they are within 100 yards of the lamb flock. Hungry lambs respond to this stimulus by leaving the flock and running directly to their mothers. Each young one reacts exclusively to the voice of its own parent.

The responses of female rodents to their young involve several types of stimulation. Audition contributes to parental behavior in meadow mice and rice rats. Bailey (1924) and Svihal (1931) noted that young of these species that have fallen out of the nest utter a series of shrill squeaks. In response to this stimulus the female becomes highly active and continues to search until the pup is found and returned to the nest. Young Norway rats squeal in response to painful stimulation, and this sound elicits marked agitation and hyperactivity in the lactating female.

Female cotton rats bred in the laboratory can be induced to adopt and rear offspring of the Norway rat (Meyer and Meyer, 1944). This indicates that the stimuli to maternal behavior are not always species-specific. Lactating albino rats will sometimes nurse young mice (Shadle, 1945), and under certain conditions they may retrieve young rabbits to their nests (Wiesner and Sheard, 1933).

However, the writer has noted marked differences between female rats of the same strain. Some parturient individuals do retrieve baby rabbits, but other nursing rats invariably attack and kill them. A few domestic rats retrieve their young that have been sprinkled with oil of lavender, but others reject a pup that has this pungent and foreign odor. Some females display a consistent tendency to retrieve their own young and to ignore foster pups of the same age, but other females persistently steal the litters of other mothers inhabiting the same cage.

It is obvious that the sensory cues responsible for parental and filial behavior are poorly understood and that systematic studies of the problem are needed. Present evidence makes it clear that species and individual differences are often pronounced, that several forms of stimulation are usually involved, and that the entire situation is further complicated by the fact that learning enters the picture at a very early stage.

Some slight insight into the sensory basis for parental reactions is afforded by studies of the nervous mechanisms mediating such behavior.

Studies of the Nervous System

There have been very few experimental studies of the neural correlates of parental behavior and no investigations of the nervous basis for filial responses.

Fishes. Noble (1939) states that the removal of all the forebrain in the male jewel fish eliminates any tendency to care for the eggs or young. Partial decerebration is followed by disruption of the pattern and usually by loss of one or more of the separate responses constituting it. The number of behavioral elements eliminated depends principally upon the amount of brain tissue removed and is independent of the locus of injury within the forebrain. Female jewel fish with small bilateral forebrain lesions court and mate normally, but instead of permitting their mate to help care for the eggs and the young the brain-operated females drive the male away as they would any stranger. The survival of sexual responses in these individuals is important. The tendency for the female's parental performance to deteriorate as a result of cerebral lesions that do not interfere with mating is found in several vertebrate classes.

It was noted earlier that decerebrate male African mouthbreeder fish do not pick up the fertilized eggs and incubate them in the mouth as do normal individuals of this species (Aronson, 1948).

Birds. Decerebrate hen pigeons may mate and lay fertile eggs but will not brood them (Schrader, 1889), another illustration of the relative importance of forebrain mechanisms in sexual and maternal reactions. Ceni's (1938) experiments with several species of birds convinced him that the "frontal pole" of the brain contains a center essential to maternal behavior. According to Rogers (1922) male and female pigeons with lesions in the corpus striatum show various deficiencies in the care of squabs. The details of the deficit are not described, but Rogers states that certain reactions are dependent upon localized mechanisms within the forebrain.

Mammals. Golz (1874) described a bitch that showed normal gestation and maternal care of the litter despite complete section of the lumbar cord. And Ranson (1934) found that female cats with "large bilaterally symmetrical lesions in the tuber, lateral to or behind the infundibulum," give birth to normal litters and suckle their young.

The only systematic studies of nervous functions in mammalian maternal behavior have dealt with the laboratory rat. Wiesner and Sheard (1933) reported that anosmic and deaf female rats continue to retrieve young to the nest. Unpublished experiments by the present writer showed that nest building, cleaning of the newborn young, and retrieving responses survive in primiparous females despite enucleation of the eyes, removal of the olfactory bulbs, or section of the sensory nerves to the snout and lips. The combination of any two of these operations greatly interfered with the female's maternal behavior without eliminating any essential reactions, but rats suffering interruption of all three afferent pathways were unable to retrieve or care for their pups.

Furthermore animals deprived of any one sensory receptor were slower and less accurate than normal females in their maternal responses. A few females that consistently discriminated between their own young and the offspring of other mothers lost this ability

after destruction of the olfactory bulbs. It appears that several sensory modalities contribute to maternal efficiency in the rat, although no one receptor system is essential.

Davis (1939) found that female rats deprived of the cerebral cortex were unable to rear their litters. Unilateral hemidecortication did not have this effect, but no special tests were conducted, and the operated animals were permitted to raise their offspring under conditions that demanded a minimum of adaptability. Stone's (1938) studies of maternal reactions in partially decorticated rats indicate that large lesions may produce quantitative reduction in the female's performance without preventing the survival of the litter.

Beach (1937) reported that several elements in the rat's maternal pattern are affected by cerebral injury. Normal females start to build a nest several days before parturition, but animals with cortical lesions tend to delay until just before the litter is born, and if the brain injury is sufficiently extensive there is no nest building at any time. Removal of more than 30 per cent of the cortex decreases the female's tendency to collect her young into the nest and to clean them as they are born. When the litter is scattered about the cage, the normal mother begins at once to return her pups to the nest and completes this task in a relatively short time. Cortically operated rats are slower to begin retrieving, wait longer between trips from the nest, and tend to stop before all the young have been gathered (Fig. 8).

Females with cortical lesions are less efficient than unoperated animals in moving their nests from under an air blast or electric heater. The type and severity of behavioral loss bear little relation to the site of the lesion within the cortex, but in general there is a positive relation between the amount of brain tissue removed and the extent of deterioration of the maternal pattern.

All three studies of maternal behavior in rats sustaining cerebral injury show that ex-

tensive brain loss seriously interferes with the female's ability to care for her young, although it does not prevent her from mating and becoming pregnant. Male rats with similar lesions do not mate. The maternal reactions of female rats and the sexual responses of males are comparable in several ways. First, maternal females and sexually

Studies of Blood Chemistry

The parental and filial responses of some invertebrate and many vertebrate species are modified by certain changes in the chemical constitution of the blood.

Diet and drugs. The need for nourishment tends to intensify the young animal's positive reactions to its parents. Gaping re-

FIG. 8. Records of retrieving behavior in normal and cortically operated female rats. The numbers on the curves show the per cent of cortex removed. The litter is scattered by the experimenter, and the female retrieves the pups to the nest, one at a time. Speed and completeness of retrieving behavior decrease with increasing size of cortical lesion. (Redrawn from Beach, 1937.)

active males are required to take the initiative in responding to another animal. This is not true of the female's estrous behavior. Second, their performance depends upon a combination of sensory cues involving several modalities. The female's coital pattern depends primarily upon sensations of touch and pressure. Third, maternal responses and masculine mating reactions are less dependent upon specific hormonal secretions than is the feminine sexual pattern. Finally, both types of behavior are dependent upon cortical mechanisms, whereas estrous reactions are not.

responses of nestling birds depend upon the time elapsed since the last feeding. Recently fed fledglings do not gape; but when the preceding meal has been digested the response reappears and grows increasingly vigorous until the young one is fed again. Seward (1940) found that satiated infant guinea pigs will cross a barrier that separates them from the mother, but unfed babies surmount the barrier more rapidly than nonhungry ones.

Special physiological demands of pregnancy often produce spontaneous changes in the diet selected by female mammals. Martins (cited by Riess, 1948) found that preg-

nant guinea pigs display a preference for meat, although nonpregnant females choose vegetable foods. Domestic and wild ungulates are herbivorous, but pregnant females frequently masticate old, dry bones which presumably augment the calcium content of the diet. Richter (1938) maintained female rats on a self-selection diet from 1 month before pregnancy until lactation was completed. The daily caloric intake rose from 45.3 to 59.8 in the course of gestation, and to 118.3 at the end of the lactation period. Protein consumption increased during gestation, and the amount of fat ingested rose during pregnancy and lactation. The appetite for sodium chloride, calcium lactate, and dibasic sodium phosphate increased. There was no significant change in the intake of wheat germ oil, cod-liver oil, potassium chloride, or carbohydrates.

Manganese deficiency in the diet of parturient rats interferes with lactation, interrupts nursing, and sometimes causes females to eat their litters. Diets containing excessive amounts of vitamin B have the same effect. An oversupply of vitamin B combined with excessive manganese does not affect lactation or maternal behavior. Perla and Sandberg (1939) who reported these results suggest that under normal conditions manganese acts as an oxydative catalyst in the utilization of the vitamin. The toxic effects of too much vitamin B are neutralized by increasing the amount of manganese, and in the absence of manganese normal amounts of the vitamin are not neutralized and therefore exert their harmful effects on behavior.

Poisons introduced into the mother may affect her reaction to the young. Rats given a diet containing lead tend to destroy their litters toward the end of the lactation period (Dalldorf and Williams, 1945).

Hormones. We noted earlier that the sexual responses of insects do not depend upon gonadal hormones. There is no direct proof that the female's maternal behavior depends upon hormones, but the response to certain

stimuli is a function of conditions in the reproductive organs, and this suggests some form of hormonal control.

INSECTS AND SPIDERS. The cabbage butterfly lays its eggs on the green leaves or stems of plants, and gravid females will alight upon objects that are emerald green to greenish blue and execute the characteristic "drumming reaction" associated with oviposition. Infertile females show no response to green but readily approach red, yellow, blue, and violet stimuli. The latter hues are normally associated with flowers on which the insect feeds, and they evoke no reactions on the part of females that are ready to lay eggs (Isle, 1937). Just before oviposition the female hawk moth responds positively to green and to the odor of etheric oil of Galium. This combination of visual and chemical stimuli occurs normally in the plants on which the species deposits its eggs. The same combination does not attract males or nongravid females (Bodenheimer, 1938).

Savory (1936) noted that the behavior of the wolf spider toward its cocoon is a function of the presence or absence of ripe eggs in the ovaries. For approximately 5 weeks the female carries her cocoon with its embedded eggs; then the young emerge and are carried upon the mother's back for another week. Two weeks later a second cocoon is produced, and the cycle recurs. The readiness with which a female will seize and carry a cotton pledget or her own cocoon after it has been taken away from her varies inversely with the time elapsed since the last eggs were produced. The implied relation between ovarian condition and parental responsiveness is similar to the gradual waning of the retrieving behavior in mammals, which is discussed below.

FISHES. Noble, Kumpf, and Billings (1938) found that female jewel fish that have not mated or spawned will care for foster eggs after treatment with progesterone (from the ovaries) or prolactin (from the anterior pituitary). Thyroid extract and phenol produce similar results, but the be-

havior is less complete and intense. The pre-oviposition nest building of some fishes depends upon a gonadal hormone that transforms part of the kidney into a mucous-producing organ that aids in nidification (Cohen, 1942).

AMPHIBIANS AND REPTILES. Female salamanders treated with fresh pituitary substance at times other than the normal breeding season extrude their eggs and attach them to the underside of stones in the characteristic manner (Noble and Richards, 1932). Comparable results have been obtained by Barden and Kezer (1944) with other salamandrian species.

The spiny swift lizard normally lays its eggs during the spring and early summer, but Evans (1946) induced this behavior in the winter by the administration of sheep or frog pituitaries.

BIRDS. Prolactin from the anterior pituitary stimulates parental responses in various avian species, and gonadal hormones tend to inhibit such behavior. The ovaries of the broody hen are relatively inactive, and she does not produce eggs. Conversely, the active secretion of ovarian hormones reduces or eliminates the tendency to care for chicks. Ceni (1927) observed the persistence of parental reactions in ovariectomized fowl and was able to inhibit this behavior by implanting a functional ovary. Actively laying hens injected with prolactin cease producing eggs and begin to show maternal responses (Riddle, Bates, and Lahr, 1935). Virgin pigeons treated with this substance produce crop milk and incubate foster eggs (Riddle, 1935). The effect is not specific, however, for unmated pigeons of either sex will incubate eggs and feed squabs after treatment with progesterone or adrenocortical hormone (Riddle et al., 1942-43).

Androgen inhibits parental responses in male birds of some species and facilitates the same reactions in others. Castration is followed by the appearance of broodiness and care of the chicks in brown leghorn males (Goodale, 1918). Roosters implanted with

ovarian tissue (Ceni, 1927) or injected with prolactin (Nalvandov, 1945) display parental responses toward young chicks. These results may be due to a depression of androgen production by the testis or to some more direct effect of the implanted or injected material.

Males of many avian species normally care for the brood, and in such cases testicular hormone can scarcely be classified as "anti-parental." Male pigeons are as active as females in the incubation and feeding of the young. Rowan (1931) has noted that the male bobolink helps the female build a nest and care for the nestlings when the testes are maximally developed. Later in the season the gonads regress and the bird shows no interest in nesting material, eggs, or fledglings. Additional evidence that testicular hormone facilitates paternal behavior in some birds is found in the report of Noble and Wurm (1940) to the effect that black-crowned night herons become broody after treatment with testosterone propionate.

MAMMALS. There is a clear-cut relation between rhythms of glandular activity and cycles of parental behavior in many mammals. Furthermore it is possible in some cases to produce maternal responses in males and virgin females by the administration of hormones. However, the effects of exteroceptive stimulation are so powerful that in certain instances they appear to elicit parental behavior without any demonstrable hormonal change.

Shortly before parturition the lion pulls out the fur surrounding the nipples, and the same reaction is seen in pseudopregnant females whose hormonal condition resembles that of the pregnant individual (Cooper, 1942). Rabbits that are about to give birth exhibit similar behavior, and Tietz (1933) induced it in nonpregnant females by injecting gonadotrophic hormone. Under normal conditions these reactions probably depend upon estrogen, which is present in large amounts during pregnancy, or upon gonadotrophins secreted by the placenta. Tietz's

results do not permit a choice between these alternatives, since injections of gonadotrophin evoke an increase in estrogen secretion by the ovaries.

Kunde et al. (1930) produced copious lactation and maternal behavior in nonpregnant bitches by the administration of estrin. One experimental female suckled and reared a foster litter. These results are difficult to reconcile with other findings.

In the first place, the secretion of estrogen decreases abruptly after parturition and remains minimal throughout lactation. Maternal responses, which are maximal at this time, would not be expected to depend upon estrogen. Second, although estrogen stimulates the growth of the mammary glands, the actual production of milk depends upon hormones from the pituitary, the adrenal cortex, the thyroid, and probably other glands as well. Finally, estrogen evokes complete heat behavior in spayed or intact dogs, and under normal conditions sexual and maternal patterns of behavior do not occur concurrently. The estrous bitch is not maternal, and the lactating one is not receptive. The most likely explanation for the appearance of parental responses in estrin-treated dogs is that the extract contained impurities that stimulated the pituitary to secrete hormones capable of supporting lactation and the associated behavior.

It is known that estrogen depresses maternal behavior in some mammals. Hain (1942) injected this hormone into lactating rats and found that, although lactation continued, nursing and retrieving disappeared after 5 days of treatment, and the litters died. Confirmatory results have been reported by Weichert and Kerrigan (1942).

Experiments dealing with the role of pituitary hormones in maternal behavior of mammals have yielded conflicting results. According to Wiesner and Sheard (1933), virgin rats display retrieving responses after receiving injections of anterior pituitary extracts; and Riddle, Bates, and Lahr (1935) found that the administration of prolactin

from the pituitary induced nest building, retrieving, and "cuddling" of newborn young in approximately 60 per cent of the virgin rats in their colony. However, Leblond and Nelson (1937) removed the pituitary from lactating mice and found that maternal behavior survived although lactation ceased. And hypophysectomy is reported to induce maternal reactions in some virgin rats (Riddle et al., 1941-42). It is probable that prolactin normally contributes but is not essential to maternal behavior. Estrogen exerts an inhibiting effect in most species. Progesterone probably is involved in prepartum activities but not in parental behavior after the arrival of the young.

Maternal behavior changes as the lactation period progresses. Seward and Seward (1940) tested the female guinea pig's willingness to climb over a barrier that separated her from her young, and found that the strength of the tendency declines progressively in the first 3 weeks after parturition. Control experiments showed that the behavior does not depend upon decreasing amounts of milk in the mammary glands, nor upon increasing size of the young. It was concluded that a gradual change in hormonal activity is responsible for the decline in maternal responsiveness. Wiesner and Sheard (1933) described a comparable reduction in the tendency of female rats to retrieve young ones. They also showed that during the latter stages of the lactation period the stimulus value of a rat pup depends upon its age. Shortly after parturition females will retrieve young ones of any age; but toward the end of the lactation they carry to the nest only the small, hairless pups and disregard older animals that would have been retrieved earlier in the nursing period. The essential characteristics of the adequate stimulus for retrieving behavior are thus seen to vary according to the physiological condition of the responding individual.

During the final stages of lactation the bitch disorges before her litter part of the

food she has eaten. This behavior continues for several days after lactation has ceased and helps the puppies make the transition to a solid diet. Females usually disgorge within 15 minutes after returning to the nest, but if the pups are removed the bitch will retain the ingested food for three-quarters of an hour and then promptly disgorge it when allowed access to her litter. The reaction is not given in response to toy dogs or to kittens. Martins (1949), who recorded these findings, considers the behavior to be hormonally controlled.

Endocrine secretions characteristic of late pregnancy and the period of lactation undoubtedly contribute to maternal responsiveness in many mammals; but they cannot be regarded as indispensable in every instance. In some species parental behavior is normally exhibited by individuals that are neither pregnant nor lactating. It is possible that these reactions are hormonally conditioned, but there is as yet no support for any such interpretation. Male mice of several species regularly assist the female in cleaning and protecting the litter (Blair, 1941; Horner, 1947), and field studies of chimpanzees suggest that adults other than the parents sometimes protect and care for immature members of the band (Nissen, 1931). Murie's (1944) careful observations of feral wolves show that care of the pups may be shared by several adults. Unmated females are particularly solicitous of another's litter and often remain with the young when the mother joins in the pack's nocturnal hunt. After the pups are weaned they eat food brought to the den by all members of the pack.

Development in the Individual and Modification by Experience

Parental behavior involves many responses, some of which also occur in conjunction with other patterns of reaction. A few elements in the parental complex, such as the delivery and cleaning of young, do not appear in any other context. The de-

velopment and modification of both types of response have been studied by several investigators. The ontogenesis of filial reactions has been described in some fishes, birds, and mammals.

Parental behavior. Egg-laying behavior that does not occur during mating has been arbitrarily classified as a parental response, and the initial step in this pattern is the selection of the oviposition site. Some insects invariably leave their eggs on certain kinds of plants or insert them into the bodies of living hosts of a particular species. The gravid female's positive response to a given type of plant or animal depends in part upon previous events in her own life history.

In England there are two races of the moth, *Hyponometa padella*, which lay their eggs upon different hosts. One oviposits upon hackberry hedges, and the other upon apple trees. Thorpe (cited in Imms, 1931) showed that females of the apple race, given a choice of oviposition sites, laid 90.2 per cent of their eggs upon apple and only 9.8 per cent on hackberry. Larvae of the apple race were then transferred to hackberry upon which they grew and developed normally. When the experimental larvae became adult females their preference for oviposition sites was measured, and they laid 30.8 per cent of their eggs on hackberry. In comparison with the behavior of the parent generation this represents a 21 per cent decrease in the strength of the original preference.

Summarizing a large number of similar studies upon different insect species, Imms (1931) offered the following tentative interpretation:

The repetition of the habit of specific host-preference appears to be explainable as the result of a chemical influence, derived from the food-plant, acting upon each successive generation. Specific host-preference and its repetition in each generation seems to afford an analogy with what Pavlov has termed a conditioned reflex. The conditioning takes place during the developmental cycle of the insect and influences the chemotropic responses of the female during oviposition.

The analogy to Pavlovian conditioning is questionable, but the effect of environmental conditions during development upon parental responses in adulthood is well established.

Parental behavior normally appears in some birds before the attainment of reproductive maturity. Watson (1908) described the carrying of nesting material by noddy terns 16 days after hatching, and Craig (1909) observed a 21-day-old ringdove that became broody and incubated eggs laid by its parents. According to White (1941) it is common for young swallows of the season's first brood to help feed those of the second.

The maternal behavior of some mammals includes nest building, but this type of activity is not confined to the pregnant or lactating female. Under appropriate environmental conditions it occurs in males and in immature animals. Wood rats bred in captivity begin random transportation of small objects at about 30 days of age, long before they are sexually mature. Bits of nesting material are collected and nests are begun although they are rarely completed (Richardson, 1943). Juvenile domestic rats of both sexes display some nest building shortly after they are weaned (Kinder, 1927).

It might be supposed that the primiparous female's ability to build an adequate nest depends upon practice gained earlier in life. Against this conclusion is the observation that inexperienced rats build serviceable nests even though they have been reared in cages containing no nesting material (Beach, 1937). However, these animals have been able to carry food pellets and wood shavings about the cage, and this sort of experience might conceivably contribute to nest building at a later date. In an exploratory experiment Riess (1948) reared female rats in an environment containing nothing that could be picked up or transported. When these animals delivered their first litters they failed to build nests although appropriate material was available. This study was repeated with a second group of animals

(Riess, personal communication) reared in complete isolation from other rats and under conditions that prevented carrying responses. They showed some nesting behavior at parturition, but the paper strips were heaped loosely over the litter, and afforded relatively little protection for the young. More significantly, the females made no attempt to suckle their offspring but treated them as though they were strips of paper or inanimate objects to be carried and manipulated. This type of behavior is typical of the male rat, and indeed the experimentally isolated females were no more "maternal" than the normal male. Confirmation of these preliminary findings is needed, but the results emphasize the necessity for rigorous control in any study of the effects of experience upon a given behavior pattern.

Wiesner and Sheard (1933) were unable to detect any difference between the parturitional behavior of primiparous and multiparous rats. Beach (1937) also noted that female rats clean their first litter effectively and care for the young throughout lactation. Birch (cited in Riess, 1948) reared rats under conditions that prevented self-grooming. Each animal was fitted with a large shield that encircled the neck and made it impossible for the rat to reach any part of the body with its mouth. The shields were removed during the last stages of pregnancy, but when the young were born the females failed to clean them. Additional data are desirable on this point, but the potential value of the method is evident.

The female's tendency to clean and suckle her young appears in some cases to improve after the first parturition. Freud and Uylert (1948) induced lactation in nonpregnant rats by hormonal treatment. They found that females that had previously delivered and cared for litters would adopt and nurse foster young, whereas lactating rats without any maternal experience would not permit young ones to suckle. Cooper (1942) re-

ports that infanticide is more common in primiparous than multiparous lionesses.

Inexperienced chimpanzees often show marked deficiencies in their maternal responses. The multiparous ape supports the head of the baby during birth and picks the infant up immediately after delivery. A great deal of time is spent licking up the fetal fluids and chewing the afterbirth. If the baby cries, the experienced mother attempts to quiet it. Some primiparous chimpanzees appear puzzled by the presence of the infant and treat it as they would any unfamiliar object. Curiosity is evinced, but the resultant behavior is not appropriate. A few inexperienced chimpanzees observed in captivity have shown intense emotional disturbance during parturition and have immediately and permanently rejected their offspring (Yerkes and Elder, 1936; Budd, Smith, and Shelley, 1943). Total avoidance or completely inadequate care occurs as far as is known only in the case of the first delivery. And it remains to be discovered whether similar deficiencies ever appear under natural life conditions.

The female animal's tendency to suckle and protect her young may be inhibited by emotionally disturbing experiences. Pallen (1944) has described the cessation of lactation and the killing of kits that occurred when female minks were frightened by aircraft flying close to their pens. According to Petersen (1944) dairy cattle with well-filled udders display inhibition of milk release in response to noxious stimulation. The inhibition can be conditioned to a variety of normally innocuous stimuli.

Naturalistic descriptions of maternal responses in sheep and seals that react discriminatively to their own offspring indicate the importance of learning in parental behavior although the process has not yet been analyzed.

Filial behavior. The tendency of young birds and mammals of many species to react selectively to their own parents rests in part upon the effects of early experience. We

have described the findings of Noble and Curtis (1939) to the effect that recently hatched jewel fish respond positively to their parents and that this behavior depends to a large extent upon the red coloration of the broody adult.

Young jewel fish hatched and reared without parental contact were tested in the apparatus illustrated in Fig. 7. They displayed a clear-cut discrimination in favor of red as compared with black stimulus disks; but the preference was less marked than in young reared by adults, and it was concluded that the fry inherit a tendency to approach moving red objects which under normal conditions is strengthened by association with the parents.

A related species of fish assumes bluish-black body colors when brooding young, and offspring of this species placed in the experimental tank moved to a dark blue disk and away from a red one. Eggs laid by black-colored adults were given to broody pairs of the red-colored species, and the foster parents accepted and reared the young. When the fry were tested for color preference they were found to move toward a red disk and to avoid the dark-blue one. Apparently the coloration of the adults with whom these young fish associate during the first week after hatching influences their color preference and determines the type of adult to which they will respond. Species differences were apparent in the results of this study. Young born of red-colored parents and reared by the black species did not develop a positive response to black or dark blue although the strength of the reaction to red was materially reduced.

Young birds of some precocial species are able within a few days after hatching to discriminate between their own mothers and other adult females. Learning is undoubtedly involved, but the process has never been analyzed. Bruckner (1933) artificially altered the physical appearance of the hen and discovered that this interfered with the chick's ability to recognize its mother. Vision

is not essential, however, for, when two broods of chicks were mixed and placed in total darkness with the hens, all young birds were found grouped under the proper female 2 hours later.

To account for the reactions of young animals to the parents and others of the same species Lorenz (1935) advanced the concept of "imprinting." The process is described as depending upon experience but differing from what is ordinarily called learning in that it occurs very rapidly and is "irreversible." To support his theory Lorenz cites many simple experiments, most of which he conducted.

Jackdaws reared by hand responded to human beings as they would to their own parents, and in adulthood these birds oriented their sexual display to men rather than to other jackdaws. Geese hatched in an incubator and reared by Lorenz followed him about as goslings normally follow the goose, reacted to his call, and were unresponsive to adult geese. A muscovy duckling reared by a gray goose was removed from the foster family at the age of 7 weeks and placed with birds of its own kind. The following year when mating reactions appeared they were directed toward the species of the foster parents. Many psychologists would classify such behavior as a product of learning, but regardless of interpretation the evidence suggests that early filial associations may exert lasting effects upon animal conduct.

Experimenters and naturalists who do not belong to the Lorenzian school have reported data that harmonize with its major tenets. Hudson (1892) recorded the fact that young rhea birds will adopt a man as a foster parent, and when the human being imitates the loud warning call of the adult rhea the young bird rushes to him and squats at his feet. The infancy of many ungulates affords excellent opportunity for conditioning to the mother. When she is about to drop her calf the caribou cow leaves the main herd, and mother and offspring remain in se-

clusion for several days (Murie, 1944). The calf is able to walk within an hour after birth, and it maintains close contact with the female at all times. Under these conditions the calf can form associations with one female before it comes in contact with other adults, and when the pair rejoins the herd the young one responds only to its mother.

Scott (1945) concluded that the domestic lamb's tendency to remain close to its mother depends upon early reinforcement in the form of food and protection. After weaning, the response is generalized to include other sheep, and strong habits of gregariousness are thereby built up. Lambs isolated from other sheep during infancy and reared on a bottle develop a tendency to follow human beings, and when they are returned to the flock these individuals are less gregarious than animals reared by the ewe. Lambs of mountain sheep captured shortly after birth and reared by men do not join their wild relatives when the opportunity is presented, but instead they show a preference for following human beings (Murie, 1944).

Mammals that are less gregarious than sheep may show atypical behavior if deprived of normal species associations in infancy. According to Cooper (1942) lion cubs raised by hand are tamer than those suckled by the female. They do not snarl so often as normal cubs; they fail to exhibit nursing reactions directed toward the bodies of other cubs; and they tend to play with inanimate objects in their pens instead of with littermates. Levy (1934) found that when puppies reared on a bottle were returned to the bitch they were not so expert as their normal siblings in finding the teat.

Descriptions of mother-infant relations in monkeys (Tinklepaugh and Hartman, 1940) and chimpanzees (Yerkes and Tomlin, 1935) leave no doubt as to the importance of learning in the filial responses of immature primates. The infant learns to obey gestures

and vocal communications given by the mother and derives considerable advantage from her tuition and guidance.

CONCLUSIONS

In restricting our attention to studies of reproductive behavior we have been compelled to neglect many other types of activity that are usually classified as instinctive. But the fact is that very few instinctive patterns have been subjected to experimental analysis. Most of the literature in this field consists of simple description combined with speculative interpretation.

Evidence marshaled in this chapter raises some question concerning the legitimacy of classifying reproductive reactions under the heading of instinct. As a matter of fact the widespread practice of postulating a general category of instincts, as discriminable from other types of behavior, is of dubious validity. We have seen that sexual behavior develops in various ways in different animals and may be controlled by different external and internal correlates in males and females of the same species. Parental behavior appears to be affected by a variety of factors ranging from the female's diet during immaturity to her previous experience in rearing young. Species differences are pronounced, and in any one species the behavior is governed by a complex combination of processes. This kind of evidence contraindicates categorization of mating and maternal behavior as unlearned or instinctive.

The category is artificial and bears little relation to the observed facts precisely because it was not originally derived from these facts. A wide variety of responses are grouped together under the heading of instinct, not because they share any positive characteristics, but because they have been arbitrarily excluded from a rather narrowly conceived category called learned behavior. It is certain that the so-called instincts do not all belong together, even in the same "wastebasket," and the term might profitably

be dropped from the scientific vocabulary. To discard the concept of instincts does not force us to classify all behavior as "learned." Such a procedure would jump us from the frying pan into the fire. Current concepts of learning are too confused and contradictory to be useful in interpreting much of the complex behavior that occurs under natural conditions.

The most fruitful approach would seem to involve further study of a greater number of responses so that they can profitably be compared and contrasted. Once we have analyzed several kinds of reactions in a number of different species, it becomes possible to compare the same pattern in different species or different patterns in the same species. Only by this means can we hope to understand how an animal's "instinctive" behavior resembles and differs from its performance in a maze or puzzle box. Only after such an analysis will interspecies differences and similarities in any given type of activity become intelligible.

Learnable Drives and Rewards

NEAL E. MILLER

Yale University

People are not born with a tendency to strive for money, for the discovery of scientific truths, or for symbols of social status and security. Such motives are learned during socialization. Many of them (such as jealousy when another man makes love to one's wife) vary greatly in different societies and even among the social classes in our society (cf. Ford, 1949). Even the primary drives themselves may be modified by learning, so that hunger becomes a desire for a particular type of food appetizingly prepared. Many Frenchmen abhor sweet corn and like snails.

Many writers have used the concept of secondary or learned drives and rewards.* Woodworth (1918) advanced the thesis that habits can become drives and used it to attack McDougall's doctrine of instinct. Davis (1948) indicated that the scholastic inferiority of lower-class children is due partly to a failure to acquire interests that provide motivation and reward for school work. Roethlisberger and Dickson (1941) described the importance of social motivations in in-

dustry. They showed that the direct effects of improved illumination or added rest periods may be completely overshadowed by motivational changes, depending on whether the workers feel that management is taking an interest in their welfare. Miller and Dollard (1941) discussed the social conditions apparently responsible for the learning of certain drives, such as a tendency to copy people with prestige. Allport (1937) emphasized the crucial role of learned drives in his book on personality, and Shaffer (1936) used them in his discussion of abnormality and adjustment. Dollard and Miller (1950) assigned great importance to learned drives and learned reinforcements in the higher mental processes, personality, and psychotherapy.

Freudian theory contains many assumptions about how drives are changed by experience and how these changes affect the personality. Mowrer (1939) translated Freud's (1936) assumptions about one of these drives, anxiety, into stimulus-response terms. He postulated that anxiety can motivate trial-and-error behavior and anxiety reduction can reinforce the learning of new habits. He used this hypothesis to interpret phenomena ranging from conditioning experiments to rituals and superstitions. Dollard (1945) used the same hypothesis to explain how certain symptoms of war neuroses are learned.

The experimental work on learned drives and rewards is limited almost exclusively to

Work on this chapter was supported by the Institute of Human Relations, Yale University. The ideas in it have been materially extended and sharpened by collaboration with John Dollard on problems of psychotherapy. Robert F. Grose and Martin Kohn helped to assemble and check the references. The colleagues who read a preliminary mimeographed version are warmly thanked for their helpful suggestions.

* As used in this chapter the following words are roughly equivalent: drive and motivation; reward and reinforcement; cue and distinctive stimulus; learned, acquired, and secondary.

(1) fear as a learnable drive and fear reduction as a reward or (2) learned rewards and drives based on hunger and food. This work will be discussed first and will constitute most of the chapter. It will be followed by a brief discussion of other drives as sources of learned motivation, some general problems, and studies of complex social motives.

We shall try to integrate the facts around a theory of learning built on drive-stimulus-response-reward, which Hull (1943) has described mathematically, and Miller and Dollard (1941) more simply. Different theoretical approaches have been made by Allport (1937), Tolman (1943), and Lewin (1942, 1946).

Criteria of Learnable Drives and Rewards

A learnable drive or reward is one that can be acquired by a previously ineffective cue as a result of learning. Thus, if a child that has not previously feared dogs learns to fear them after having been bitten, it shows that fear is learnable. Similarly, if appropriate training causes a previously ineffective token or coin to serve as a reward, we may call it a learned reward. This criterion rules out drives or rewards that are produced by changes other than learning, for example, those cases of drug addiction that are primarily caused by severe withdrawal symptoms.

The fact that a drive is learnable as a reaction to new cues does not rule out the possibility that it may also be an innate response to certain stimuli. Thus, although fear may be an innate response to pain, it may also be learned as a reaction to many other stimuli.

The ultimate test of drive and reward is their ability to produce the learning and performance of new responses. When, as a result of learning, previously neutral cues gain the capacity to play the same functional role in the learning and performance of new responses as do other drives, such as hunger and thirst, these cues may be said to have a learned drive value; when they gain the

capacity to function in the same way as other rewards, such as food and water, they may be said to have a learned reward value.

FEAR AS A LEARNABLE DRIVE, AND FEAR REDUCTION AS A REWARD

Fear, or anxiety as it often is called when its source is vague, has been studied most thoroughly, and it provides the clearest examples of the basic concepts we are concerned with here.

Basic Principles

Fear is an important drive because it can be learned so readily and can become so strong. Fear is called *learnable* because it can be learned as a response to previously neutral cues; it is called a *drive* because it can motivate the learning and performance of new responses in the same way as hunger, thirst, or other drives. These attributes are demonstrated by the following experiment.*

The apparatus, illustrated in Fig. 1, consisted of two compartments: one white with a grid as a floor, the other black with a smooth solid floor. These compartments were separated by a door which could be opened in any one of three ways: by the experimenter's pressing a button, by the rat's moving a wheel above the right-hand half of the door, or by the rat's pressing a bar near the upper left-hand corner of the door.

Albino rats tested before training in this apparatus showed no marked preference for either compartment. In order to teach them to fear the white compartment, they were given an electric shock from the grid, and allowed to escape into the black compartment. They received ten such trials.

After this they were given five test trials *without shock*. They continued to run rapidly, but this might possibly be explained

* For a preliminary report, see Miller (1941); for a more complete one, see Miller (1948a).

FIG. 1. Learned-drive apparatus. The left compartment is painted white, the right one black. Electric shocks are given through the grid which is the floor of the white compartment. Under different conditions the door (painted with horizontal black and white stripes) drops out of the way when the experimenter presses a button, the rat turns the wheel, or the rat presses the bar. Automatic records are made of the time from the rat's contact with the grid to his performance of the correct response, and of each quarter rotation of the wheel. (From Miller 1948a, p. 90.)

as the mere persistence of the habit of running.

The most rigorous test for a learned drive was made by determining whether or not the cues in the white compartment could lead the animals to learn a *new* response without further electric shocks. The conditions were changed: the door was left closed, but the rat could open it by moving the wheel a fraction of a turn. On the first of these nonshock trials the animals showed symptoms of fear, such as urination, defecation, tenseness, and crouching. They also performed a variety of other responses, and eventually most of them moved the wheel, caused the door to drop, and ran through into the black compartment. As shown in Fig. 2 the speed of operating the wheel increased on subsequent trials. In other

words, previously neutral cues in the white compartment were able to motivate the learning of a new response in the same way as do hunger, thirst, and other drives.* Similarly escape from the white into the black compartment had acquired the functional properties of a reward.

If running from the white into the black compartment served as a reward, we should expect that preventing it would extinguish the habit of moving the wheel. This prediction was tested by giving the rats additional nonshock trials with the control of the door changed from the wheel to the bar. At first the rats responded vigorously to the

* For evidence that these cues cannot produce such learning unless they have been associated with moderately strong shocks, see the 90-volt group in Fig. 6.

wheel. Eventually these responses were extinguished, and other responses emerged. As would be expected, the one response (pressing the bar) that caused the door to

FIG. 2. Learning the first new habit (turning the wheel) during nonshock trials with fear as a learned drive. Rats received electric shocks in the white compartment (see Fig. 1). They escaped by running through the already open door. Then they received trials without shock, during which the door was closed but could be opened by turning the wheel. (From Miller 1948a, p. 94.)

drop and permitted escape was learned, and wheel turning was displaced. This is shown in Figs. 3 and 4. From this it can be seen

FIG. 3. The response of turning the wheel extinguishes when it fails to open the door that prevents escape from the frightening white compartment. During this extinction the rat was also learning the competing response of pressing the bar, shown in Fig. 4. (From Miller 1948a, p. 95.)

that escape from the white compartment played a crucial role, similar to that of a primary reward, in the learning and the maintenance of new habits.

Control on the possible effects of tension created by conflict. Brown and Jacobs (1949) pointed out that the drive attributed to fear in the foregoing experiment might have been caused by tension created by the conflict and frustration produced when the door prevented the animals from running. Similarly the effect of fear reduction cannot clearly be separated from the disappearance of this conflict when the door opens.

In order to avoid this difficulty they locked albino rats in one of two identical

FIG. 4. Learning a second new habit (pressing the bar) during nonshock trials with fear as a learned drive. (From Miller, 1948a, p. 96.)

compartments and gave them trials during which a rapidly interrupted light and tone were paired with an electric shock. Then they gave nonshock trials with the two compartments separated by only a small hurdle. On each trial the light and tone were turned on and kept on until the rat crossed the hurdle into the other compartment; then they were immediately turned off. The speed of shuttling across the hurdle increased in a typical learning curve. Control rats, who had not had the preliminary pairing of the light and tone with shock, did not learn. Since no interruption of a running response was involved, it could not have produced the learning.

Higher-order conditioning. Experiments on higher-order conditioning also show that cues previously associated with pain can motivate the learning of new habits. Instead of learning a new response, however,

the subject learns to perform the same response to a new stimulus. Foursikof (Pavlov, 1927) first used electric shock to condition a dog to lift his front foot to a previously neutral mechanical stimulus on the hind foot. After this he used the mechanical stimulus without the primary drive of shock to condition the dog to lift his foot to the sound of bubbling water. Eventually he used the sound of bubbling water (without the mechanical stimulus or shock) to condition withdrawal to a tone. By primary reinforcement to the mechanical stimulus, secondary to the bubbling water, and tertiary to the tone, he maintained these responses for over a year.

Hypothesis that learnable drives are strong stimuli produced by responses. External sources of stimulation and overt responses can be observed directly, and we know many of their properties. At present learnable drives, such as fear, cannot be observed directly and have not been studied thoroughly. On the basis of what we do know, two related hypotheses are advanced: (1) that learned drives, such as fear, obey the same laws as do overt responses; and (2) that they have the same drive and cue properties as strong external stimuli.

These hypotheses are purely functional and do not say anything about the anatomical location of the inferred process. As a short way of expressing the first hypothesis, learnable drives will be called responses; to express the second hypothesis, they will be called stimulus-producing responses. This is a somewhat unorthodox expansion of the use of these two words.

If fear is a strong response-produced stimulus, anything that produces a sudden decrease in the fear response should have a rewarding effect. The same factors that reduce other responses should reduce the fear response, namely: (1) removal of the cues eliciting the response (for example, getting out of the white compartment); or (2) introduction of cues eliciting incompatible re-

sponses (for example, cues that have been associated with the extinction of fear or with other responses, such as eating when hungry, that are more or less incompatible with fear). In dealing with these other responses we are handicapped by not knowing exactly which ones are incompatible with fear or their different degrees of incompatibility. Furthermore, with many if not all such responses, other primary and secondary rewards occur in addition to those produced by the reduction in the strength of the fear.

According to the drive-reduction hypothesis, a primary drive (e.g. pain) is necessary before a response producing a learnable drive (e.g. fear) can be acquired. But, once it is learned, the fear is observed to persist on nonshock trials without pain. This raises three possibilities:

1. Some other drive is present to motivate the onset of the fear during these trials.

2. There are two kinds of responses: (a) those producing learnable drives, such as fear, which can be elicited without a drive to motivate them, and (b) those involved in instrumental behavior, such as bar pressing, which cannot be elicited without a drive.

3. Once any response is learned, its strength varies with the strength of drive, but some strength may remain at zero drive.

According to the third possibility, a drive is necessary for learning and also to prevent eventual extinction, since rewarding drive reduction cannot occur without a drive to be reduced. A well-established response, however, might persist without drive for many trials before extinction. Some evidence for and against this assumption is presented in Miller (1948b). Further work is needed to determine which possibility is correct.

The foregoing hypotheses may be summarized as follows: Learned drives depend on responses that produce strong stimuli. (Fear is a strong stimulus in the same sense that pain is.) Furthermore fear may be an innate response to certain stimuli, such as pain, and the fear response innately pro-

duces the fear stimulus, just as electric shock produces pain. The only difference is that it is easy to attach the fear response to new cues. Similarly, learned rewards are pro-

sign and theoretical expectations are summarized in the following diagram, in which the dotted arrows represent learned connections:

duced by responses that remove sources of strong stimulation. Thus the basic mechanism of motivation (strong stimulation) is the same for primary and learned drives, and the basic mechanism of reinforcement (a reduction in strong stimulation) is the same for primary and learned rewards.

Secondary generalization mediated by fear. If fear is a strong response-produced stimulus, it should function not only as a drive but also as a cue mediating secondary generalization. May (1948) first trained rats to jump over a low hurdle that separated two identical compartments, in order to escape an electric shock from the floor of the compartment. He assumed that the shock elicited fear and that the rats learned hurdle jumping to the fear stimulus as well as to shock. His second step was to train the animals to fear a buzzer. He paired the buzzer with shock while the animals were penned in the center of the apparatus (with the hurdle removed) so that they could not perform an escape response. His third step was to put the animals in the apparatus with the hurdle present and to test their response to the buzzer without shock. During these trials he expected the stimulus produced by the fear response to mediate transfer of the hurdle-jumping habit from the shock to the buzzer. His experimental de-

Control animals were trained in exactly the same way except that in the confinement pen they got the buzzer and shock in random order, not paired. Thus they learned the same hurdle-jumping habits but did not have any specific training to fear the buzzer.

On the first test trial the experimental animals gave more hurdle-jumping responses to the buzzer than did the controls. This was in line with the deduction that the response-produced stimulus of fear should serve as a cue to mediate secondary generalization of the hurdle-jumping response from the shock to the buzzer.*

The experiments described earlier show that fear has the functional properties of a response-produced drive; the present experiment suggests that it has the functional properties of a response-produced cue. These results agree with the everyday observation

* It is possible that the buzzer produced quicker hurdle jumping by an increase in random activity without any transfer of that specific response. But untrained rats usually respond to fear of this sort by crouching. An additional group trained to fear the buzzer but not to jump the hurdle would have clinched the matter. The fact that the difference between the experimental and control groups appeared on the first trial was learned through personal discussion with Mark May; the appearance of this difference on the first trial rules out the effects of learning to jump the hurdle in order to escape the buzzer.

that fear can motivate people to learn a great variety of responses, and that it is sufficiently distinctive so that people can be taught to respond to it with a verbal label that transfers to a variety of new frightening situations.

Characteristic responses to fear. The preceding experiment indicates that when fear is learned as a response to a new situation it tends to bring with it responses that have been learned in other situations. It should also bring with it responses that are either a part of the fear pattern itself or are high in the innate hierarchy of responses to the fear stimulus. These responses will influence the course of subsequent learning.

Two of the most obvious behavioral effects of fear present a striking contrast. One is the tendency to remain motionless and mute, which reaches its extreme form in the death-feigning of certain animals, and sometimes produces results suggestive of the waxy flexibility of catatonics.* The other is the pattern of startle, withdrawal, running, and vocalization. Both of these incompatible patterns seem to be activated by fear, and behavior may shift rapidly from one to the other, as when a frightened animal first freezes, then suddenly scurries to shelter.

Other reactions are described in studies of the strong fears produced in military combat (Dollard, 1943, p. 19; Wickert, 1947, p. 128; Hastings, 1944). In these studies it is difficult to differentiate between the symptoms produced directly by fear and those produced indirectly by the conflict between fear and loyalty. Whatever the causal sequence, the studies agree that the most frequent reactions to strong fear in combat are a pounding heart and rapid pulse, a strong feeling of muscular tenseness, trembling, exaggerated startle, dryness of the throat and mouth, a sinking feeling in the stomach,

* It seems probable that this tendency is involved in the temporary inhibition of the barpressing activity that Estes and Skinner (1941) have used as a measure of anxiety.

perspiration, a frequent need to urinate, irritability and aggression, an overpowering urge to cry, run, or hide, feelings of unreality, confusion, faintness, nausea, and sometimes subsequent amnesia. Common chronic effects of fear between air missions are fatigue, a feeling of depression and a slowing down of movements and mental processes, restlessness, aggression, loss of appetite, trembling, being easily startled, not wanting to go on any more missions, insomnia, nightmares, interference with speech, making meaningless gestures, and maintaining peculiar postures. Grinker and Spiegel (1945) give a vivid picture of severe states of combat anxiety and report that the symptoms can resemble closely those of schizophrenia.

On the other hand, we must remember that fear, like any other drive, can motivate the learning and performance of socially useful responses such as driving carefully or having a medical examination. Even in aerial combat, 37 per cent of the men reported that they performed their duties better when they were very afraid, and 50 per cent reported that mild fear had a beneficial effect (Wickert, 1947, p. 131).

A study by Mahl (1949) suggests that it may be necessary to differentiate between the effects of acute and chronic fear. According to Cannon (1929) acute fear decreases the secretion of hydrochloric acid by the stomach, whereas Mahl found that chronic fear greatly increases the stomach acidity of dogs. Since there are other differences between the two situations, one cannot certainly attribute the results to the chronic-acute variable.

Summary of ways in which fear can influence behavior. Fear can influence behavior in the following three ways:

1. It can be learned and bring with it the innate responses to fear, such as an increase in stomach acidity, immobility, or exaggerated startle responses.

2. It can be learned and serve as a cue to mediate the transfer of responses previously learned in other situations.*

3. It can be learned and serve as a drive to motivate (whereas fear reduction serves as a reward to reinforce) the learning of new responses. This learning will be influenced by the preceding two factors through their role in determining which responses are likely to occur.

Applications of Basic Concepts

After Mowrer (1939) put forward the hypothesis that fear (or anxiety, as he called it) operates as a drive, and fear reduction as a reward, he applied it in a series of experiments. Although, as he pointed out, most of these experiments may yield to alternative interpretations, taken as a group they support his hypothesis.

In one experiment Mowrer and Lamoreaux (1942) conditioned rats to avoid shock by running to the cue of a buzzer. The experimenters found that better learning was produced when the buzzer was turned off as soon as the animals made the response than when it was turned off either before or 5 seconds after. They had expected this on the grounds (1) that fear should become conditioned to the buzzer with the result that turning the buzzer off would produce a rewarding reduction in the strength of the fear, and (2) that this reward should be more effective when given immediately after the response than either before or 5 seconds after it.

Another experiment by Mowrer and Lamoreaux (1946) used a change in the pattern of illumination as the conditioned stimulus in shock-avoidance training. For half of the rats this change consisted in turning off two lights above them and turn-

ing on a nearer one below; for the other half it was the opposite. In this way any possible influence of a change in the overall intensity of light was ingeniously controlled. One part of this experiment demonstrated that rats would learn to jump if, whenever they performed this response within 5 seconds after the onset of the conditioned stimulus, it was turned off (i.e. changed back to the normal pattern) and not followed by shock. By a similar procedure a control group was taught the different response of running to the conditioned stimulus. In both cases the shock, given whenever the animal failed to respond properly to the conditioned stimulus, lasted for exactly 2 seconds, irrespective of what the animal did.

Another part of this experiment indicated that the animals could learn to make one response to turn off the fear-producing conditioned stimulus and a different response to turn off the unconditioned stimulus of electric shock.

The results of both parts of this experiment are what would be expected from the hypothesis that the animals learn to fear the conditioned stimulus and that turning it off serves to reward whatever response is occurring at that time. Two variables, however, are involved: (1) turning off the conditioned stimulus when the selected response (running or jumping) occurs, and (2) having all responses other than the selected one followed by shock. It is simplest to assume that the sole effect of the second variable is to allow fear to be reduced, but it may have had other effects, such as a tendency to eliminate all responses except the correct one.

Whenever an electric shock is used to train animals to make a specific response, such as bar pressing, the animals tend to make this response "spontaneously" between trials during the first part of learning. Coppock and Mowrer (1947) reasoned that the making of such responses between trials was probably motivated by the learned drive of fear, and that it was rewarded by the reduction of

* One will expect fear to be able to become a part of a pattern in the same way as do other cues (Hull, 1943, pp. 349-380). Thus a subject can learn to respond to fear by crouching in one situation and by running in another. In such cases transfer will depend on the external situation as well as on the fear.

the strength of this fear. If this were so, the making of such responses between trials should help learning. To test this deduction they trained rats to avoid shock by touching a bar whenever a light changed. For the experimental animals the bar was present between trials so that they could "rehearse." For the controls it was absent so that they were prevented from making "spontaneous" responses between trials. As expected, the experimental group learned reliably faster than the controls.

Fear reduction as an explanation for fixation. When animals that have learned a specific habit (such as turning right in a T-maze to secure food) are given a few electric shocks at the choice point, it "fixates" their behavior. In other words, if the food is shifted to the left, they will keep going to the right much longer than will animals that have not been shocked. Farber (1948) deduced such fixation from the assumption that the animal is being reinforced by a reduction in the strength of fear every time it turns to the right and escapes the cues at the choice point. He supported this deduction by showing that reducing the fear of the cues at the choice point (by confining the animal and feeding him there) greatly reduces the tendency for the "fixated" habit to persist after the location of the food has been changed.

The response that occurs can differ from the one that is reinforced. If an animal runs down an alley, receives a shock at a distinctive place, and runs ahead to escape it, on the next trial he may not run ahead but stop and crouch near the place where he was shocked. Such differences between the response that was reinforced by escape from shock and the response that subsequently occurs have been used by exponents of an expectancy theory of learning (Hilgard, 1948, p. 108; Tolman, 1932, p. 325) as an argument against the principle of reinforcement. This behavior can be deduced, however, from the cue function of fear that was shown in May's (1948) experiment.

On the first trial the shock elicits running ahead and also fear, and both responses are reinforced at the distinctive place. On the next trial, therefore, the cues at this place tend to elicit both running ahead and fear. But since crouching (and perhaps turning around and withdrawing) are either innate or learned reactions to the fear stimulus, it will tend to elicit these responses.* Thus the animal may stop, and, if he does this and turns away, the reduction in the strength of fear will reinforce this new response.

Which of the two opposing tendencies (running ahead or crouching) will be dominant is a quantitative matter. The author has secured evidence for the existence of both tendencies. He gave hungry rats a brief shock at a distinctive place halfway down an alley to the goal of food. When he increased the shock rapidly on successive trials, rats that had escaped the last shock by running forward tended to stop as they approached the shock area. When he increased the shock slowly and alternated shock and nonshock trials, some of the rats dashed ahead into the shock area faster than they had ever run for food and continued doing this after they were too excited to eat.

Reinforcement theory leads one to expect this difference. When shock is given on alternate trials and gradually increased in strength, there is more chance for running to be reinforced and crouching eliminated as a response to ever greater amounts of fear. Further evidence for the two opposing tendencies, the conflict between them, and the way this varies with different conditions was secured in a series of experiments by Gwinn (1949). In interpreting these experiments Gwinn had to assume that an in-

* It is also possible that the animals come into the situation with a hierarchy of functionally equivalent avoidance habits somewhat analogous to Hull's (1934a) habit-family hierarchy, or that fear produced by a stimulus ahead of the animal elicits crouching or withdrawal, whereas fear produced by a stimulus behind him elicits running.

crease in fear, not just its absolute value, serves as a cue.

Somewhat similar dynamics appear to be involved in the differences between conditioned and unconditioned responses found by Wever (1930) with cats, and by Upton (1929) with guinea pigs.

Fear and alcoholism. An experiment by Masserman and Yum (1946) suggested that fear, or a conflict induced by it, may motivate cats to learn to choose an alcohol solution instead of avoiding it. First they trained cats to perform a complex series of manipulations to secure food. Next they put two dishes in the same apparatus and found that the cats regularly preferred plain milk to milk containing 5 per cent alcohol. Then, returning to the complex series of manipulations, they established a conflict between hunger and fear by giving the animals a blast of air or an electric shock just as they were taking the food. After several trials the animals showed a marked fear of the food box and other parts of the apparatus.

Then they forced the cats to take mild doses of alcohol and found that intoxication tended to restore the original behavior of operating the apparatus to secure food. After the cats had experienced this relief from fear and conflict, they developed a progressively increasing preference for the 5 per cent solution of alcohol. Finally, after a series of trials in which the animals manipulated the apparatus without punishment, all signs of fear were extinguished and the preference for alcohol disappeared.

It is clear that fear was involved in producing the preference for alcohol. Whether its effects were direct or indirect is not so clear. It seems possible that the preference for alcohol was reinforced in one or more of the following ways: by a reduction in the strength of the fear, by a reduction in the strength of stimulation from the conflict produced by the fear, and by the food itself when the fear was reduced enough to allow the hungry cat to reach it.

Acquisition of Fear

The main psychological functions of fear have been described. The next step will be to investigate the factors determining the acquisition of fear and, after that, those involved in its elimination.

Stimuli innately arousing fear. In all the preceding experiments the fear was originally elicited by pain produced by an electric shock. Studies of children and young animals suggest that sudden and intense enough stimulation through any sense modality may have an innate tendency to produce fear (Jersild, 1946; Cruikshank, 1946). Clinicians and anthropologists observe that even a slowly mounting drive, such as hunger, can be a source of strong fear (Freud, 1936; Holmberg, 1950), but so much of the subject's complex life history is unknown that it is impossible to be sure that such fears are not learned.

Certain weak but distinctive cues may also have an innate capacity to elicit fear. For example, Tinbergen (1948) summarized studies of the reactions of several species of birds raised in isolation to the silhouette illustrated in Fig. 5. When this figure was moved on an overhead wire in one direction so that it resembled a hawk with a short neck and long tail, it was an adequate stimulus for flight and other responses of fear. When it was moved in the opposite direction so that it resembled a harmless long-necked goose, it did not elicit any fear.

The subjects had never had experience with hawks or adult geese. Hence the response must have been innate. Since fear appeared only when the stimulus was moved in one direction, it must have depended on the pattern rather than the suddenness or strength of the stimulus.

Sometimes innate fears are not present at birth but appear only at later stages of maturation. For example, in geese raised in isolation, fear of the silhouette described above did not appear until they were about 4 weeks old. The fact that a fear is absent

at first and appears later does not necessarily mean that it has been learned.

On the other hand, the fact that an animal fears a stimulus that it has never before experienced does not necessarily mean that this fear is innate; the fear may have generalized along some continuum of similarity with another situation in which it was learned. For example, Watson and Rayner (1920) conditioned a child to fear a rabbit and found generalized fear of dogs, fur coats, and Santa Claus masks.

FIG. 5. Silhouette that frightened inexperienced birds raised in captivity when it was moved overhead to the right but did not when moved to the left. (From Tinbergen, 1948, p. 34.)

Both children and animals tend to fear the unexpected, the sudden, and the strange. It is possible that such fears are spontaneous, as Hebb (1946) concluded from studies of chimpanzees born and raised in captivity. He advanced the provocative hypothesis that the disruption of an established neural pattern of response is the physiological basis of fear. Sometimes learning may be indirectly necessary to establish the pattern and to define strangeness, but the fear produced by strangeness itself is not supposed to be learned.

On the other hand, it is possible that such fears are the product of generalization. Different forms of strangeness, suddenness, or unexpectedness (i.e. conflict with an established habit of responding) may produce similar cues. It seems possible that children and chimpanzees learn to fear a large number of different situations of this type when they unexpectedly trip and fall, or have a

strange feeling in the stomach followed by sharp pains of colic, or are unexpectedly burnt or cut after reaching for a shiny object. After such fears are learned, they could generalize to other situations with similar elements of strangeness or unexpectedness.

Between the two extremes of completely innate and completely learned there is another possibility. Certain cues that do not spontaneously arouse fear may have a latent tendency to elicit it, with the result that (1) the subject will learn to fear these cues much more quickly than others, and (2) if he is already mildly afraid these cues can intensify the fear. In other words, fear may be high in the innate hierarchy of responses to a stimulus without being the dominant response.

Such latent fears may be involved in sensitization or pseudoconditioning. Sometimes a stimulus seems neutral at first, but after the subject has received a few electric shocks he shows strong fear of the stimulus in spite of the fact that it has never been paired with the shock (May, 1949). It is necessary to control for this pseudoconditioning in designing experiments on the learning of fear.

Thorndike (1935) criticized the classic experiment of Watson and Rayner (1920) on the grounds that the rabbit used as a conditioned stimulus may have had some inherent capacity to frighten the child so that learning was exceptionally easy. Thorndike believed that the rapid learning in this experiment did not agree with the extreme difficulty of teaching children to avoid many dangerous objects. One of his students, Bregman (1934), failed to reproduce Watson's results when she used stimuli believed to be more nearly neutral.

Finally, it is known that general susceptibility to fear varies widely from species to species and even among different strains of the same species (Hall, 1941).

Nature of reinforcement in learning fear. We can teach an animal to fear a neutral stimulus by pairing it with some other stimu-

lus that already elicits fear. Thus rats were made to fear the white compartment of the apparatus shown in Fig. 1 by receiving electric shocks there. Theories of learning differ in their interpretation of this fact. Such differences may yield a crucial test of some of these theories. Some of the main possibilities follow:

1. Drive reduction for all learning. One hypothesis is that all reinforcement is produced by a reduction in the strength of a drive (Hull, 1943; Miller and Dollard, 1941). According to this hypothesis, running out of the white compartment is reinforced by the reduction in pain when the animal escapes. In order to apply it consistently, we must also assume that fear is reinforced by a reduction in the strength of the pain rather than by its onset. According to this hypothesis it does not matter whether or not a response, such as fear, causes the drive reduction as long as it is contiguous with it.

At first glance this hypothesis might seem inadequate to explain the obvious fact that people learn to fear an experience, such as a severe burn, that produces prolonged pain. Electrical recording from afferent nerves, however, shows that the sudden onset of a new stimulus produces at first a strong burst of impulses, followed by a rapid reduction until a plateau is reached (Adrian, 1928, pp. 67, 116). This is called adaptation. Thus, when a person is subjected to a strong stimulus such as a burn, it is possible that this reduction in stimulation after the sudden onset, plus the other temporary reductions occurring during throbbing changes in intensity, could reinforce the fear even though the peaks of pain might continue to increase for some time.

2. A separate mechanism for emotions. A different hypothesis, advanced by Skinner (1938) and elaborated by Mowrer (1947), states that there are two different mechanisms of reinforcement: (a) drive reduction, which is the sole principle for the skeletal muscles under the somatic nervous sys-

tem, and (b) conditioning by contiguity, which is the sole mechanism for the smooth muscles, glands, and emotions controlled by the autonomic nervous system. Fear falls into the second category.

In order to obtain evidence on this problem, Mowrer and Suter (1950) gave rats a conditioned stimulus followed by an electric shock lasting 10 seconds. The conditioned stimulus always preceded the shock by 5 seconds, but in one group it ended with the onset of the shock and in another it lasted until the end of the shock. The authors reasoned that, if the end of the shock constituted the reinforcement, the second group should fear the conditioned stimulus more because it persisted until the shock was turned off. No such difference occurred. They interpreted this to mean that reinforcement occurred with the beginning of the shock, not with its end.*

Though it poses an important problem, this experiment is open to the following criticisms:

(a) The animals probably escaped shock several times by jumping, so that drive reduction was not limited to the end of the 10-second shock period.

(b) The crucial thing that had to be reinforced by drive reduction may have been the response of starting to be afraid at the onset of the conditioned stimulus, and this response may be different from the one of maintaining an already elicited fear while the conditioned stimulus persists.

* Cognition or expectancy theories would also lead one to think that the association of a stimulus with the beginning of shock would cause the stimulus to elicit fear, and that association of a motor response with the end of the shock would cause the response to be selected. The author makes this statement, however, on the basis of what he feels would be reasonable, i.e. what he would do. Thus it is circularly based on the type of behavior it is trying to explain rather than on certain explicitly stated principles. This of course does not deny the possibility that expectancy or cognitive postulates could be specifically formulated so that one could make this a rigorous deduction.

3. Conditioning by contiguity for all learning. The third possibility is to assume, as Guthrie (1935) did, that all learning occurs through conditioning by contiguity and that drive reduction acts only by removing the opportunity to learn conflicting responses to the drive. Thus, if the animal makes a number of different motor responses while the shock persists, the strongest association will be with the last response to the shock, because the conditioning of each response tends to uncondition all preceding ones. Turning off the shock will have a selective influence by determining which response will be the last one. But, if fear is a response that always persists throughout the shock, there will be no chance for it to be unlearned during the shock. Since it will always be a last response, its selection will not depend on when the shock is turned off.

It can be seen that the first and third of these hypotheses are alike in stating that a single mechanism is involved in all learning; the second one assumes that there are two different kinds of learning.

Factors influencing strength of fear. Only a few studies have used the most rigorous test for fear as a drive, namely, the use of fear to motivate the learning of new responses. This survey will therefore include studies that used pain or other intense stimuli as the primary drive, and that measured responses such as withdrawal. It is assumed (but by no means certain) that fear is involved in the persistence of these responses on test trials without the primary drive of pain. It will be noted that the variables influencing the strength of the learned drive of fear seem to be the same as those governing the learning of other responses.

1. Strength of primary drive. Miller and Lawrence (1950) studied the effect of the strength of the shock used during original training upon the strength of the acquired drive produced. The apparatus was like the one shown in Fig. 1, and the procedure was similar to the one used in that experiment. The stronger shock produced a

stronger learned drive, presumably fear. During the subsequent nonshock trials there was a higher level of performance of the new response, as is shown in Fig. 6, and also a greater resistance of this new response to experimental extinction. These results confirm those of other studies (Estes, 1944; Miller, 1944) which almost certainly involved fear, although its effects were not unequivocally isolated by forcing the animals to learn a new habit.

2. Number of trials with primary drive. In their classic experiment on the child, Watson and Rayner (1920) observed only mild fear of the rabbit after the first trial on which it was paired with the sudden loud sound. On subsequent trials they observed signs of stronger fear. Similar results have been secured in experiments on conditioned galvanic and other responses (Hovland, 1937*b*). In another part of their experiment on strength of shock, however, Miller and Lawrence (1950) failed to find any reliable difference between animals that had received 4 and those that had received 24 trials of original training with electric shock. It is possible that this anomalous result occurred because the animals received a large and variable number of shocks while they were jumping around and learning to escape from the white compartment on the first trials. It is also possible that when the cues are distinctive fear is learned to maximum strength in very few trials.

3. Time interval. Delayed electric shocks are less effective than immediate ones in preventing albino rats from performing the punished response (Miller, 1944; Mowrer and Ullman, 1945). Furthermore the conditioning of avoidance responses is less effective when the conditioned stimulus deviates from a position slightly in front of the unconditioned one. From this it may be inferred that the fear of a stimulus will decrease when the interval between it and the punishment is lengthened.

4. Generalization. Conditioned responses established to one stimulus tend to generalize

to other similar stimuli, and the generalized response is stronger, the more similar the stimuli. In the experiment by Watson and Rayner (1920) the conditioned fear of the rabbit spread to fur muffs, fur coats, Santa Claus masks, and a variety of other objects.

change in the rate of breathing, both of which are presumably correlated with the amount of fear elicited by electric shock. Temporal summation, which occurs when a stimulus is repeated a number of times in rapid succession, is presumably involved in

FIG. 6. The effect of the strength of electric shock as a primary drive on the strength of fear as a learned drive. This was measured by the learning and performance of a new habit during trials without shock. Different strengths of shock were used to establish fear in different groups of rats. Then, during trials without shock the rats were tested for their motivation to learn a new habit (bar pressing) in order to get out of the place where they had been shocked. (Miller and Lawrence, 1950.)

Hovland (1937a) plotted curves for the generalization of conditioned galvanic responses based on shock from tones of one pitch to those of different pitches. Both May (1948) and Miller (1941) observed generalization in their experiments on fear as a learned drive.

5. Summation. If two stimuli such as a buzzer and a vibrator have been separately associated with electric shock, the responses elicited when both of them are given simultaneously will be greater than when either is given separately (Hull, 1934b). This has been shown for finger retraction and for

warming up and pseudoconditioning as summarized by May (1949).

6. Primary versus secondary reinforcement. In general, conditioned responses seem to be weaker than unconditioned ones (Hull, 1934b). Similarly higher-order conditioned responses (secondary, tertiary, etc.) seem to be weaker than those of lower order (Pavlov, 1927), although it is just possible that a finding by Eccher and Culler (1941) is an exception to this principle. In these experiments the higher-order responses were established without primary reinforcement.

Experiments in which thoracic shock is used to maintain fear (Brogden and Culler, 1935) are not relevant to this particular problem since the thoracic shock is a primary reinforcement.

Elimination of Fear

Experimental extinction. If a learned response is repeated without reinforcement, it tends to become weaker. This is called experimental extinction. It occurs with a wide variety of overt responses. It also occurs with the covert, drive-producing response of fear, although this response may sometimes extinguish very slowly.

In the apparatus shown in Fig. 1, turning the wheel should continue to be reinforced as long as the subject fears the white compartment and as long as this response allows him to escape and reduce that fear. Two kinds of extinction are possible:

1. The turning of the wheel can be extinguished by preventing escape. In Fig. 3 we have already seen rapid extinction of this kind. The fear remained, as is shown by the rapid learning of the new response of pressing the bar (Fig. 4).

2. The fear can be extinguished by means of repeated trials without shock. The subject is no longer motivated to turn the wheel, and this response cannot be reinforced because there is no drive to be reduced.

The second type of extinction is shown in Fig. 7. Each rat received 20 shock trials in the white compartment. These were mixed with a larger number of nonshock trials to increase resistance to extinction. The new habit of pressing the bar to escape from the white compartment was then learned during trials without shock. This new habit persisted at a high level for many trials without shock. One animal continued to improve for almost 200 trials. Observing only this many trials, one might think that the fear motivating this habit was not subject to extinction, that it was, in other words, functionally autonomous (Allport, 1937). But addi-

tional trials produced a definite curve of extinction.

A large number of other animals trained in this apparatus have shown similar curves of extinction. Furthermore, experimental extinction during nonreinforced trials seems to be a characteristic of the conditioned psychogalvanic response, as well as of conditioned

FIG. 7. Resistance to extinction of a habit motivated by fear. Each rat received 20 shocks, mixed with a larger number of nonshock trials, in the white compartment of the apparatus shown in Fig. 1. During these trials they learned to escape through the already open door. Then, during trials without shock they learned the new habit of pressing the bar to open the closed door so that they could escape. Each point on each curve is the average of 20 trials given to a rat on 1 day. (From Miller, unpublished data.)

defense reactions and various forms of escape and avoidance behavior that are presumed to indicate fear.*

In the study of any given instance, the following related questions may be raised: (1) Does any extinction occur? (2) Does the curve of extinction reach zero, or does it become flat at some point above zero? (3) How permanent is extinction, and what factors determine its permanence? (4) What factors determine resistance to extinction? The difficulty of answering these questions

* Sheffield (1948) showed the fallacy of interpreting Brogden, Lipman, and Culler's (1938) results to mean that successful avoidance strengthens fear.

is increased by the possibility of exceedingly slow extinction, cyclic fluctuations in its course, generalization from other sources, and extreme variability. Fluctuations will introduce a constant error if subjects are discarded upon reaching a criterion of failure to perform.

Factors influencing resistance to extinction. The factors listed below are known to influence the resistance of fear to extinction. The search for additional ones should have theoretical and practical importance.

1. Strength of fear. Other things being equal, stronger fears should be more resistant to extinction than weaker ones. Each of the variables that increase the strength of fear should increase its resistance to extinction, but only a few of them have been experimentally tested. Miller and Lawrence (1950) found that a stronger primary drive of pain during the original training increased the resistance of fear to extinction. Hovland (1937a) found that generalized conditioned galvanic responses are extinguished more rapidly than nongeneralized ones.

2. Escape or avoidance training (partial reinforcement). Sheffield and Temmer (1950) found that rats that were shocked only when they failed to run within a given time resisted extinction much better than those shocked on every training trial. This was to be expected because the former procedure, called avoidance training, specifically trains the subject to remain fearful and run under conditions similar to those he will encounter in extinction. To illustrate, it is just when the subject relaxes, stops, and sits down that he exceeds the time limit and is shocked. Thus the responses of fear and running get attached to the cues produced by relaxing and sitting down. During extinction, therefore, whenever the response to the cues in the alley is so weakened that the animal starts to relax and sit down, he gives himself new cues eliciting more fear and running. Conversely, the animals given an immediate shock on every trial (a procedure called escape training) are not specifically

trained to remain fearful and to run under the conditions of extinction. As a result their responses extinguish much more quickly.

Similarly Estes (1944) increased the resistance of punishment to extinction by interspersing nonpunished trials among punished ones. He called this partial reinforcement.

3. Interval between extinction trials. Using an apparatus similar to the one in Fig. 1, Burros (1949) found that massed extinction trials reduced fear more than did daily trials. This would be expected on the basis of spontaneous recovery. It is also possible that other effects, such as perseveration or summation of fear, might reverse the curve somewhere between the two extremes Burros used. Furthermore, although extinction should be faster with massed nonreinforced trials, it probably will be more permanent with distributed trials.

4. Habit learned with pain versus habit learned with fear. In the same apparatus Burros (1949) used the primary drive of shock to train one group of rats to press a bar that opened a door and permitted them to escape. For a second group the door opened as soon as they touched it. Then he gave nonshock trials to both groups. The first group continued the old habit of pressing the bar, but the second group had to learn this as a new habit. In short, bar pressing was learned with shock plus fear for the first group and with fear alone for the second group.

As nonshock trials were continued, Burros found that both groups extinguished at approximately the same rate. This suggests that the extinction of fear was the crucial factor determining when the subjects would stop pressing the bar.*

In Burros' experiment the fear remained attached to the same cues, those in the white compartment. This is different from higher-order conditioning where the fear is trans-

* It should be noted that the two groups were compared on the type of extinction produced by trials without shock rather than by trials without the door dropping.

ferred from one cue, the original conditioned stimulus, to another, the higher-order conditioned stimulus. From the fact that higher-order conditioned responses seem to be weaker than those based directly on primary reinforcement (Pavlov, 1927), we would expect them to be less resistant to extinction. An experiment by Brogden and Culler (1935) seems to confirm this expectation in spite of the fact that it was complicated by some primary reinforcement from thoracic shock during the "higher-order" conditioning.

Forgetting. Experimental extinction, which occurs when a response is elicited without reinforcement, must be distinguished from forgetting, which occurs during the time when a response is not elicited. Masserman (1943) found that fears are not easily forgotten. After as much as 5 months of rest, his animals showed little if any permanent reduction in their fears of the food device in which they had received air blasts or electric shock. On the first trial after a long rest the animals tended to show a temporary great reduction in fear, but on additional trials without air blasts or shock strong avoidance reappeared.

Role of anticipatory relaxation. If a reduction in the strength of fear reinforces the response of bar pressing, we may ask, why doesn't it reinforce the fear response enough to prevent its extinction? A possible answer follows. According to the gradient of reinforcement the responses most closely associated with the reduction in the strength of fear should be those most strongly reinforced. If fear stimuli require a moment to die out, the responses most closely associated with their reduction must inevitably be those involved in ceasing to be afraid. These responses will be those most strongly reinforced. Thus they should tend to become anticipatory and should eventually crowd out the fear.

This is exactly what seems to happen during extinction trials in the apparatus shown in Fig. 1. At first the rats dash to the far end of the black compartment. Gradually

they begin to stop sooner. Finally they fail to go through the door after pressing the bar. Although there is considerable variability, it appears that the tendency to stop becomes progressively more anticipatory until the animals stop before they get started.

Similarly, although it is harder to observe in detail, general relaxation seems to move forward in the series. At first the animals do not relax until they have been sitting in the black compartment for some time; eventually they go through the whole sequence nonchalantly and seemingly without drive. That fear has not been completely lost as a potential drive, however, can often be shown by disrupting the patterned sequence that elicits the anticipatory relaxation. For example, if the switch is disconnected so that the door does not open, the rats often become tense again, press the bar vigorously, urinate, defecate, and show other signs of strong fear.

We may venture the hypothesis that learned anticipatory drive-reducing responses often obscure the true role of drive in smoothly functioning human behavior. Similarly interruptions of well-established habits may release motivation by removing the cues that elicit the anticipatory relaxation and also by creating new sources of strong stimulation such as conflict and anger. For example, in driving to class the author often seems to be proceeding mechanically from sheer force of habit without any drive. But, if he is sufficiently delayed by one bad snarl of traffic after another, obvious signs of strong drive begin to appear so that he blows his horn, tries detours, and fervently resolves to allow more time the next day. It can be seen that having motivation reappear just when a sequence is threatened with failure is a highly adaptive mechanism worthy of further experimental analysis.

An experiment by Mowrer and Viek (1948) further illustrates how anticipatory relaxation, or conditioned inhibition, may reduce fear. On each trial hungry rats were offered food on a stick for 10 seconds. If the rat

ate, he was given an electric shock 10 seconds later. For one group the shock was left on until the rat performed a specific response, i.e. jumping. Each rat had a control partner who upon eating was shocked for exactly the same length of time. The animals in the first group could perform a definite response to stop the shock; their controls received an equally long shock that was out of their control. The authors reasoned that, for the first group, the anticipatory tendency to jump should bring with it some of the relaxation that ordinarily follows the end of shock. Therefore these rats should be less frightened and more likely to eat. This is exactly what happened. It is possible, however, that more of the rats in the first group sat on their haunches in an anticipatory jumping position so that their more sensitive front feet were off the grid. If this was true, their shocks may have been less painful than those of the rats in the second group.

However this experiment is interpreted, evidence from the studies of military combat, cited above, shows that a feeling of helplessness intensifies fear, and that having something to do tends to reduce it. At present it is not known how much of this effect is due to the distraction of attention from the fear-producing cues and how much is due to cues similar to those previously associated with escape from pain or danger.

Specific reinforcement of responses antagonistic to fear. According to the hypothesis just discussed, experimental extinction reinforces the responses involved in ceasing to be afraid. In certain other techniques of eliminating fear the reinforcement of antagonistic responses is more obvious. In one such procedure a hungry subject is fed in the fear-arousing situation. Eating and the emotional responses that accompany it are apparently incompatible with fear, and the attaching of these responses to the stimuli that arouse the fear suppresses it. Thus, in order to eliminate a child's fear of a rabbit, Jones (1924) first showed the rabbit at a distance while the child was eating, and then

gradually brought it nearer until the child ate with one hand and petted the rabbit with the other.

Sometimes this method can eliminate even the presumably innate fear of painful stimuli. Thus Pavlov (1927, p. 30) used electric shocks, cauterization, and pricking of the skin as conditioned stimuli for feeding. Starting with mildly painful stimuli and working up to strongly painful ones, he observed that the original defense responses of very hungry dogs disappeared. To quote him:

Subjected to the very closest scrutiny, not even the tiniest and most subtle objective phenomenon usually exhibited by animals under the influence of strong injurious stimuli can be observed in these dogs. No appreciable changes in the pulse or in the respiration occur in these animals, whereas such changes are always most prominent when the noxious stimulus has not been converted into an alimentary conditioned stimulus.

The results depended on the relative strengths of the two drives. With extremely strong pain it was impossible to eliminate the fear.

We do not know yet exactly which responses are antagonistic to fear or the degree of incompatibility of each. Pavlov's results show that, for the hungry animal, eating is at least partially antagonistic to fear. Tinklepaugh and Hartman (Cruikshank, 1946) found that small monkeys are much less likely to be frightened if they are clinging to some object. Watson and Rayner (1920) reported that Albert had a strong tendency to put his thumb in his mouth as soon as they presented frightening stimuli. They also reported that they could not elicit any conditioned fear responses as long as he had his thumb in his mouth.

Method of exposing subject to fear-producing stimuli. Avoidance responses reinforced by escape from fear often keep the subject out of the frightening situation, with the result that extinction does not occur and responses antagonistic to fear cannot be re-

inforced. Even when it is easy to expose the subject to the frightening stimuli, there is still the problem of which procedure is best.

One technique emphasized by Guthrie (1935) is to start with stimuli exceedingly weak, distant, or only remotely similar to the ones feared, and to approach the strongly feared stimuli so gradually that no fear is elicited. One often has to use this procedure in order to get the responses antagonistic to fear to occur so that they can be reinforced.

The opposite technique—that of physically forcing the hungry animal toward the frightening food box—was used with some success by Masserman (1943). According to the conflict theory (Miller, 1944, p. 441), this technique should be especially effective when the original punishment coincides with stimuli that precede the food box. At least two other possibilities should be considered: (1) Shoving the animal toward the food with a movable barrier changes the stimulus situation and weakens the avoidance more than the approach, because the generalization of avoidance based on fear falls off more rapidly than does the generalization of approach based on hunger (Miller, 1948b). (2) Experimental extinction is more effective when the animal is in the original punished situation that evokes the most intense fear.

In general, extreme coercion does not seem to produce good results with children (Jersild, 1946).

Masserman (1943) also gave hungry cats a chance to press a pedal they had been trained to use. They could thereby produce the feeding signals they had learned to fear. Given this "control over the situation" some of the cats produced the phobic stimuli until they lost all fear of them. Jersild (1946) described the successful use of somewhat similar techniques with children.

Social factors. In various studies summarized by Jersild (1946) social example and imitation sometimes helped children to eliminate their fears. Similarly Masserman (1943) reported that watching another cat eat without getting punished had some effect on a

frightened cat. Sometimes gentle stroking by the hand of an experimenter who customarily fed and cared for the cat also had a reassuring effect. Children's fears are often greatly reduced by the presence of a parent or other person whom they love and trust.

Drugs. As has been mentioned, Masserman and Yum (1946) found that alcohol can cause frightened cats to resume manipulating an apparatus to secure food. The same effect is produced by morphine (Masserman, 1943). Similarly Conger (1949) trained hungry rats to approach the distinctively lighted end of an alley to secure food and then threw them into an approach-avoidance conflict by giving them electric shocks at the goal. Five minutes after a control injection of water the rats would not approach the food-shock end of the alley; 5 minutes after an alcohol injection (1.5 parts of alcohol to 1000 of body weight) they ran up to get the food.

The results of the preceding experiments could have been produced in a number of different ways: for example, the alcohol might have either strengthened the approach habits based on hunger or weakened the avoidance ones based on fear. In order to analyze the results, Conger (1949) trained one group of rats to approach the lighted end of the alley for food and a different group to avoid the lighted end of the alley to escape shock. The rats wore a harness, and on test trials the strength of approach or avoidance was measured by the strength of pull they exerted against a temporary restraint. These tests showed that the alcohol produced a slight reduction in the strength of the approach response motivated by hunger and a much greater reduction in the avoidance response motivated by fear. This result fits in nicely with the hypothesis, previously mentioned, that the habit of drinking alcohol in a conflict situation is reinforced by a fear-reducing effect of the alcohol. On the other hand, it is possible that the greater effect of alcohol on the avoidance group was due not to any effect specific to fear but to

some other factor, such as the fact that the avoidance habit was established in fewer trials and hence was more recent than the approach habit.

Sympathectomy. Solomon and Wynne (1949) trained dogs to jump out of a darkened compartment into a lighted one in order to avoid electric shock. Normal dogs learned the avoidance habit quickly and showed overt signs of fear during the early stages of learning and whenever the experimenters introduced a block that delayed their jumping out of the darkened compartment. When the shock was turned off, the normal dogs continued jumping for more than 500 trials with no signs of stopping. Dogs that were completely sympathectomized learned the avoidance but showed no overt signs of fear. When the shock was turned off, their jumping extinguished in less than 100 trials. These results suggest that sympathectomy removed (or greatly reduced) the fear so that avoidance was not reinforced by fear reduction on shockless trials.

LEARNED REWARDS AND DRIVES BASED ON FOOD AND HUNGER

Experiments in which pain is used to establish fear have illustrated the functions of learnable drive; those in which hunger and food are the primary drive and reward point up the role of learned reward, or, as it is often called, secondary reinforcement. Early experiments of this kind were reported by Pavlov (1927) and Williams (1929). Since certain later experiments bring out the principles more clearly, they will be used as the models. These are the experiments in which Wolfe (1936) and Cowles (1937) trained chimpanzees to value poker chips somewhat as human beings value money.

Learning reinforced by token reward. In order to give reward value to the tokens (poker chips) Cowles (1937) first trained hungry chimpanzees to insert them into a vending machine which delivered a raisin

for each token inserted. As a preliminary test, and as a further means of establishing the reward value, he repeated Wolfe's (1936) procedure of requiring the chimpanzee to work for the chip by pulling a handle against a weight. First the animals were allowed to exchange the chip immediately for a raisin; then by stages they were forced to accumulate 20 chips before they could spend them.

In order to determine whether or not the poker chips could serve as a learned reward, he took the animals into another room where they were confronted with two boxes. If they opened the one to the left they found a token, and if they opened the one to the right they found nothing. They quickly learned to open the box on the left in spite of the fact that they were not allowed to exchange the tokens for food until the end of the day's session. The next day they were taught to select the box on the right.

In later experiments they were taught a variety of more complicated habits. In some of these experiments the possible innate reward value of the token was controlled by giving the animal a token that had been associated with food if he performed the correct response, and a different colored token, that the animal had learned could not be exchanged for food, if he performed the incorrect response. The learning of the correct response under these circumstances showed that the reward value of the token depended on its previous association with the primary reward of receiving food when hungry.

Additional experiments. Table 1 summarizes other experiments on learned reward. It can be seen that successful results have been secured with subjects ranging from rats to people. Lower animals, however, seem to have a tendency to respond to the position of the token object. Thus it is much harder for them than for chimpanzees or children to establish a generalized response to the object as such, irrespective of its position.

Other stimuli, ranging from the click of a food-delivery apparatus to the cues in the food box of a maze, have been given learned

TABLE 1 (Continued)

SUMMARY OF STUDIES OF LEARNED REWARD BASED ON HUNGER AND FOOD

Investigator	Subjects	Acquisition of Learned Reward (Under Hunger Drive) by	Learned Reward	Performance (P) or Learning and Performance (L) Based on Learned Reward	Chief Principles Demonstrated *
Pavlov (1927)	Dogs	Sounding metronome and then blowing meat powder into mouth.	Conditioned stimulus of metronome.	Higher-order conditioning of salivation to stimulus of black square (L).	1. Prod. learn. 5. Pri. sup. to learned.

* Key to principles demonstrated.

1. Prod. learn. Learned (i.e. secondary) rewards can be used to produce new learning.
2. Incentive. The sight of a learned reward can be used as an incentive to induce striving.
3. Prolong perform. Learned rewards can be used to induce or prolong the performance of a learned response in the absence of primary reward (i.e. stave off experimental extinction).
4. Bridge delay. Learned rewards can be used to lessen the decrement produced by a delay in the primary reward.
5. Pri. sup. to learned. Primary rewards are more effective than learned rewards. (I = learned reward followed quickly by primary one; D = delay between receiving learned reward stimulus and its reinforcement by primary reward.)
6. Little diff. pri. vs learned. No great difference was found between the effectiveness of primary and learned rewards (I and D, see 5 above).
7. Subj. ext. The learned reward value of stimuli is subject to experimental extinction.
8. Spontan. recovery. Extinguished learned rewards are subject to spontaneous recovery.
9. Generalization. Learned reward value of stimuli generalizes to other similar stimuli.
10. Discrimination. A discrimination can be established so that an object associated with primary reward has greater learned reward value than a similar one not associated with primary reward.
11. Strength pri. drive. The effectiveness of learned reward is dependent on the strength of the primary drive at the time of the test.
12. Other.

reward value. This reward value has been used to reinforce the learning of a variety of habits, ranging from running a maze to higher-order conditioning. Until evidence to the contrary is forthcoming, we may assume that any response the subject can learn can be reinforced by learned reward, and that any stimulus to which he can respond can acquire reward value.

It should be noted, however, that Pavlov (1927) found that higher-order conditioning was successful only if the new stimulus was withdrawn before the already conditioned one was given. This poses the problem of determining whether some stimulus conditions are much more favorable than others for the learning of reward, and, if so, why.*

* Cowles (1937) believed that it is important for the chimpanzee to have the token with him during the interval between earning and spending

Relative effectiveness of primary and learned reward. In judging the effectiveness of tokens and other learned rewards, we must differentiate between experiments that allow the subject to exchange the token quickly for a primary reward and those in which the exchange is delayed. In the former the effects of the almost immediate primary re-

it. Intuitively this seems correct, but from the present formulation of reinforcement theory one might make the opposite prediction, since having the token during this time when it cannot be spent should tend to extinguish its reward value. Similarly intuition suggests that the reward value of the token would be reduced greatly if there were no relation between the number earned in the first part of a session and the number that could be spent at the end of the session, even though the discrepancy in one session counteracted that of the next so that no change was made in the total amount of primary reinforcement received for the tokens during the whole experiment.

ward are added to those of the token and may cause its effectiveness to be overestimated. Table 1 shows that, when the effects of learned reward are clearly separated from those of primary reward, they tend to be weaker. None of these experiments have produced a learned reward that is stronger than the primary one used to establish it.

Extinction of learned reward value. Experiments cited in Table 1 show that the learned-reward effect of a stimulus is weakened if it is used for many trials without reinforcement by a primary reward. An experiment by Saltzman (1949) suggests that the interspersing of a number of nonrewarded trials during training with primary drive and reward (i.e. partial reinforcement) may increase the resistance of a learned reward to experimental extinction.* Virginia Sheffield's (1949) experiment indicated, however, that this effect should be weakened or eliminated if the intervals between the original training trials were long enough to allow the cues produced by nonreward to die out. Then the subjects are not rewarded for continuing to respond in the presence of these cues. Finally, Mitrano (1939) and Lambert and Solomon (1950) found that, when children perform a task to get a token they can spend for candy, interruption of this sequence near the goal (token yields no candy) produces more rapid extinction than interruption near the start (task yields no token).

Generalization and discrimination of learned reward value. Both Wolfe (1936) and Cowles (1937) found that chimpanzees trained to use tokens of one color would work to secure similar tokens of other colors, thereby demonstrating generalization from one type of token to another. When food was given consistently in exchange for tokens of one color but never for tokens of another

color, the responses to the nonfood token gradually extinguished. A discrimination was established.

That the discrimination was not quite complete and thus left the nonfood token with a small amount of generalized reward value is suggested by Cowles' (1937) experiment. He found that learning to make a correct choice was somewhat slower if the animals received the nonfood token when they made an incorrect response than if they received nothing. This result indicates that receipt of the nonfood token tends to reward the incorrect response.

Similarly Denny (1948) found that rats learn a T-maze more rapidly if the end box on the incorrect side is different from the correct one, and Ehrenfreund (1949) found that they learn a visual discrimination faster if both the food and food dish are absent on the negative side than if the food is absent but the food dish present.

When learned reward generalizes to the cues that follow the incorrect response, learning is hindered. Similarly, when it generalizes to the cues that follow the correct response, learning should be helped. Thus Saltzman (1949) trained rats to learn a simple maze in order to get to a distinctive box that had been associated with food but no longer contained it. He found that learning was improved if the rats ran down an alley and received food in the same box on alternate trials. The learned-reward value of the box was maintained by generalization from the situation where it appeared at the end of the alley to the one where it appeared at the end of the maze. As we shall see, generalization of learned reward can also help to offset the effects of a delay in the primary reward.

Learned reward and the gradient of reinforcement. Wolfe (1936) studied the effects of the following two conditions upon the length of time the primary reward of food at the vending machine could be delayed without causing the animal to stop his performance of the task: (1) the chimpanzee

* Ehrenfreund (1948) found that partial reinforcement seemed to produce a weaker learned reward as measured by the rate of learning of a new habit reinforced by the learned reward. This would not necessarily be incompatible, however, with a greater resistance of the learned reward to experimental extinction.

received a token immediately after performing the task but was not permitted to use it for food until the end of a period of delay; and (2) the chimpanzee learned to execute the task and wait (without receiving any token) until the food reward was given at the vender. As a control, two additional conditions were tested: (3) the subjects did not receive food tokens for work but had nonfood tokens in their cage during the delay; and (4) immediately after the work task the subjects received a token which they promptly deposited in the vender, after which they had to wait until the food appeared. After the animals had been thoroughly trained in a given condition, the period of delay was gradually increased to determine the limit beyond which the animal would stop working.

Wolfe found that the first condition was far superior to all others. In other words, when the animals received a token and were allowed to keep it during the delay, the degree to which the primary reward could be postponed was greatly increased. Presumably the token had this function because (1) it appeared as a learned reward immediately after the performance of the work task, and (2) it had its learned reward value maintained by immediate association with food. That the token was only partly effective in neutralizing the effects of the delay in the primary reward was demonstrated by the fact that the animals would work harder when the exchange was immediate than when it was delayed, and they tended to stop work altogether if the delay was too long.

Hull (1943) pointed out that the effects of the gradient of reinforcement may be extended by the progressive higher-order conditioning of secondary reinforcement. Spence (1947) advanced the hypothesis that all the effects of reward upon preceding responses are due either to this mechanism or to what he believes is probably more important in most situations, the generalization of learned reward. In Wolfe's (1936) experiment the token was present as a stimulus element to

mediate this generalization of learned reward; in other experiments positional and other external cues, and the proprioceptive stimulus traces of different responses, are presumed to mediate similar generalization. After analyzing experiments on delayed reward, Spence concluded that the more such opportunities for the generalization of learned reward are excluded, the steeper is the temporal gradient of reinforcement. When both the external and proprioceptive cues that mediate such generalization are made as alike as possible after the correct and incorrect responses, delays in the primary reward as short as 5 seconds will prevent learning from occurring in either rats or chimpanzees.

Satiation on food tokens. In one test, chimpanzees were permitted to work for 10 minutes and to secure as many tokens as they wanted, and at the end of that time to exchange them all for food. In this situation Wolfe (1936) found that he could decrease the number they were willing to work for by giving them tokens at the beginning of the session. One animal worked for an average of 21 tokens when he began the session without any, and for only 2.6 tokens when he began with 30.

Effect of amount of primary reward. Wolfe (1936) found that his chimpanzees could learn to select a token that yielded two grapes in preference to a different colored token that yielded only one grape. He did not test the effect of these two types of tokens on the amount of work performed or on the speed of learning.

Effect of immediacy of primary reward. Jenkins (1950) gave rats 80 training trials during which a buzzer was followed by food. For different experimental groups the intervals between the buzzer and food were, respectively, 1, 3, 9, 27, and 81 seconds. For a control group the buzzer was sounded without food. On test trials 30 minutes long, a lever was available for the first time. Pressing the lever produced the buzz but no food. During these test trials the animals in the experimental groups pressed the lever more

frequently than those in the control group, and the amount of lever pressing was greater, the shorter the interval had been between buzzer and food. Apparently the buzzer became a stronger learned reward when the interval between it and the food was shorter.

Effect of strength of primary drive on reward value of token. The strength of the primary drive can be varied at two different places: (1) when the reward value of the token is being reinforced by exchange for food, and (2) when the tokens are being used to reinforce the learning or performance of a new habit. The effects of changes of the first kind have not been investigated separately; there is some evidence on the second. Wolfe (1936) reported that an animal satiated on bananas will not beg for tokens and does not seem interested in them. When hungry, the same animal is very much interested in getting tokens. Similarly Bruce's (1932) experiment suggested that an increase in the hunger drive raises the reward value of the sight and the smell of food that rats are prevented from eating by the presence of a screen. Wolfe (1936) also found that chimpanzees can be trained to discriminate among drives so that they use one kind of token to secure water, another for food, and still another for certain activity privileges.

Estes (1949) showed that, if the relevant primary drive is satiated, the effects of learned reward will vary with the strength of an irrelevant primary drive. First a click was associated with the delivery of water to thirsty rats. When they had been satiated on water, the click was found to be more effective as a learned reward when the rats were 23 hours hungry than when they were only 6 hours hungry.

Learned Drive Based on Hunger and Food

Incentive value of token. In the foregoing experiments the chimpanzees worked in order to receive a token they could see and did not work when they saw that the apparatus was empty. In other words, the sight of the

token served as an incentive. Wolfe (1936) also observed that after the token had acquired reward value the sight of it caused the animal to perform without further training habits previously established on the basis of food.

Food preferences. Harris et al. (1933) showed that if a vitamin B₁ concentrate is added to a distinctively flavored food rats deficient in vitamin B₁ will learn to prefer food of that flavor. Those without a vitamin deficiency do not learn to prefer this mixture. Rats are unable to develop any preference for the vitamin-containing food in the absence of the distinctive flavor, and the preference for a given flavor lasts for a time after the vitamin has been removed and put into a differently flavored food. Thus the preference is not due to the taste of the vitamin itself; it is a learned response to the distinctive flavor serving as a cue. This learning seems to depend on the fast action of the vitamin, since similar results are not produced by slower acting vitamins such as A or D, or by proteins.

Perhaps other specific hungers are learned in a similar way. Additional work showing that food preferences can be learned is summarized in the *Manual for the Study of Food Habits* (1945) and by Young (1948). Lewin's (1947) studies of group decision will be mentioned later.

Learning by satiated animals. In Wolfe's (1936) experiments the chimpanzees' motivation to secure tokens seemed to disappear, or at least it was not clearly demonstrated, when the hunger drive was satiated. In Anderson's (1941) experiments animals learned a new habit when apparently they were not hungry. First he gave hungry rats 73 trials on one maze with food as a reward. Then he fed them to satiety and found that they would learn a different maze with food at the goal, or even without food. A satiated group without the previous training with primary drive and reward in the first maze failed to learn the second one.

Brogden (1942) trained hungry dogs to lift their paws to get food. When the dogs were satiated he found that they continued to respond longer if he kept giving them food (which they did not eat) than if he disconnected the food-delivery mechanism. Presumably some learned drive must have been present to make the sight of food effective as a learned reward in the absence of hunger.

A different experiment by Myers (1949) showed a similar effect. In order to get rats that were satiated on food to run on a T-maze he used social lures, other rats, in the goal boxes at the ends of *both* arms of the T. On the way to the goal box, one arm also contained food. The satiated rats learned to prefer this arm, and when the food was shifted to the opposite arm they learned to reverse their preference in spite of the fact that they did not eat. Thus the mere sight of the food must have had some reward value, a result obviously relevant to the interpretation of experiments on latent learning.

Gregariousness in sheep. Scott (1945) observed that adult sheep usually follow their mothers in the flock. When he fed two orphan lambs from bottles, he found that they grew up to be much less gregarious than other sheep. Furthermore they had a greater tendency to follow people.

Hoarding behavior in rats. Under some conditions, described in Morgan's (1947) review, rats have a strong tendency to hoard food. Although hoarding seems to be partly instinctive, it can be modified by conditions that seem to involve learning. A period of food deprivation increases hoarding, and this increase is greater if the animals have been severely deprived during infancy. Rats will store pellets in a familiar cage but not in a strange one. The increased hoarding produced by lighting the alley that contains the food persists for a considerable time after the alley is darkened again.

It would seem profitable to determine (1) whether these changes in the strength of the urge to hoard actually follow the laws of

learning and experimental extinction, (2) whether this urge can be used to establish new learning if conditions are arranged so that the animals get no immediate primary reward by eating the food, and (3) to what extent the "value" of the object hoarded is determined by previous experience in which the hunger drive was reduced by a similar object. Studies aimed at these points might elucidate the relation between learned and instinctive motivations.

Sucking and oral activity. On the basis of Levy's (1934) experiment it has been assumed that there is an innate drive to suck and that the frustration of this drive during early infancy produces an abnormal amount of sucking later on. A recent experiment by Davis et al. (1948) throws doubt on this hypothesis applied at the human level. They gave a standard sucking test and also sampled incidental oral movements and crying in three different groups: breast-fed, bottle-fed, and cup-fed babies. If sucking is an innate drive that requires a certain amount of satisfaction, the cup-fed babies should show more nonnutritional sucking, more mouth-movements, and perhaps more crying than the breast-fed babies. This did not occur. In fact, toward the end of the 10-day observation period the breast-fed babies showed the most nonnutritional sucking, though the difference was not highly reliable.

Another study by Sears and Wise (1950) compared groups of children that were weaned at different ages: before 2 weeks, between 2 weeks and 3 months, and after 4 months. On the basis of evidence that the vigor of frustration reactions is directly related to the strength of the frustrated drive, they assumed that, if the strength of the sucking drive increases with practice, the expression of rebellion and resentment at weaning should be greater, the older the child is at the time of weaning. Their data confirmed this expectation; the average strength of frustration reaction was reliably greater in the groups that were weaned later. The children that were weaned later also

showed somewhat more thumb sucking, but the difference was of a size that would be expected to occur by chance 15 times in 100.

These studies suggest that the drive to suck (which can cause children to learn a variety of new ways to outwit their parents) may be acquired by reward in the feeding situation. Furthermore it was much harder for Watson and Rayner (1920) to frighten the child Albert when he had his thumb in his mouth. If thumb-sucking should reduce fear, this reduction should strongly reinforce that habit.

OTHER DRIVES AS SOURCES OF LEARNED MOTIVATION

Practically all the experimental studies of learned drive and reward have used either pain or hunger as the primary drive. Since the evidence for other drives is so scanty and indirect, only a few samples will be given.

Thirst. Wolfe (1936) showed that chimpanzees can learn to use tokens of the appropriate color to get water when thirsty, and Estes (1949) that the click of a Skinner bar-pressing apparatus can acquire reward value by association with the giving of water to a thirsty rat.

Aggression. Miller and Dollard (1941) described conditions that are likely to reward aggression as a response to frustration. They advanced the hypothesis that the pattern of aggression can be modified at the following three points:

There is considerable evidence that the tendency to respond with aggression can be modified by training. Goodenough (1931) reported a relation between the frequency of outbursts of anger and the proportion of instances in which the issue is yielded to the child. Allee (1942) and his collaborators trained meek and submissive mice to be-

come exceedingly pugnacious and dominant. Children (Whiting, 1941) and goats (Scott, 1948) respond to frustration by aggression against a submissive competitor and by withdrawal from a dominant one. It is not known, however, whether these changes in overt behavior involve similar learned changes in the strength of anger.

Drug addiction. Spragg (1940) showed that morphine-addicted chimpanzees will strive to get the syringe and other objects they have learned to associate with an injection. Sometimes the use of morphine may be reinforced by a reduction in fear like that described for alcohol, but in this experiment it seems probable that the motivation was produced by physiological withdrawal symptoms and hence was not a learned drive. Furthermore, the animals worked for the syringe only when they had withdrawal symptoms. Later in the experiment, however, incidental observations suggested that temporary relief from withdrawal symptoms could be produced by injections of physiological saline. Such relief must have been the product of learning and would be expected to give reward value to the cues involved in the injection.

Sex. Sexual behavior should be a good source of learnable drive and reward. Since some of the preparatory acts, such as tumescence, increase stimulation and may be learned as responses to environmental stimuli, they should be sources of learned drive. Since the orgasm, which is a goal response

followed by a decrease in total stimulation, seems to be capable of being conditioned to a variety of external cues, it should be a basis of learned reward.* (See also Chapter 12).

* With certain aspects of sexual behavior, an attempt to formulate a consistent drive-reduction theory of learning appears to run counter to

Relative learnableness of different drives and rewards. Using an apparatus similar to the one illustrated in Fig. 1, Miller (1947) found that the moderately strong pain from an electric shock produces a much stronger learned drive than the hunger from a 22-hour period of food deprivation superimposed on a diet that held the animals considerably underweight. Was this difference produced by the greater strength of the pain, or by the suddenness of its beginning and end, in contrast to the slow changes in hunger? The pattern of cue without hunger cannot be quickly followed by reinforcement based on hunger and food; the pattern of cue without pain can be quickly followed by reinforcement based on pain. When such factors are controlled, will both these primary drives produce learned drives that are equally strong?

The verbal reports of human subjects indicate that, when a learned drive is acquired on the basis of pain, the cues do not elicit an hallucination of pain but, rather, only a part of the original pain-fear reaction, the part that is called fear. It is clear that fear is much more learnable than pain. Clinical evidence on hallucinations of pain suggests, however, that sometimes even the primary drive of pain may be learnable. This raises the question of whether the difference between the drives and rewards that are learn-

able and those that do not seem to be is one of kind or degree.

Lorenz's imprinting of releasers. Lorenz (1937) described instances in which complex behavior patterns involving strong motivations seem to be innately organized with the exception of one crucial link, namely, the determination of the stimulus pattern that will release them. The behavior pattern is innate, but the cue depends upon experience. For example, he reported that newly hatched ducks will follow the first moving object they see, be it a mother duck or a human being. He claims that this tendency is very quickly established, can occur only during a specific brief period of development, and, once set up, is irreversible. Furthermore it may determine the objects toward which later patterns, such as courting behavior, are exhibited.

Having observed ducks following Lorenz in typical formation, the author believes that they would probably learn a new response in order to get out of a cage that prevented them from following. Further work is necessary to determine (1) whether this type of behavior follows the same laws as other learnable drives, or (2) whether its mode of acquisition, its alleged irreversibility, and its limitation to a particular period of development are enough to set it apart as a new type of learning or as a phenomenon (imprinting) entirely different from learning.

Some General Problems

Learnable drives versus learnable rewards. According to the drive-reduction hypothesis, stimulus situations acquire drive value if responses that increase stimulation are reinforced by a subsequent reduction in the total strength of drive. They acquire reward value if responses that reduce stimulation are reinforced. It is impossible for the same situation to be a drive and reward simultaneously, but these two effects could be produced in rapid succession or in slightly different contexts. For example, entering a food box could first serve as a

introspective experience. The overall picture of the mounting tension from sexual motivation, the orgasm, and the consequent sharp decrease in tension seem to fit the pattern, but many of the subgoals are experienced as pleasant and striven for in spite of the fact that they appear to involve increases rather than decreases in the total amount of stimulation. These, however, often may be observed to lose their goal value and be avoided rather than sought if they consistently fail to be associated with eventual drive reduction, either directly or through the mediation of fantasies associated with masturbation or nocturnal emission. On closer examination these subgoals may be found to involve rapid fluctuations between increases and decreases in total stimulation, or they may turn out to be genuine and instructive exceptions to the generality of the drive-reduction principle.

learned reward, and then, if food were not forthcoming, it could arouse learned drive. Furthermore an increase in external stimulation may produce a reduction in total stimulation, as when a fairly strong light seen by a person lost at night reduces a very strong fear.

Other theories of reinforcement (contiguity, confirming reactions, pleasure, or

expectancy) might allow the same stimulus to act simultaneously as drive and reward. To date there are no experiments that indicate whether a given stimulus can act simultaneously as a learned drive and reward or that show the conditions that determine whether it will act as one or the other.

Mediated learned drives or rewards. An experiment by Miller (1935*b*) illustrates a

FIG. 8. Conditioned galvanic skin responses mediated by thoughts. The subject was presented with *T* followed by an electric shock, and *4* not followed by shock, in an unpredictable order. He named each symbol when he saw it. After a discrimination had been established, the subject was presented with a series of dots and instructed to think *4* when he saw the first dot, *T* when he saw the second, *4* when he saw the third, etc. The figure shows his galvanic responses to presentations 1 to 5, 11 to 15, and 21 to 25. (From Miller, 1935*b*, p. 65.)

mediated response, presumably fear. To human subjects he presented in unpredictable order the symbols *T* (followed by electric shock) and *4* (not followed by shock). The subjects soon reported that *T* always preceded shock and *4* never did, but it took them much longer to learn the emotional discrimination of giving a large conditioned galvanic response to the *T* and a small one to the *4*. During this training the subjects read each symbol aloud. From this we should expect the galvanic responses to be conditioned not only to the sight of the symbols but also to the cues produced by pronouncing them. If this is true, any other stimulus causing the subject to say the same words should also elicit the same conditioned galvanic responses. In order to test this the subjects were presented with a series of dots and told to say *4* to the first one, *T* to the second, *4* to the third, etc. When they did this, the small and large galvanic responses were immediately transferred to the alternate dots. As a further test subjects were instructed to think *4* and *T* instead of saying them aloud. As Fig. 8 shows, the thinking of *T* in response to one dot elicited a large galvanic response, and the thinking of *4* a small one. This apparent functional equivalence between saying a word aloud and thinking it is the justification for tentatively calling them both "cue-producing" responses. It shows that the cues produced by these two responses are similar enough for generalization to occur from one to the other.

In another experiment Miller (1935*a*) predicted that rats should behave "foresightfully" because fear and avoidance would be mediated by cues from a distinctive anticipatory goal response. This prediction was confirmed.

A simplified social example of a mediated fear is shown in the accompanying theoretical diagram. (1) By actual punishment

a child is taught to fear the thought of punishment. (2) By purely verbal threats he is taught to respond to the sight of a new forbidden object with the thought of punishment. After this the sight of the forbidden object elicits the thought of punishment, which evokes fear. If the child withdraws, the sight of the object and the thought of punishment are removed and the fear subsides. This reinforces withdrawal. (3) Eventually the sight of the forbidden object directly elicits fear and withdrawal.

Presumably, learned rewards can be mediated in a similar manner. For example, once the phrase, "this is good," has acquired the capacity to elicit relaxing, rewarding responses, these responses should be transferred to any new situation the subject learns to label as "good." Many of the techniques of advertising and propaganda seem to involve this mechanism. An attempt is made to change a subject's motivational responses to a given stimulus situation by getting him to label it with phrases such as "in style," "out of style," or "aggressor nation" that already have drive or reward value.

When a person is convinced that something he has not yet experienced is a means to an end he already desires, that thing tends to become a subgoal. Presumably this behavior is produced by mediated learned drives and rewards.

An important feature of mediated learned drives and rewards is that by the simple expedient of the learning of a new label (i.e. cue-producing response) complex motivational habits built up over a period of many years can be quickly elicited. Thus, labeling an idea as "the Chief's" or getting the subject to label it as his own may immediately elicit motivations that have been slowly learned during the subject's previous life. Similarly, making a decision or labeling one course of action as the one that is accepted and others as rejected may produce an immediate shift in the balance of

motivations, as Lewin (1947) has pointed out.

Removal of inhibition from responses that produce learned drive or reward. One of the properties of responses is that they can be inhibited by conflicting responses. Thus response-produced drives and rewards should be subject to inhibition, and the removal of the inhibition should produce an increase in the net strength of the drive or reward. For example, a young man might be motivated by fear to suppress all the responses that would normally produce sexual excitement in the presence of a girl. The fear that produces the inhibition might be removed directly by experimental extinction in that situation, indirectly by the generalization of extinction from other situations involving girls, or by the introduction into the situation of reassuring stimuli. If the fear was aroused indirectly via some cue-producing response, such as the thought that she was married, it might be reduced by eliminating that response, as would occur if the young man heard that the girl was divorced. However produced, the effect of any reduction in the inhibiting fear would be to increase the net sexual drives and rewards.

Goal-directed learned drives. Miller and Dollard (1941) made a stimulus-response analysis of the learning of one goal-directed drive, copying. In one example a subject who could not sing on key was trying to copy the notes sung by a teacher who also served as a critic. In this case the goal was to sing the same note as the teacher. They analyzed the process of learning to copy into the following factors which are roughly sequential but overlap considerably.

1. In the beginning the subject's trial and error was almost entirely random and completely dependent on the corrections of the critic.

2. Eventually the subject learned to respond with mild tension and anxiety to the cue of a difference between his own response and that of the teacher. As he learned to discriminate smaller differences, he was moti-

vated to try to correct his own mistakes without the need for criticism from the critic. The reduction in tension whenever he approached a perfect match rewarded the correct response.

3. The subject learned to respond to the direction of the difference by singing higher when he was flat and lower when he was sharp. Thus trial and error was restricted to the direction of the goal.

4. The subject learned to respond to the size of the difference by making a larger correction when he was farther off and a smaller one when he was nearer.

5. The subject learned to respond immediately with the proper note. This eliminated the need for random behavior and for approximation and correction.

It can be seen that having the drive attached to the cues produced by a difference and the corrective responses attached to the direction and size of that difference is what gives the goal-directed quality to the behavior in this example.

This type of analysis could probably be extended to situations in which the subject learns to attach responses producing a drive to cues produced by the conflict between an anticipatory goal response and the direct responses to the features of the immediate environment that prevent the complete goal response from occurring. In human behavior the cue for the learned drive may be a discrepancy between a verbal statement of a goal and the current stimulus situation. For example, a subject may learn to feel anxious in a situation that arouses the two thoughts: "I must get to this class on time," and "I am late." It is obvious that the rigorous analysis of complex examples of this kind will pose many problems of perception and language.

Whiting (1949) observed that many of the drives children learn during socialization are directed toward definite goals. He advanced the hypothesis that the conflict between an anticipatory goal response and the direct responses to the immediate environment pro-

duces a stimulus that is strong enough to serve as a drive, instead of merely as a cue. Some evidence suggesting that conflict can produce stimuli strong enough to function as a drive was presented by Miller (1944, p. 462).

Combinations of a number of drives and rewards. If learnable drives are produced by responses, it should be possible to attach a number of them to the same cue. In our society the desire for money is the focus of many drives, and possession of it is reinforced by many rewards. To date none of the experiments on learnable drives or rewards has shown how the effects of a number of different primary drives or rewards summate when they are all attached to the same stimulus.

Differentiation. If learnable drives and rewards obey the same laws as responses, discrimination training should narrow the range of cues that elicit them. General observation suggests that learning can make drives and rewards more specific, but this has not been experimentally analyzed.

When, as a result of differentiation, the same drive-producing response is attached to two quite different sets of socially defined cues, it may seem like two different motives. To take an extremely simple example, one animal might be motivated to escape from white compartments, and another to turn off buzzers. The observer who did not know that both responses were based on fear might be tempted to describe these motives by different names, white avoidance and buzzer drive, and from a practical point of view these two motives would be quite different. Similarly one might speculate that many socially acquired drives, such as guilt, pride, the desire for power, and the need for approval, are composed of a considerable element of fear. This fear might be blended with different mixtures of other motives, but according to this hypothesis the main distinctiveness of these drives lies in the conditions of social training that cause specific categories of cues to arouse the fear, and

other specific categories of cues to serve as goals because they reduce it. It is interesting to note that we speak of the fear of disapproval, the fear of failure, and the fear of losing status, money, or love.

Differences between innate and learned drives. If a drive is innate, it should follow the principles of physiology; if learned, it should be governed by the principles and conditions of learning. Thus learned drives should exist in a baffling variety of combinations that vary with the specific conditions of learning. It seems impossible to make a definitive list of them. A number of apparently different learned drives (such as claustrophobia, ambition, and conscience) all may involve the same physiological mechanism (such as fear), and they may be distinctive only because the social conditions of learning have caused different classes of stimuli to elicit the drive in each of the different cases. The situation is further confused by the fact that some learnable drives, like nausea, are named by the internal mechanism involved, and others, like avarice, by their external goal objects. Finally, as Miller and Dollard (1941) noted, learned drives may extinguish when innate ones would persist, and they may be reinforced instead of satiated by success in achieving a goal.

STUDIES AT A COMPLEX HUMAN LEVEL

Thorndike's studies. Thorndike (1940) has illustrated the great diversity of human wants. He studied what people spend their time and money on and attempted to measure the strength of various motivations by equating them with different sums of money in a questionnaire technique, the generality of which has not been tested against other criteria. He also reported (1935) a lengthy series of experiments that demonstrate that changes in the subject's ratings of his liking or disliking of objects, such as poetry, Christmas cards, and colored papers, can be

produced by the rewarding of certain responses and not of others. He believed that these experiments indicated that mere contiguity is not effective in producing such changes, but, as he himself pointed out, they are not completely controlled in this respect. Furthermore his ratings have not been validated against other indices, such as the amount the subjects actually would pay for the objects.

Subjects who were hired to repeat unpleasant acts, such as handling a snake or drinking cod-liver oil, rated them as being less unpleasant after many repetitions. Thorndike noted, however, that repetition is not always effective (some people never lose their distaste of cod-liver oil or alarm clocks, or their love of turtle soup or golf). He concluded that it is safer to look for specific causes than to attribute decreases to a general tendency for negative adaptation. He pointed out that one of the difficulties in the teaching of new motivations is in being able to elicit and identify them so that they can be immediately rewarded. In general Thorndike's (1935, 1940) two books are full of important observations on human motivation. His experiments raise many interesting questions without giving definitive answers.

Level of aspiration. Studies of the level of aspiration, summarized by Lewin et al. (1944), yield insights into human motivation. Some workers have focused their attention on contemporary factors in the field; others (e.g. Sears, 1940) have tried to include the social conditions and principles of learning. A systematic development of the latter approach should throw additional light on learned drives and rewards. Davis (1948) and Ford (1949) showed how much cultural conditions of learning, such as social class, influence the tendency to strive for specific goals.

Effect of barriers. Studies of the effects of barriers illustrate the advantage of taking learning into account. From his ingenious experiments Wright (1937) concluded that a

barrier usually enhances a positive valence. But Child (1946) showed that this preference for the more difficult goal is not present with young children. It increases with age and thus presumably with social training. Furthermore, when children are asked about it, their answers reveal a great variety of motives, many of which are obviously products of social learning.

Experiments on "group decision." Lewin (1947) summarized a series of studies that compared the effectiveness of different techniques in motivating people to change their behavior. In a typical study the problem was to get housewives to try serving a non-preferred kind of meat during World War II. The investigators found that a group of housewives who participated in a discussion, made a public decision by raising their hands, and were told that there would be a follow-up study to check on what they did were much more likely to serve the non-preferred meat than another group who listened to a lecture without making a public decision and without being told to expect a follow-up study. In this pioneer stage these investigators have tended to lump together a number of factors, such as hearing the views of other group members, having a chance to express one's objections, being required to make some immediate public or private decision, etc. Their emphasis upon the contemporary factors in the field has tended to make them relatively less interested in determining how the various motivational effects, such as copying other members of the group (Miller and Dollard, 1941), were learned.

Other studies of changes in human needs and goals are summarized in Lewin (1946).

Human personality. If many of the important adult human motivations are learned or are greatly modified by learning, they should exist in a baffling array of combinations and blends that are difficult to decode without a detailed knowledge of the great variety of learning conditions to which the different individuals have been exposed. As

Allport (1937) pointed out, this is exactly what seems to occur; there is a great variety of human motives and goals, and these are an important aspect of what is commonly referred to as differences in the ego, or personality.

Allport also maintained that once these drives are learned they may become functionally autonomous so that they do not extinguish. This position has been criticized by McClelland (1942) and Rethlingshaefer (1943). In Fig. 7 we saw that a strong learned drive might seem to be unaffected for many trials and still eventually extinguish. When generalization, higher-order reinforcement, and shifts from one reinforcing agent to another are added to this possibility, it can be seen how difficult it is in complex human situations to determine whether or not a habit actually is functionally autonomous.

Although the answer may be difficult, the general problem is exceedingly important. Some learned drives are amazingly resistant to change; others change easily. Great differences may be observed in this respect between different motives in the same person and between the same motive in different people. Sometimes a motivation can be changed with relatively little effect upon the rest of the personality; at other times its removal produces a profound effect upon the whole personality. What are the exact principles (including constitutional factors) determining such differences? How are hierarchies of learned drives and rewards built up, and how do they interact?

It can be seen that the theoretical and experimental work has a long way to go before it bridges completely the gap between the fundamental biological drives and the wonderfully complex web of socially learned motives that determine adult human behavior.

Emotion

DONALD B. LINDSLEY
Northwestern University

Emotion is one of the most complex phenomena known to psychology. It is complex because it involves so much of the organism at so many levels of neural and chemical integration. Both subjectively and objectively its ramifications are diffuse and intermingled with other processes. Perhaps therein lies the uniqueness, and possibly the major significance, of emotion.

It appears that any final description of emotion must be in terms of a reacting mechanism; furthermore it appears that the scientific study of emotion must be confined to emotional behavior, broadly interpreted, and to its underlying mechanisms. Nevertheless the problem is not simple, even when we approach it in this objective manner, because in emotional behavior many bodily changes occur within the organism that are not directly observable. Postural orientations, facial expressions, gestures, and vocalizations provide some external indications, but even these, because of their dynamic qualities and their relation to other bodily processes, require more detailed examination than casual observation can provide. These external indications are not universally acceptable criteria of emotion, because they are highly susceptible to cultural and social modification and they are admixtures of voluntary and involuntary modes of response. Skin reactions such as blanching, blushing, and sweating provide external signs of a reflexive character in some of the more intense emotions, but only sweating (galvanic skin response) can be used very

adequately as an index of mild emotional responsiveness. Although the overt signs of emotion are utilized daily in social adjustments and personal evaluations, it is difficult to be sure just what aspects of the various expressive changes constitute the basis of prediction. It is hard to know how adequately behavior can be interpreted on the basis of these clues alone, independent of the stimulus situation and the projection of one's own feelings into the interpretation of the emotional expression of another.

In general the topic of emotion has been approached via two principal aspects: the experiential or feeling aspect, and the expressive or behavioral aspect. The former has been studied by introspective methods; the latter by way of inferences based upon observed behavior. Both procedures are notably unreliable and both have led to highly speculative theories of emotion.* Nevertheless such basic data as there are on emotion have come largely through the study of its expressive aspects and objectively recorded bodily changes.

BODILY CHANGES AND THEIR MEASUREMENT

Emotion is characterized by many combinations of bodily change. There are overt

* For an excellent historical account, see *Feeling and Emotion: A History of Theories* by Gardiner, Metcalf, and Beebe-Center (1937). Another source of historical reference is *The Psychology of Feeling and Emotion* by Ruckmick (1936).

manifestations that are readily observable, and there are organic and physiological changes that are revealed only by special procedures and recording devices. All bodily changes during emotion are dependent on complex underlying processes that become integrated by the autonomic nervous system, the cerebrospinal system, and the endocrine glands. The complexity of these interactions makes it clear that the measurement of bodily change in emotion can never be definitive or exhaustive. We can only hope, by judicious choice, to make our procedures reasonably representative of the activity of the organism as a whole. A single measure may be useful under certain conditions, but two or more well-chosen measures will usually facilitate the interpretation of results.

Some of the measurable bodily changes in emotion and the techniques for recording them have been described by Landis (1934), Ruckmick (1936), Darrow (1943), Wenger and Ellington (1943), Young (1943, 1948), and Davis (1948). Therefore it will suffice to describe briefly each process or bodily change and to indicate one or more methods of measurement. Reference will be made to only a few selected studies, usually those that have a particular bearing upon the technique of measurement. A complete bibliography of all the studies employing one or more of the methods of measurement would be prohibitive.

The development of polygraphs, multi-channel amplifiers, and associated inkwriting and optical oscillographs has greatly facilitated the simultaneous recording of autonomic and somatic responses that occur in emotion. Electrical recorders make possible the study of phenomena whose processes are accompanied by electrical activity, or whose movements or pressures may be transduced to electrical form. Among those having an electrical basis are brain waves, muscle action potentials, galvanic skin responses, electrocardiograms, and eye blinks. Skin temperature measurements are transduced electrically by means of a thermocouple. Respi-

ration and blood pressure, usually recorded by a pneumatic system, can be recorded electrically by means of suitable mechanical-electrical transducers such as microphones and strain gauges. It has even become possible to record remotely, without encumbering wires, the electrical phenomena originating in a subject at a distance. This is accomplished by a miniature transmitting system worn by the subject as he moves about, and a suitable receiving system at the recording station (Prast and Blinn, 1949; Breakell, Parker, and Christopherson, 1949).

Electrical Phenomena of the Skin

One of the most popular measures of autonomic activity associated with affective and emotional states is the *galvanic skin response* (GSR). This phenomenon is known by various other terms such as psychogalvanic reflex, skin resistance, palmar resistance, palmar conductance, electrodermal response, and skin potential. They are all related to *sweating*, the effector mechanism for which is the sweat gland membranes, activated by the sympathetic nervous system.

Féré introduced the method of measuring resistance of the skin to a current externally applied. Consequently this method of measuring sweat gland activity is known as the *Féré method*, or the exosomatic method, since an external source of current is utilized in the measurement. The resistance of the skin is believed to be due to a polarization-capacity effect that varies as a function of the sweat gland activity (Gildermeister, 1915; McClendon and Hemingway, 1930). Tarchanoff discovered the skin potential change known as the *Tarchanoff method*. Since this potential difference arises from currents in the skin, it is said to be an endosomatic method. It may be that the skin potential, like the resistance of the skin, arises as a function of the polarization-capacity effect due to secretion of sweat. Another explanation is that it is associated with the contraction of the smooth muscles in the sweat glands. Favoring this latter view

is the fact that the form and time characteristics of the potential wave are similar to those of smooth muscle potentials recorded elsewhere in the body.

The exosomatic method has the advantage that it provides a measure of skin resistance level and a measure of the transitory changes in resistance that accompany sensory or emotional stimulation. An unfavorable aspect is that the resistance level frequently increases steadily as a subject relaxes, and rises to still higher levels during sleep. When discrete responses are recorded they are accordingly superimposed on a shifting resistance level. This means that two responses of the same magnitude, but superimposed on different resistance levels, will not be recorded as equal. To avoid this confusion Darrow (1934, 1937) adopted a method of expressing the resistance change in terms of log conductance multiplied by a factor of 100. Conductance, or the reciprocal of resistance, is expressed in micromhos. Such a measure is similar to a percentage resistance change, which has been employed by others to compensate for the variation in resistance level. The unit of measurement of the GSR has been discussed by Hunt and Hunt (1935), Haggard (1945), Lacey (1947), and Lacey and Siegel (1949).

The neural and effector mechanisms of the sweat glands underlying the GSR have been the subject of study and discussion by Richter (1930), O'Leary (1932), Greenwald (1935), Solomon (1935), Schwartz (1937), Darrow (1937), and Richter and Levine (1937). The evidence indicates that the nerve supply is exclusively sympathetic, but the neurohumoral agent at the effector is acetylcholine rather than an adrenergic substance. In this connection Darrow (1943) points out that electrical response may therefore be complicated by factors other than sympathetic nerve discharge. Skin resistance increases under light anesthesia and during sleep, and it is high in newborn infants; in all these instances the level of diencephalic and forebrain excitation or acti-

vation is reduced, probably owing to decreased sensory influx. In line with this explanation is the fact that the GSR is particularly sensitive to sensory and ideational stimuli, especially those associated with alertness, attention, apprehension, and arousal. The resistance level is lower, and the magnitude of response (drop in resistance) is greater to specific sensory stimuli. The GSR, perhaps more than any other indicator of bodily change (with the possible exception of blood pressure and heart rate), is a sensitive index of cortical and higher-level mental functions. Its use in lie detection and deception studies attests this fact.

Circuits and recording methods in use prior to 1935 have been critically evaluated by Greenwald (1935); others who have published details of circuits and recording methods are Floyd (1935, 1936), Forbes (1936), Jeffress (1937), Lauer and Anderson (1938), Hoelandt and Stovkis (1939), Stoddard and Fisk (1940), Grant (1946), Haggard and Gerbrands (1947), and Lacey and Siegel (1948). Although most investigators have used the resistance method, there are certain advantages to the endosomatic or potential method. With amplifiers of high input impedance it is relatively free of influence from the changing resistance level, although the resistance level as a measurement per se may well be an important factor. Furthermore the potential method is less complicated to handle experimentally and in all probability is actually a less complex response. Ordinary resistance-capacity coupled amplifiers, such as those employed in recording brain potentials, are applicable to the study of latency and magnitude of the response, but they do not provide a true picture of waveform. The ideal would be a d-c amplifier, but stable d-c amplifiers of adequate sensitivity unfortunately have not yet become available. An example of the GSR recorded as an electrical potential from two small electrodes in the palm of the hand is shown below (see Fig. 5).

Blood Pressure and Volume

Of the various measures of bodily change in emotion, Darrow (1936) argues that blood pressure and galvanic skin reflex (sweating) are probably the best indicators of facilitative, preparatory, or emergency functions mediated predominantly by the sympathetic system. In animals under anesthesia, or with cord or brain stem transected, blood pressure may be measured by a direct method with a cannula inserted in an artery so that pressure effects may be transmitted directly to a pressure capsule and a recording instrument. However, with intact animals or human subjects one must resort to an indirect method such as balancing an external pressure against an artery. This is usually accomplished by inflating a pneumatic cuff around one of the limbs and connecting it to a pressure recorder. The device for measuring blood pressure is called a *sphygmomanometer*.

There are two measures of blood pressure, *systolic* and *diastolic*, and the difference between them is known as *pulse pressure*. Systolic pressure is the maximal pressure reached during the contraction of the heart; diastolic pressure is the least pressure during expansion. In measuring these by the auscultatory method of Korotkow, a stethoscope is applied over an artery below the blood-pressure cuff. The pressure in the cuff is raised to a point where circulation in the artery is occluded and the heart sounds can no longer be heard in the stethoscope. The pressure is immediately but gradually released, and the first pulse sounds heard indicate the point at which the systolic pressure is to be read from the mercury manometer. As the pressure in the cuff decreases further, a point is reached where the pulse sounds disappear or only muffled sounds are heard. A reading at this point gives the diastolic pressure. There are also devices that give visual indications of the beginning of pulse oscillations at the systolic level and their cessation at the diastolic level.

For experimental purposes a continuous method of recording is usually desirable. It is extremely difficult to measure systolic pressure continuously, although several methods have been developed (Darrow, 1937; Stovkis, 1938; Doupe, Newman, and Wilkins, 1939). Many experimenters have accepted a compromise and record what is known as *relative blood pressure*. The cuff is inflated to a level above diastolic pressure, but where it is not uncomfortable and does not occlude circulation. Variations in pressure from this level are recorded continuously. The significance of these changes is not always apparent in terms of absolute pressures, but the relative pressures can be correlated with other happenings during the course of an experiment.

The effect of vasomotor changes, vasoconstriction and vasodilatation, are reflected in the size or volume of a particular part of the body. Usually a finger, hand, or foot is used for this purpose, the particular part being enclosed in a *plethysmograph*. Variations in volume increase or decrease the pressure in the closed system and reflect vasomotor changes. Unfortunately what occurs in peripheral parts is not always correlated with vasomotor changes elsewhere, especially those in cerebral vessels. Nevertheless this measure of the changes in peripheral vessels has been used in a number of studies (see Lhamon, 1949). In animals such as the rabbit, light shone through the thin ear tissues permits photometric measures of vasomotor changes.

Electrocardiogram and Heart Rate

The electrocardiogram (EKG) may be recorded from electrodes attached to the two arms or to either arm and the left leg. These are the standard EKG leads, but electrodes attached to the body wall in the neighborhood of the heart will also pick up the spreading electrical potential that accompanies the cycle of the heart beat. The pattern has a typical recurring form that enables a cardiologist to analyze the perform-

ance of the heart, but in general the pattern has not proved very useful as a measure of emotional change. The heart rate, which can be measured from the recurring pattern (see Fig. 5), reflects both sympathetic and parasympathetic effects, but, as Darrow (1943) pointed out, it should be used with caution as an index of balance between these two systems since it is subject to subsidiary reflexes via the carotid sinus and other moderator nerves. Another consideration is the fact that the slightest movement of a part of the body may produce a temporary change in rate. Heart rate may be measured by plotting the duration between individual beats or by counting the number of beats during an interval of time.

The *cardiotachometer* is a useful device for counting the number of heart beats. Another device is the Fleisch *Zeitschreiber*, also known as a *cardiochronograph*. It draws successive lines whose height is proportional to the duration of each heart cycle, so that heart rate per minute is immediately apparent. The use and description of cardiochronographs is given by Whitehorn, Kaufman, and Thomas (1935), Whitehorn and Richter (1937), and Henry (1938).

Respiration

The usual method of measuring respiration is by thoracic and/or abdominal pneumograph—a flexible air-filled tube connected to a sensitive rubber or metal diaphragm that moves a pen or stylus (see Higley and Renshaw, 1937). A strain gauge or carbon microphone button may be adapted for use as a mechanical-electrical transducer for the electrical recording of respiration. Another method of recording is by spirogram (see Finesinger, 1944). The principal respiration variables are rate, depth, pattern, and inspiration/expiration ratio. Although respiration is a complex indicator subject to voluntary control, it is mainly regulated reflexly through the respiratory center in the medulla, which responds to changes in blood chemistry, especially carbon dioxide and

oxygen levels. Respiration is also subject to interference by various other reflexes such as coughing, sneezing, sighing, and yawning. Despite these complications respiration is frequently a sensitive indicator in certain emotional situations, especially startle, conscious attempts at deception, and conflict (Brower, 1946). The respiratory pattern is frequently disturbed in anxiety states.

Skin Temperature

The measurement of skin temperature in emotion has not been used extensively, apparently because of technical difficulties. The usual method is to apply a thermocouple to the skin area concerned. Variations in temperature produce a change in the electrical current in the thermocouple. Skin temperature is mainly a function of local vasoconstriction, although the temperature of the blood, and of the body generally, is regulated by a variety of factors. Emotional stress is reported to produce a fall in skin temperature when the sympathetic supply to the part is intact, but it does not vary with emotional state when the sympathetic is interfered with, as in Raynaud's disease (Mittelmann and Wolff, 1939, 1943). Conflict is associated with vasoconstriction and a fall in temperature, whereas uninhibited action and emotional security are said to result in vasodilatation and a rising skin temperature.

Pupillary Response

The antagonistic action of the sympathetic and parasympathetic systems is manifest in the action of the pupil. Dilatation is mediated through the sympathetic system; the preganglionic fibers originate in the upper thoracic region of the cord, and the postganglionic fibers in the superior cervical ganglion (see Fig. 1). Constriction is mediated by the parasympathetic system with preganglionic fibers originating in the midbrain and traversing the oculomotor nerve (III cranial) to the ciliary ganglion, whence impulses are transmitted via postganglionic

neurons. However, the pupillary response is complicated by synergic action of the sphincter and dilator muscles whereby inhibition of tone in one may facilitate the action of the other. Midbrain, diencephalic, and even cortical points have been found where stimulation will produce changes in pupillary diameter.

Pupillary response to pain and to emotional stimuli has been studied by Bender (1933), who made motion pictures of the pupil. A similar procedure was used by Lindsley and Sassaman (1938) in studying the latency and size of the pupillary response associated with a generalized sympathetic reaction. A pioneer in the study of the pupil in a variety of clinical conditions, including emotional reactions, was Löwenstein, who also reviewed progress in pupillography (Löwenstein and Friedman, 1942). A recent development in pupillography is the use of infrared illumination and infrared sensitive film. This eliminates the constriction induced by the light reflex when the illumination necessary for ordinary photography is used.

Salivary Secretion

The secretion of the salivary glands has not been used extensively in the study of emotion, although the secretion of the parotid gland in particular has been studied in connection with conditioning procedures. Wenger and Ellington (1943) described a method of measuring salivary output as an index of autonomic activity. Finesinger, Sutherland, and McGuire (1942) studied the output of the parotid gland in psychoneurotic patients in response to an auditory stimulus. Winsor and Korchin (1938, 1940) studied parotid outflow during different kinds of stimulation and mental activity.

The salivary glands are supplied by both sympathetic and parasympathetic nerves, if not directly, at least to the blood vessels. The secretion resulting from parasympathetic stimulation is usually thin and watery, whereas that after sympathetic stimulation

tends to be thick and mucouslike. This corresponds to the general observation that emotional excitement, anticipation, fear, and anger often seem to produce a dryness of the mouth due to predominance of sympathetic activity. It would appear that greater use might be made of parotid secretion in studies of emotion.

Pilomotor Response

The small smooth muscles that lie at the base of hairs and cause them to stand up when one is afraid or chilly are innervated solely by sympathetic fibers. Therefore this response should constitute a good measure of sympathetic activity. It is evoked by a wider variety of stimuli than is generally recognized and seems particularly subject to conditioning. In some person it accompanies a sneeze, probably as a conditioned element to the reflex elevation of hairs and the production of "goose flesh" when chilly. The scraping of a piece of chalk on a blackboard will also often produce a shivering response and pilomotor activity. Lindsley and Sassaman (1938) studied a subject who had gained voluntary control over the ability to erect the hairs on the surface of the body and who could put them up or down at will. They studied the pilomotor response by two methods. Motion pictures of the hairs were studied in order to determine latency and magnitude of the response. A hypodermic needle electrode system inserted at the base of the hair permitted the electrical recording of smooth muscle potentials from the arrectores pilorum muscles responsible for the elevation of the hairs. A number of associated sympathetic effects were also studied. This voluntary phenomenon is believed to be a type of conditioned response. A movie made of this case is listed with the Psychological Cinema Register.

Dermographia

A reaction that has been utilized by Wenger and Ellington (1943) is that of red dermographia. It is produced by a firm,

constant pressure stroke, with a rounded instrument, on the arm of a subject. The immediate appearance of the stroked area is one of blanching or whiteness, followed in a few seconds by redness. Latency is measured to the beginning of redness, and total duration of the response until the redness disappears, which may require from 3 to 30 minutes or more. Such a reaction is probably a better measure of autonomic balance or stability than of emotional response or susceptibility per se.

Skin Sweating

In addition to the galvanic skin response as an index of palmar sweating and sympathetic activity, there have been several types of chemical applications that reveal the distribution of sweating on the surface of the body. A colorimetric method was described by Silverman and Powell (1944). Wenger and Gilchrist (1948) tested this method against the galvanic skin response in the case of palmar sweating and found it to be less reliable than the GSR. Since it reveals areas of differential sweating, the method is probably mainly useful for diagnosing clinical cases where lesions affecting the sympathetic system are suspected. It seems possible that it might also be applied to probiems involving differential autonomic activity in certain emotional states.

Analysis of Blood, Saliva, and Urine

A number of chemical constituents of the blood have been shown to be affected by emotional stimulation (Gellhorn, 1943). Among them are blood sugar level (Gildea, Mailhouse, and Morris, 1935), adrenin content (Diethelm, Doty, and Milhorat, 1945), pH or acid-base balance, red blood cells, blood platelets, and numerous other factors. The taking of blood samples can be accomplished at intervals, but it is a somewhat complicated procedure if many samples are to be taken during the course of an experiment. Tests of reaction to the injection

of glucose and insulin are made by taking blood samples at specified intervals, and these tests frequently reveal activity of both the sympathico-adrenal and vago-insulin systems (Diethelm, 1936). Urine may be analyzed for excess sugar excretion from samples taken at intervals before, during, and after emotional stimulation. A significant factor revealed by urine analysis appears to be the output of ketosteroids, a metabolic product resulting from steroids secreted by the adrenal cortex during stressful activities, especially those involving emotion (Pincus and Hoagland, 1943; Hoagland, 1947). Salivary samples can be taken continuously. A factor of interest in connection with salivary secretion is the pH or acid-base balance (Gaskill, 1933; Winsor and Korchin, 1938), which has been shown to vary with stimulation, mental activity, fatigue, etc.

Gastrointestinal Motility

A good deal of work has been done on the motility of the stomach and intestine in animals under emotional, electrical, and chemical stimulation. Cannon (1915, 1929) demonstrated that emotions of fear or anger inhibit activities in the gastrointestinal tract. Todd and Rowlands (1930) demonstrated similar reactions in man by X-ray and fluoroscopic examination after barium milk and buttermilk meals. The action of the stomach has also been studied by means of an inflated stomach-balloon, connected to a recording device.

Metabolic Rate

The rate of oxygen consumption or basal metabolic rate (BMR) is generally increased in emotions involving excitement and general bodily mobilization. It is likewise increased following a meal, even though action of the parasympathetic system may at such a time predominate, and excitement and activity may be minimal. Metabolism is usually recorded on a fasting stomach after a period

of relaxation and rest. A standard BMR machine is used for this purpose. Metabolism is markedly affected by the activity of the thyroid gland, which in turn is under the influence of the pituitary gland.

Muscle Tension

A common symptom of anxiety is somatic tension. Many emotional reactions of more sporadic nature involve varying degrees of generalized muscular tension. It seems particularly important in the study of bodily changes in emotion to secure measures of visceral change and also of somatic activity. Muscle tension can be recorded by means of mechanical tension recorders, but a more convenient and perhaps more adequate sampling of muscular activity can be obtained from the recording of muscle action potentials.

With electrodes placed over the active muscle group, Travis and Lindsley (1931) showed that with increasing intensity of contraction the frequency and voltage of the recorded waves increase. This can also be demonstrated by means of needle electrodes inserted in the muscle mass (Lindsley, 1935), where the response of a group of muscle fibers innervated by a single nerve fiber, known as a motor unit, will show increased frequency with increasing tension, but the magnitude of the unit response remains constant.

For purposes of recording the muscle tension associated with emotional reactions, surface leads are preferable since more of the muscle activity can be surveyed.

The relation of muscular tension to frustration and performance has been studied by Davis (1938). Courts (1942) has reviewed the literature in this field. Jacobsen (1938) has summarized his results of studies of muscle tension in relation to therapeutic measures for inducing relaxation. In general, insufficient use has been made of electromyography or muscle action potentials as indicators of muscle tension in emotional

states. More than one muscle group should be sampled in recording muscular tension since postural factors and shifting body movements can produce differential degrees of contraction in the various muscle groups.

A method of recording muscular tension in psychiatric patients mechanically has been described by Ruesch and Finesinger (1943) who used handwriting pressures as an index.

Tremor

The tremor of emotional excitement, anger, fear and even grief is well known. Tremor is found in conditions of tension where antagonistic muscle groups are pitted against one another, but it is also found under some conditions in relative relaxation and rest. The extended fingers of any normal individual will manifest a fine, rhythmic tremor of about 10 to 12 oscillations per second (Travis and Hunter, 1931). Jasper and Andrews (1938) attempted to determine the relation between tremor rhythms of the fingers and the cortical alpha rhythm, which typically has a frequency about like the tremor frequency. Although they concluded that there was some relation between cortical rhythms and peripheral tremors, the evidence does not seem to be unequivocal, and it appears that the correspondence in the frequency may be partly fortuitous.

Luria (1932) recorded tremor mechanically by means of a pneumatic system. He found that emotional conflict externalized in motor performance led to tremor and disorganization of motor response. An improved form of the Luria tremorgraph has been described by Langer (1936). Others who have used or discussed this technique are Runkel (1936) and Reymert and Speer (1939). Berrien (1939) has used finger tremors as indices of emotion.

Eye Blink and Eye Movement

The significance of the eye blink as a measure of emotion or emotional tension is not known. Excessive eye blinking, like other

facial tics, seems to suggest a kind of "nervousness." There are evidences that it may be increased with emotional arousal and excitement. The electrical potentials associated with eye blink may be recorded by attaching small electrodes to the skin at the corner of the eye and above the eyebrow, or for that matter anywhere in the neighborhood of the eye. Records of eye blink show that there are different patterns of blinking in different people; in some there may be continuous blinking; in others, sporadic groups of rapid blinks; and in still others blinks may occur singly or doubly at irregular intervals. The eye blink needs further study in relation to emotional tension and anxiety.

Eye movement can be recorded by appropriately placed electrodes in the region of the eye. With one electrode on the edge of the nose and another above the eyebrow, movements of the eyeball either laterally or horizontally will be recorded (Lindsley and Hunter, 1939). The effect is due to the static polarity potential of the eyeball, which when rotated produces an electrical change relative to the two electrodes. The significance of eye movements for emotion is little understood. Nevertheless, it is a motor outlet that seems to participate in excitement, embarrassment, and other emotional reactions.

The foregoing bodily changes are all possible indicators of emotional response. However, it should be strongly emphasized that in order to use them intelligently, we need a thorough knowledge of the underlying processes they signal or indicate. Furthermore it should be recognized that each of these possible measures represents a dynamic process integrated in various ways with other processes. This is especially true of the autonomic and endocrine systems, and of the central nervous system as well. The following section attempts to provide an overview of some of the basic factors underlying emotional mechanisms.

NEURAL AND HORMONAL MECHANISMS

The importance of emotion and the nature of its widespread influence have been emphasized by Sherrington (1948) in the foreword of a new edition of a book first published in 1906. He says, "The process by which a reaction of merely 'quantum' order is biologically raised to molar dimensions is called by some biologists 'amplification.' A means to 'amplification' is emotion. As physical stimulus a ghost may be of barely threshold power; but given emotion, and it can convulse the whole individual."

Elsewhere in the same book he states:

Of points where physiology and psychology touch, the place of one lies at 'emotion.' . . . It has a special physiological interest in that certain visceral reactions are peculiarly colligate with it. Heart, blood-vessels, respiratory muscles, and secretory glands take special and characteristic part in the various emotions. These viscera, though otherwise remote from the general play of psychical process, are affected vividly by the emotional. . . . To the ordinary day's consciousness in the healthy individual the life of the viscera contributes little at all, except under emotion. The perceptions of the normal consciousness are rather those of outlook upon the circumambient universe than inlook into the microcosm of the 'material me.' Yet heightened beating of the heart, blanching or flushing of the blood-vessels, the pallor of fear, the blush of shame, the Rabelaisian effect of fright upon the bowel, the secretion by the lachrymal gland in grief, all these are prominent characters in the pantomime of natural emotion. Visceral disturbance is evidently a part of the corporeal expression of emotion. [P. 257.]

Since emotional response may involve somatic and visceral activities, both the autonomic nervous system and the central and peripheral parts of the cerebrospinal nervous system enter the act. We need, therefore, to understand both the autonomic system and the phylogenetically newer cerebrospinal

system. We need to understand the neuro-humoral factors concerned with the transmission of impulses at synapses as well as with the final disposition of impulses at neuro-effector junctions. And we need also to appreciate the role played by the hormonal factors secreted by the endocrine glands. A general description of these systems and functions is given in Chapter 6. Here we shall review those aspects of them that are of particular significance in emotion.

The Autonomic Nervous System

For much of our basic knowledge of the peripheral autonomic system we are indebted to Gaskell (1916) and Langley (1921). It was Langley who distinguished its two principal parts, the *sympathetic* and *parasympathetic* divisions.

Figure 1 shows the widespread ramifications of the autonomic nervous system. For the sake of simplicity, only the *efferent* outflow of the autonomic is shown on the left, and only the *afferent* pathways are shown on the right. Actually it is debatable whether there are any true autonomic afferent pathways at all, since most of the incoming sensory pathways from the viscera have their cell bodies in spinal or cranial dorsal root ganglia rather than in the ganglia of the sympathetic or parasympathetic systems. However, there is a sensory influx from the various receptors and nerve endings of the viscera, blood vessels, etc., but these incoming pathways may be more properly called *visceral afferents*. Furthermore these pathways pass through the sympathetic ganglia, although they do not have their cell bodies in the ganglia, nor do they synapse there; instead they enter the cord with the dorsal roots of the somatic sensory nerves (see Fig. 2).

These visceral afferent pathways may synapse in the lateral horn of the gray matter of the spinal cord upon visceral efferents, thereby forming *viscero-visceral reflexes*; they may synapse upon internuncial neurons in

the gray matter which connect with somatic efferents, thereby forming *viscerosomatic reflexes*; or they may synapse in other spinal segments or proceed to the region of the nucleus solitarius in the medulla, where they may participate in brain stem reflexes or be relayed to the thalamus. Buchanan (1948) states that visceral sensations, like somatic pain sensations, reach the conscious level in the thalamus. However, there does not yet appear to be any clear evidence of this. Although localization and intensity differentiation for somatic pain are thought to be functions of the cerebral cortex, it is doubtful that such differentiations are made for visceral sensations. This is an important point, and whether visceral afferent impulses reach the thalamus (for which there is at present no conclusive evidence) and the cortex (for which there is also apparently none) are crucial factors for the James-Lange theory and perhaps also for other theories.

Let us now return to the efferent autonomic pathways. There are three principal groups of efferent outlets for autonomic impulses, but two of them may be combined because of structural and functional similarities. These are the *cranial* and *sacral* divisions of the *parasympathetic system*. In Fig. 1 it will be noted that the efferent neurons of the cranial division of the parasympathetic system issue from the III, VII, IX, and X cranial nerves, whereas those of the sacral division originate in the I, II, III, and possibly IV sacral segments of the lower cord. In this figure all parasympathetic efferent cells of origin (preganglionic neurons) in the brain stem or cord are symbolized by an open circle. Likewise the postganglionic neurons of the parasympathetic, which are always in or near the structures they innervate, have their cell bodies represented by open circles. Note that the parasympathetic components of the III, VII, and IX cranial nerves send their preganglionic processes to special ganglia where, after synapse, a postganglionic neuron then conducts the impulses to a nearby effector.

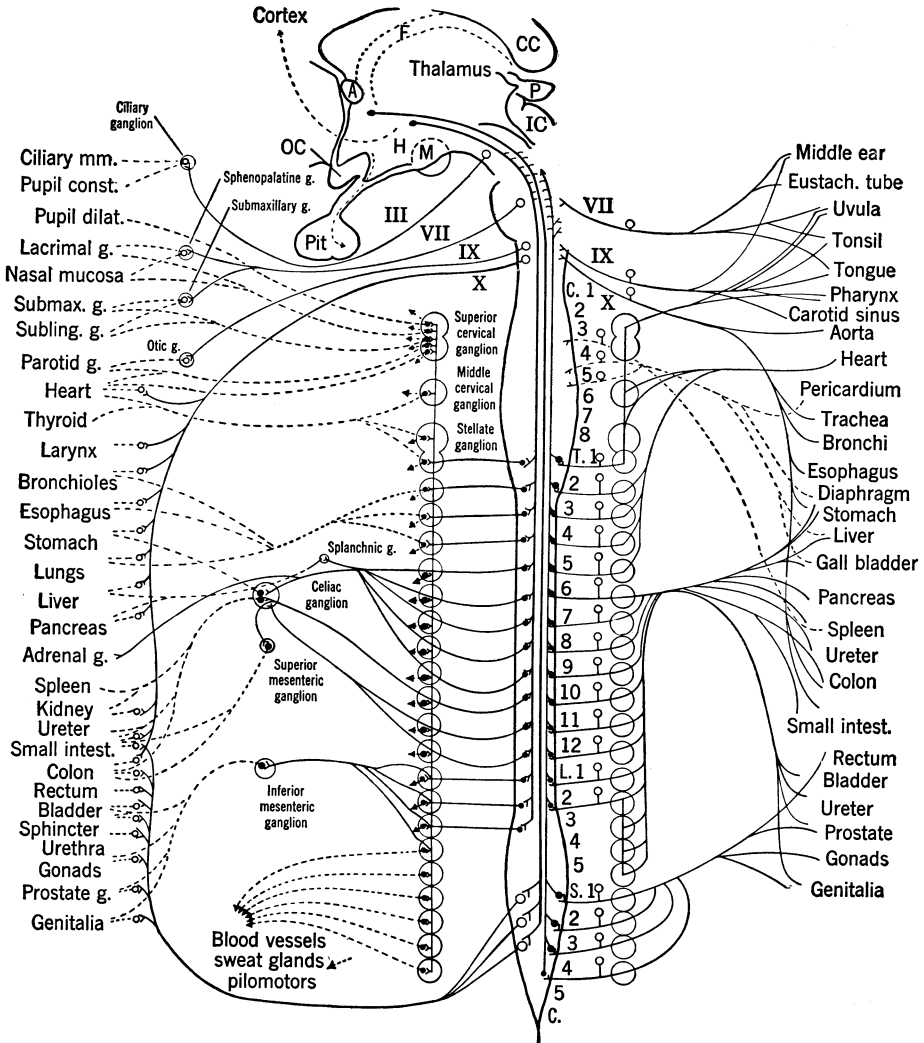

FIG. 1. Schematic representation of the autonomic nervous system, showing the central origin and the peripheral termination of *sympathetic* and *parasympathetic efferent pathways* on the *left* and the origin of *visceral afferent pathways* on the *right*. Cell bodies of pre- and postganglionic neurons of the parasympathetic system are symbolized by open circles; those of the sympathetic system, by solid circles. Arrows projecting from sympathetic chain ganglia symbolize postganglionic fibers to blood vessels, sweat glands, and pilomoters. Dotted lines on left of figure represent efferent postganglionic fibers; those on right are nonautonomic fibers of the phrenic nerve. Key: A—anterior commissure; CC—corpus callosum; F—fornix; H—hypothalamus; IC—inferior colliculus; M—mammillary bodies; OC—optic chiasma; P—pineal body; Pit—pituitary or hypophysis. (After Mettler, 1948; Buchanan, 1948; Strong and Elwyn, 1943; with modifications.)

Note also that each of these effectors has counterbalancing innervation by the sympathetic system, shown by the dotted lines emanating from the superior cervical ganglion of the sympathetic chain.

We may now turn to the sympathetic division, whose preganglionic efferents (cell bodies shown by solid black circles) have their cells of origin in the lateral horn of the gray matter of the spinal cord. These preganglionic neurons either terminate in a chain of ganglia lying alongside the cord, where they make synapse with postganglionic fibers, or they proceed through these ganglia without synapse to special ganglia, where postganglionic neurons transmit the impulses to the effectors. There is one exception to this arrangement for sympathetic pathways, namely, the adrenal glands. The schema shows the preganglionic neuron issuing from the fifth thoracic segment and giving off a branch, which without synapse extends to the adrenal medulla, where it may synapse with a local postganglionic neuron, although there is a possibility that it has direct access to the adrenal medulla by means of a chemical mediator (acetylcholine). In either case, in contrast to most other sympathetic innervation of autonomic effectors, which are said to be *adrenergic* and liberate sympathin, an adreninlike substance, the chemical mediator at the adrenal gland is acetylcholine, and therefore the innervation is classed as *cholinergic*. Other exceptions to the general rule that parasympathetic nerve endings liberate acetylcholine as a chemical mediator, whereas sympathetic endings liberate an adreninlike substance, will be mentioned later.

The manner in which the trunks and ganglia connect with the spinal cord is shown in Fig. 2. The autonomic or visceral efferent preganglionic neurons have their origin in the lateral horn of the gray matter of the cord and exit through the ventral root of the spinal nerve, from which they proceed via the white rami to the particular ganglion of the chain in which they are to synapse.

When synapse occurs between pre- and postganglionic neurons, the latter rejoin the spinal nerve via the gray ramus. In some cases the preganglionic neuron passes through the trunk ganglion and synapses at a special ganglion nearer the organ innervated. This is also illustrated in the diagram.

These arrangements, it will be recognized, permit a diffuse and widespread interconnection of the effects of sympathetic discharge. Another condition favoring diffuse discharge, especially in the sympathetic system, is the fact that for each preganglionic neuron entering a sympathetic ganglion there are as many as thirty-two postganglionic neurons represented. Since it is conceivable that a whole pool of postganglionic neurons is activated by the discharge of a single preganglionic neuron, the possibilities for summation and diffusion of peripheral response are great. In essence, this diffusion and reinforcement of sympathetic discharge is what Cannon and others have demonstrated: the sympathetic system is primarily one for meeting emergency situations by rapid mobilization of the bodily resources. Furthermore the adrenal medulla is at least partly innervated by preganglionic fibers, and medulliadrenal secretion or adrenin in the blood stream reinforces the effects of sympathetic nerve impulses.

As Cannon and Rosenblueth (1937) point out, however, there are exceptions to the diffuse discharge of the sympathetic system. For example, impulses from sympathetic nerves are continuously discharging into certain smooth muscles of the blood vessels and the nictitating membrane (a covering of the eye of the cat).

Despite its usefulness in emergencies the sympathetic system is not absolutely essential for existence. The complete ganglionic chains and special sympathetic ganglia may be removed from animals such as cats without serious detriment to their existence in the well-regulated environment of the laboratory. Cannon et al. (1927, 1929) did this as a test of the James-Lange theory and found

it made no difference in the animal's emotional response. However, when such an animal is exposed to marked changes in temperature, loss of blood, or lowering of blood

eral sympathetic control, Cannon and Rosenblueth (1937) describe a substance thought to be liberated at sympathetically controlled effectors. This substance, called *sympathin*,

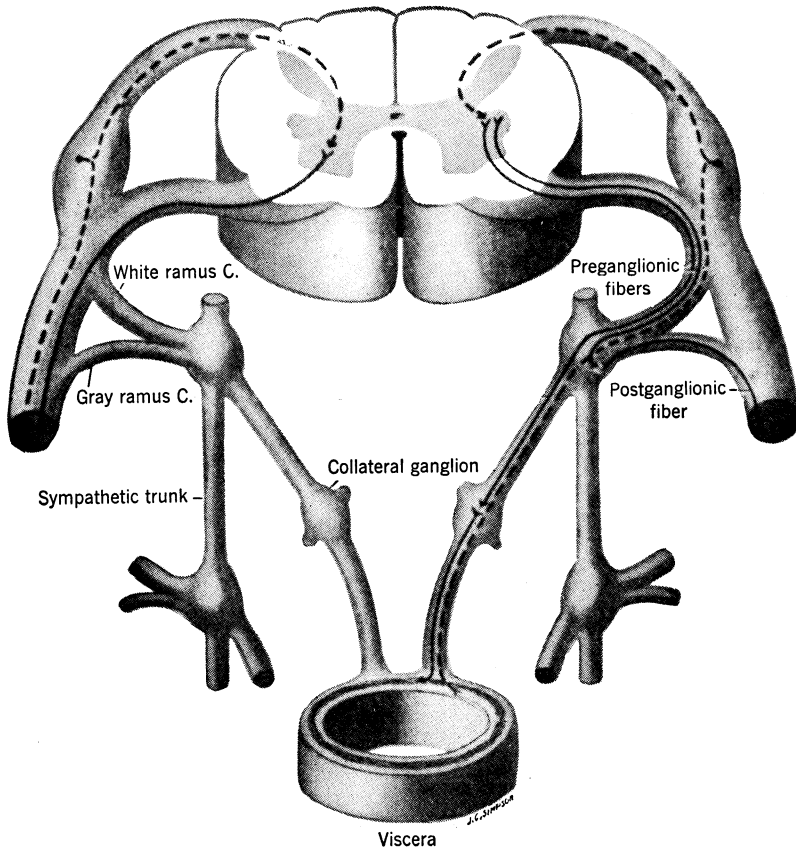

FIG. 2. Schematic diagram illustrating relation of sympathetic ganglia and pathways to spinal nerves and the spinal cord. Somatic afferent and efferent paths are shown on the left; visceral afferent and efferent paths are shown on the right. Afferent neurons are shown by broken lines; efferent neurons by continuous lines. [After Cunningham's *Textbook of Anatomy* (J. C. Brash and E. B. Jamieson, Eds., 7th Ed., 1937), London: Oxford University Press; with two modifications.]

sugar level, the deficiencies in the homeostatic or regulating mechanism become apparent. Cannon (1935) provided numerous examples of the way in which the autonomic system tends to preserve steady states in the internal milieu of the organism.

In addition to the potentiation effects of adrenin liberated into the blood stream and circulated to responsive structures under gen-

has been shown to have many features in common with adrenin, although the two are probably not identical. Sympathin has a less strong and less widespread effect than adrenin. The excitatory substance, *sympathin E*, has effects similar to those of adrenin; another type known as *sympathin I* has an inhibitory action. Both substances are thought to be liberated by some combi-

nation of chemical processes at sympathetic nerve effectors. Because of this adreninlike substance liberated by sympathetic nerve impulses, sympathetic innervation is frequently referred to as *adrenergic*, meaning adreninlike in its action. However, as Dale (1934, 1935) has pointed out, there are some obvious exceptions to the adrenergic nature of sympathetic action. First and foremost is the fact that at the synaptic junction of pre- and postganglionic neurons in the sympathetic system a *parasympathomimetic substance, acetylcholine*, is liberated, rather than a *sympathomimetic substance* such as *adrenin* or *sympathin*. The cholinergic nature of sympathetic innervation of the adrenal medulla has already been mentioned. Another example is the sweat gland which is not aroused to secretion by adrenin (or by injections of adrenaline, a synthetic commercial product) and yet is stimulated to profuse activity by pilocarpine and acetylcholine and is paralyzed by atropine, an anticholinergic drug. Obviously this is another case of a sympathetic nerve having cholinergic action. Still another example is vasodilatation of the mucosa of the dog's mouth by sympathetic discharge, but absence of this response to injection of adrenaline. Finally, it should be pointed out that the somatic innervation to skeletal muscles is also accompanied by cholinergic action. This fact, were it not for the rapid manner in which acetylcholine is destroyed by blood esterase, might lead to severe contractures, if the effects of parasympathetic activity were potentiated by circulation of acetylcholine.

Dual innervation. Figure 1 shows that most of the structures under the control of the autonomic system have a double innervation shared by sympathetic and parasympathetic divisions. In general these two systems have opposing effects that facilitate regulation of visceral activities and assist in the maintenance of homeostasis. According to Cannon (1930) the diffuse arrangement of the sympathetic tends to make it work as a unit, whereas the action of the parasympa-

thetic may be specific for individual structures. Hence, by *diffuse* action of the sympathetic division and the opposite *particular* action of the nerves composing the sacral and cranial portions of the parasympathetic division, various gradations in the activity of any structure may be provided for both locally and temporally.

It is at this point that we can see the complexity that must characterize emotional reactions and their manifestations in the various structures influenced by the autonomic nervous system. What any given indicator or measure of activity in a particular structure reveals in the way of increased or decreased activity must be evaluated in terms of what other autonomic indicators are doing, not only by way of specific adjustment to the particular stimulating situation but in relation to the total function of the autonomic system.

Cannon (1930) summarized the actions of the various divisions of the autonomic. The *sacral division* functions mainly as a group of reflexes for emptying hollow organs that are periodically filled. The pressure created by the contents in such a viscus as the rectum, the colon, or the bladder sets up visceral impulses that reflexly initiate emptying action through sacral efferent nerves. Similar reactions may occur in connection with the seminal vesicles and the uterus, although here the picture is more complex. In addition to reflex response produced by local distention, emotions may produce discharges over the sacral nerves, as evidenced by involuntary voiding of bowel and bladder at times of great fear and stress. Hall (1934) and others have made use of this fact to measure emotional behavior in the rat. Similarly the various stimulations by sight, touch, smell, etc., give rise to sexual excitement involving not only sacral discharge and activation of the sexual apparatus but endocrine and somatic activity as well (Beach, 1942a, b).

The functions of the *cranial division* are characterized by Cannon as a group of re-

flexes that serve protective and conservative functions. Examples are the protective function of pupillary constriction, the secretion of salivary and digestive juices and the maintenance of tone in the alimentary tract, and vagal control of insulin secretion for regulating glycogen storage in the liver. Like the sacral division it may be involved in emotional reactions and affective states. For example, pleasurable tastes and smells facilitate gastric functions, whereas nausea and vomiting may be induced by the sight and smell of unsavory objects.

A significant fact about the sacral and cranial divisions is that their activities are much more subject to interference by voluntary control than are the activities initiated by the sympathetic system. The striated muscle of the sphincters of the bowel and bladder under voluntary or cerebral control can oppose the actions of the sacral division. In speech and respiratory functions the voluntary control of striated muscle often interferes with, although it does not always override, activities of the cranial division.

The *sympathetic division* is concerned with the maintenance of stability in the internal fluid matrix of the organism despite disturbing external influences. In case of hemorrhage the sympathetic acts to constrict vessels and prevent further loss of blood and facilitates coagulation or clotting. In sudden extremes of temperature the sympathico-adrenal system comes into operation to regulate heat loss. Oxygen lack produces compensating heart and circulatory reactions. Under the influence of strong and prolonged muscular exercise, accumulation of metabolites and development of acidity in the blood is accompanied by compensating increases in respiratory and circulatory functions initiated by the sympathetic division.

Central connections. It appears that, upon entering the cord through the dorsal spinal roots, some of the visceral afferent axons terminate upon cell bodies in the dorsal gray columns, giving off axons that pass upward a few segments. By successive relays

these may eventually reach the medulla and possibly the thalamus. Neurosurgical evidence suggests that some of the visceral pathways, especially those conducting visceral pain, pass upward to the thalamus in the lateral spinothalamic tract, since bilateral cordotomy by Hyndman and Wolkin (1943) was found to relieve renal pelvic pain. However, anatomical evidence seems not to have traced the pathways for visceral afferents beyond the medulla. If visceral afferents reach the thalamus it is uncertain to what particular nucleus they go, and there is as yet no evidence that they reach cortical levels unless one insists that to be conscious of such pains implies cortical reception. Conscious awareness of visceral pain, but without localization and discrimination, is attributed by some to a thalamic level.

However that may be, we are concerned for the moment with higher-order reflex connections of visceral afferent pathways at the level of the medulla. Since centers for the regulation of respiration, blood pressure, and other vital functions have been demonstrated in the medulla, it is evident that the incoming visceral afferents have a good deal to do with these regulatory functions. The evidence for such reflex connections and their effects is dealt with in detail by Kuntz (1945).

There is accumulating evidence (Moruzzi and Magoun, 1949; Lindsley, Bowden, and Magoun, 1949) that exteroceptive and proprioceptive pathways in passing through the lower brain stem give off collaterals into the reticular formation which extends from the lower brain stem through the tegmentum of the midbrain and into the hypothalamus and thalamus (see Figs. 3 and 9). This system is believed to be part of a diffuse projection pathway to the cortex. That the visceral afferents also contribute collaterals to the reticular formation is a possibility, but it has not been demonstrated. Thus it may be seen that exteroceptive and proprioceptive impulses have two means of influencing cortical activities: a direct projection via relay

in the thalamus (Fig. 9; paths 1 and 1'), and a diffuse projection via the reticular formation and the intralaminar and reticular nuclei of the thalamus (Fig. 9; paths 3 and 4). The evidence for the latter is not complete, although some evidence for it will be

these statements is based upon localized lesions in the hypothalamus and more specifically upon electrical stimulation, which in general has produced sympathetic responses over a major portion of the hypothalamus. It is still uncertain whether a distinct center

FIG. 3. Sagittal section of the brain. Stippled areas represent the principal structures involved in the central integration and control of emotional behavior. These include the frontal pole and orbital surfaces of the frontal lobes, gyrus cinguli, inner surface of temporal lobes, piriform area, hippocampal formation, uncus, and amygdala. Among subcortical structures are: thalamus, subthalamus, hypothalamus, fornix, pituitary, and the reticular formation extending to the lower brain stem. Although other cortical and subcortical areas are undoubtedly involved, these probably constitute the principal centers. (See Fig. 4 for an expanded view of the diencephalic region.) The numbers indicate Brodmann's differentiation of cortical areas.

described below. If interoceptive or visceral afferent pathways may be assumed to follow a similar course, at least as far as the thalamus, it will be significant for the central integration of autonomic effects in emotional behavior as well as in homeostatic adjustments of the organism.

Turning now to the efferent autonomic pathways we find that the principal center of origin for parasympathetic discharge seems to reside in the anterior portion of the hypothalamus and in the preoptic region rostral to it, whereas the principal focus for sympathetic discharge lies in the middle and posterior regions (see Fig. 1). The evidence for

for parasympathetic discharge is present in the hypothalamus. The wider distribution of sympathetic effects by electrical stimulation in the hypothalamus is in keeping with the unitary and diffuse nature of sympathetic discharge.

The Hypothalamus

The hypothalamus, although a comparatively small structure, is an extremely important one. It is concerned with the regulation of homeostasis, reproduction, and emotional behavior (cf. Chapter 6). In addition it plays a significant part in the control of the pituitary gland. It is part of the dien-

cephalon lying below the thalamus and subthalamus at the base of the brain in a relatively inaccessible position. Portions of it form the wall and floor of the third ventricle. As may be seen in Fig. 4, it lies immediately behind the optic chiasma. For purposes of

and Ranson and Magoun (1939), and an entire volume edited by Fulton, Ranson, and Frantz (1940) is devoted to clinical and experimental aspects. It will suffice here to mention only briefly the principal functions, the connections of the hypothalamus with

FIG. 4. Expanded view of structures important in autonomic regulation and in the control of emotional behavior. Diencephalic structures are stippled. Key: AC—anterior commissure; Amy—amygdala; CA—cerebral aqueduct; Cer—cerebellum; CN—caudate nucleus; FL—frontal lobe; GH—gyrus hippocampus; GS—subcallosal gyrus; IC—inferior colliculus; M—mammillary body; Med—medulla oblongata; MI—massa intermedia; OC—optic chiasma; OL—occipital lobe; P—piriform area; PC—posterior commissure; Pit—pituitary; SC—superior colliculus; Un—uncus. gross reference it may be divided into supra-optic, tuberal, and mammillary portions. On its base the tuberal region (tuber cinereum) gives rise to the infundibular stalk to which is attached the hypophysis or pituitary gland. The latter nestles in a small bony cavity in the floor of the skull known as the sella turcica.

The principal experimental findings related to the functions of the hypothalamus have been surveyed in detail by Ranson (1937)

and its relation to the pituitary, since these all have a bearing either directly or indirectly upon the problem of emotion.

Afferent fibers to hypothalamus from cortex, thalamus, and elsewhere. The hypothalamus receives fibers from the olfactory region, from the hippocampus, and from the frontal pole of the cerebral hemispheres, possibly via the septum and medial forebrain bundle. Furthermore fibers from the frontal

cortex relay via the dorsomedial nucleus of the thalamus to the posterior region of the hypothalamus. Numerous connections have also been found between the thalamus and hypothalamus. Papez (1937*a, b*, 1939) and Vonderahe (1935, 1943) discussed these and other connections of the hypothalamus in considerable detail and especially in relation to emotion.

Visceral afferent pathways have been mentioned previously. The anatomical evidence that they reach the thalamus or hypothalamus is not clear, yet some visceral sensation, especially visceral pain, occurs. Furthermore the sham rage response described by Bard (1928, 1934) was induced in decorticate dogs, with most of the thalamus removed, by pinching or otherwise stimulating peripheral receptors. This suggests that somatic sensory pathways reach the hypothalamus, either directly or through thalamic relays. Whether the same is true for visceral sensory pathways is not known, except that Bronk, Pitts, and Larrabee (1940) have shown that vagal impulses reach the hypothalamus.

The cortical connections with the hypothalamus have predominantly an inhibitory function, and it is the release of this inhibitory control by decortication that presumably produced sham rage in Bard's cats and dogs.

Efferent pathways. There are in all probability efferent pathways from the hypothalamus to the subthalamus and corpus striatum. The motor activity of Bard's decorticate cats both in and out of sham rage would suggest this. Other efferent pathways about which there is greater assurance are those that go to the thalamus, from whence they apparently relay to the cortex. Papez (1937*a, b*) traced a path from the gyrus cinguli through the hippocampus and fornix to the mammillary body and thence via the mammillothalamic tract to the anterior nuclei of the thalamus and back to the starting point in the gyrus cinguli. He believed this

a very significant series of interconnections in the neural mechanism of the emotions.

Descending pathways, arising from the region adjacent to the third ventricle, pass through the tegmental region of midbrain and pons and end eventually in the spinal cord where they synapse with sympathetic preganglionic neurons. All these descending pathways apparently give off collaterals to the reticular formation in the brain stem, but many of the fibers from the lateral nuclei seem to end there, perhaps synapsing with visceral efferents in the lower brain stem to participate in the vital regulatory functions of this area. Pathways representing parasympathetic functions and influencing the bladder, respiration, and blood pressure are said to originate in the preoptic region and the anterior hypothalamus, although not all evidence is in agreement that there is such a parasympathetic center.

The Endocrine and Neurohumoral Systems

Since a survey of the endocrine glands and their function has been given in Chapter 6, only a brief listing will be given here.

The pituitary is often known as the master gland because of its controlling influence upon so many of the other endocrines by means of *tropic* hormones of the anterior pituitary. Attention has already been drawn to the regulation of water metabolism by the hypothalamo-pituitary complex. In addition, the anterior lobe liberates growth and sex development hormones. Some of the regulatory functions of other endocrines are: *thyroid*—metabolism and temperature regulation; *parathyroid*—blood calcium level, which along with potassium has a marked effect upon excitability of receptors and effectors; *pancreas*—digestive juices and insulin secretion, the latter influencing sugar utilization and therefore blood sugar level, which in turn affects nervous function; *adrenal medulla*—potentiation of sympathetic effects, and also influence upon blood sugar level and blood oxygen through its effects on the liver and spleen, respectively; *adrenal*

cortex — a variety of functions through its various steroids, but especially mineral, water, and sugar metabolism.

The posterior pituitary is believed to antagonize the action of insulin and to heighten sympathetic irritability, whereas insulin is believed to increase parasympathetic irritability. As previously mentioned, the neurohumors, acetylcholine and adrenin, plus the adreninlike sympathin E and sympathin I, sensitize their respective autonomic effectors. Whereas somatic effectors deteriorate with nerve section, autonomic effectors do not, and they continue to remain sensitive to their appropriate neurohumors (see Cannon and Rosenblueth, 1949; Gellhorn, 1943).

Thus we see that not only are the sympathetic and parasympathetic divisions of the autonomic generally antagonistic to one another, but the antagonism extends to their neurohumors and to some of the secretions of the endocrine glands they innervate. An example of the latter is seen in the sympathetic innervation of the adrenal medulla and its hormone adrenin, and in the parasympathetic (vagal) innervation of the islands of Langerhans and the hormone insulin. Furthermore the autonomic nervous system and the endocrine glands are seen to have mutual interactions of both inhibitory and facilitatory character. As Gellhorn (1943) put it:

Not only do autonomic centers regulate the rate of hormonal secretions, but alterations in the secretion of various hormones alter the endocrine balance in the organism and lead to disturbances in the composition of the blood with regard to organic substances and ions, thereby profoundly changing the function of the autonomic centers and the central nervous system as a whole.

We shall turn now to some of the studies that shed light on the nature of central organization and control of emotional behavior.

Central Neural Organization in Emotion

Experimental lesions. Goltz (1892) observed growling, barking, and other forms of anger and rage responses in a decerebrate

dog. These responses arose from mere handling of the dog, which prior to the lesion showed no such reactions. After the operation the dog gave no evidence of joy or satisfaction and showed no sex behavior. Woodworth and Sherrington (1904), investigating the spinal pathways for pain in the decerebrate cat, observed similar behavior which they called "pseudodffective." The responses to nociceptive stimulation of the skin were said to simulate mimetic expressions of anger and defense, such as opening of the mouth, retraction of lips and tongue, snapping of jaws, snarling, lowering of head as if to attack, and increase in blood pressure. They observed that all responses were brief and did not outlast stimulation, in which respect they were unlike anger and rage in a normal cat.

Other observations on decerebrate preparations have been made by Bazett and Penfield (1922), Rothmann (1923), Schaltenbrand and Cobb (1930), and Keller (1932). In general these have shown, in addition to a poorly organized rage response of brief duration, a number of associated sympathetic reactions. In not all cases was there a complete absence of pleasurable reaction, for the cats studied by Bazett and Penfield and by Schaltenbrand and Cobb were said to purr on occasion.

Acute decortications in cats were performed by Dusser de Barenne (1920) and Cannon and Britton (1925) with the observation that a form of organized rage response could be elicited by the stimulation of ordinary handling and care. Cannon called this sham rage. It was characterized by a better organized and more intense display than in the decerebrate preparations and in general was set off more easily. Bard (1928) followed up this work with a special effort to localize the region critical for sham rage. He utilized acute and chronic preparations (1934*a, b*) and was able to localize the sham rage mechanism in the caudal half of the hypothalamus. Later Bard and Rioch (1937) described four cats with neocortex and vary-

ing portions of forebrain destroyed. These were chronic animals and survived for several months of observation and study. The authors looked for what, in a normal cat, would constitute emotional excitement and found evidence in these chronically decorticate animals of fear, rage, and sexual excitement. Fear was induced by loud high-pitched noises. In an animal lacking the medial geniculate bodies these auditory stimuli produced only erection of hair and twitching of the skin on the back. The behavior of decorticate animals has been further discussed by Rioch (1938) and by Bard (1939).

Their description of sham rage of chronic decorticate animals, usually with only the caudal portion of the hypothalamus intact but with varying amounts of brain stem structures remaining, is as follows: lowering head and body in crouch, raising back, drawing back ears, loud angry growling, hissing, biting, striking with claws unsheathed, erection of hair, pupillodilatation, retraction of nictitating membrane, and widening of palpebral fissures. The response was prompt and strong, but poorly directed; it involved both somatic and visceral components. They concluded that the response was made possible by release of cortical inhibitory control of the hypothalamus.

Bromiley (1948), in the course of establishing discriminative conditioned responses to light and sound in a decorticate dog that survived for 33 months, made note of the fact that sham rage behavior could be elicited throughout this time. Barking, growling, snarling, and snapping characterized its rage behavior when its cage was manipulated, or in some cases when it was handled gently. Continued progressive movements against obstacles is said to occur in this and other decorticate animals, to the extent of producing sores on scalp and feet.

Bard and Mountcastle (1947) have pointed out that the responses of decorticate animals suggest *hyperexcitability* and that the low threshold for the rage response is a *release phenomenon*. Since Bard had pre-

viously located the mechanism for this response in the caudal hypothalamus, it seemed evident that some cortical region must normally suppress the sham rage response. Spiegel, Miller, and Oppenheimer (1940) have shown in acute experiments with cats that lesions involving the olfactory tubercles, the amygdala, or the hippocampal-fornix tracts are capable of producing rage reactions, although lesions of the frontal pole and elsewhere in the neocortex, or of the piriform region of the rhinencephalon, did not have this effect.

Klüver and Bucy (1938, 1939) found that bilateral temporal lobectomy in the monkey provided a marked contrast to the preceding results so far as emotional behavior is concerned. The monkeys were expressionless, and despite their curiosity about their surroundings, nothing seemed to produce anger, fear, resentment, or pleasure. Things that preoperatively would have produced marked emotional reactions did not do so after temporal lobectomy. For example, one monkey licked the fangs of a bull snake and was entirely casual about a severe bite on the hand from another monkey. The anatomic changes in these cases were later reported by Bucy and Klüver (1940) and involved among other things the hippocampus and fornix. According to Papez (1937) the hypothalamus, the anterior thalamic nuclei, the gyrus cinguli, and the hippocampus and interconnections, including the fornix, constitute a mechanism capable of emotional experience and expression.

In their later experiments Bard and Mountcastle (1947) removed the neocortex in cats, leaving the rhinencephalon and the gyrus cinguli (midline or transitional cortex) intact. Placidity was the result, with marked refractoriness to rage-producing stimuli. When the amygdala, the pyriform area, and the hippocampus were then removed in addition, the animal showed marked sensitivity to rage induction. The authors propose that inhibitory influences from the neocortex, the gyrus cinguli, and the other midline cortex,

as well as from the amygdala, all funnel through the amygdala. They also believe that a separate facilitatory or excitatory pathway by-passing the amygdala exists. The fact that Klüver and Bucy (1939), having destroyed essentially the same structures in the monkey, found their animals almost emotionless seems contradictory. However, the difference may lie in the addition of the lateral portions of the temporal lobes, or it may be that the inhibitory and excitatory functions that in the cat lie in the rhinencephalic region have migrated farther rostrally in the monkey.

Lesions of the hypothalamus in cats and monkeys were studied by Ingram, Barris, and Ranson (1936) and Ranson (1939). This region, when intact and stimulated electrically, gave rise to emotional excitement and fear and rage responses with multiple sympathetic reactions, and the opposite tendency appeared when the region was destroyed electrolytically. The animals lost all sign of emotional responsiveness, faces were masklike, and they developed a marked stolidity. In addition somnolence or a form of sleep was characteristic after lesions in the caudal part of the thalamus. Furthermore the cats with hypothalamic lesions manifested a form of catalepsy in which they could be molded to some extent and would hold the position. Although such animals are sometimes able to stand and walk, they seldom do so; they sink rapidly into sleep but can be awakened from it fairly readily.

Alert, active monkeys, Ranson (1939) found, were good subjects for hypothalamic lesions since the contrast in their postoperative behavior was so marked. Their faces became masklike, and they failed to show the characteristic amount of activity and vocalization. They slept much of the time but could be awakened by handling. In some animals the sleep took the form of drowsiness, apparently depending upon the location of the lesion. Lesions producing somnolence and sleep were generally in the region of the posterior hypothalamus and mammil-

lary bodies, sometimes toward the rostral midbrain. This general region has for some time been recognized as a sleep or waking center, depending upon one's point of view. As we have seen, stimulation of this region produces excitement and activity; lesions in it tend to produce somnolence, sleep, stolidity, and general inactivity. That sleep and its opposite, waking and emotion, may ultimately prove to have a number of features in common appears likely and will be touched upon in later discussion.

Electrical stimulation. Summaries of the results of a number of studies on electrical stimulation of the hypothalamus have been presented by Hess (1936), Karplus (1937), and Ranson and Magoun (1939). In general the results confirm the fact that the hypothalamus is a center for the excitation and integration of sympathetic effects such as are found in fear and rage reactions. For cats lightly anesthetized with nembutal, Ranson and Magoun (1939) reported that hypothalamic stimulation produced a rise in blood pressure, increased rate and depth of respiration, pupillary dilatation, and contraction of the bladder. Pilo motor and sweating reactions did not occur under light anesthesia. If stimulation is continued it will often produce somatic motor activities such as running and struggling movements. Some experimenters locate the principal focus of sympathetic activity in the posterior half of the hypothalamus, but others have observed sympathetic responses from a major portion of it. Parasympathetic responses are less definite but may be elicited from the anterior hypothalamus and preoptic region. They consist mainly of lowered blood pressure, decreased respiration, and bladder contraction.

Electrical stimulation in a waking cat with electrodes implanted in the hypothalamus produces rage reactions very much like those seen in the decorticate animals. These reactions show a sympathetic predominance with dilatation of pupils, piloerection, retraction of nictitating membrane, increased respiration, and restless behavior, with spit-

ting, biting, and struggling. Inhibition of gastrointestinal activities also occurs.

The results of electrical stimulation of the hypothalamus in animals have been partially confirmed by White (1940) in the electrical stimulation of the hypothalamus of conscious human patients under local anesthesia. He observed diffuse efferent discharge over the sympathetic system from stimulation of the wall of the third ventricle, in the region of the paraventricular nucleus. Stimulation in the anterior region of the hypothalamus near the preoptic nucleus produced some evidence of slowing of the heart and decreased blood pressure, suggesting parasympathetic activation. Of significance here are the observations that patients did not report any unusual sensation resulting from the electrical stimulation of the hypothalamus, and neither emotional changes nor alterations in the level of consciousness were noted. Mechanical manipulation in the region of the optic chiasma and anterior hypothalamus produced marked slowing of the heart, peristalsis, nausea, and vomiting, all parasympathetic reactions — which supports the belief that there is a parasympathetic center in the region of the anterior hypothalamus. Contrary to the results in animal experiments where electrical stimulation of lateral hypothalamic nuclei produced alertness and excitement together with sympathetic discharge, and where lesions produced drowsiness and somnolence, White found that electrical stimulation in human patients did not produce any alteration in the level of alertness. Manipulation near the anterior hypothalamus did tend to produce drowsiness, which he interprets as an effect of increased tone in the parasympathetic center depressing or inhibiting the "waking center" in the posterior hypothalamus.

On the basis of electrical stimulation of the hypothalamus and subthalamus in cats, Hinsey (1940) concluded that not only are sympathetic discharges produced but somatic movements as well. Apparently there are

levels of integration in the hypothalamus for somatic as well as autonomic activity.

Masserman (1941) reported a series of experiments designed to answer the questions: What are an animal's affective reactions to external situations during hypothalamic stimulation? How persistent is the response induced by stimulation of the hypothalamus? Does the induced activity modify or displace behavior occasioned by spontaneous effects? Do extensive lesions of the hypothalamus permanently change the emotional reactivity? And, finally, can the animal be trained to adapt to direct hypothalamic stimulation (hypothalamic conditioning)? Here and elsewhere (1943) he concluded that the fear and rage and other aspects of the pseudoaffective reactions induced by electrical stimulation of the hypothalamus differ significantly from true emotional states. The reaction, in addition to being undirected and brief, is described as mechanical, diffuse, stereotyped, and stimulus-bound, without apparent emotional connotation for the animal. In these respects it differs from normal expression of emotion in cats. He found further support for this conclusion in cats stimulated through electrodes implanted in the hypothalamus while they were engaged in normal behavior such as eating, purring, and cleaning. These activities were not interfered with by hypothalamic stimulation until vigorous motor components of the total pseudoaffective pattern disrupted them. He reported that an animal will continue to lap milk or respond to petting while being stimulated hypothalamically and while various sympathetic responses are in evidence.

With regard to hypothalamic lesions Masserman felt that the effects of large bilateral lesions in producing, as Ranson (1939) has shown, stuporous, somnolent, cataleptic, and emotionally apathetic states must be considered in the light of changes in metabolic and homeostatic functions. On the basis of his own experiments (1938), he concluded that if the animal recovers sufficiently to restore bodily economy the emotional be-

havior of the animal will return nearly to normal.

In an effort to determine whether the emotional reactions of electrical stimulation of the hypothalamus are accompanied by "meaningful subjective experience" Masserman attempted to condition various sensory stimuli to the response produced by electrical stimulation of the hypothalamus. The assumption underlying this procedure was that if hypothalamically induced behavior is accompanied by subjective meaning the various sensory conditional stimuli may then come to represent this experience and make possible the conditioning. He was unable to establish a conditioned response to lights, sounds, tactual stimuli, etc. He concluded that the hypothalamus does not behave as "an afferent, experience-mediating organ but as a way-station on efferent sympathetic and motor pathways." Another possible explanation of the failure of Masserman and others to condition electrically induced behavior is that the effect of an electrical field created in the region where the neural connection must be made follows so soon after the spreading of impulses from the conditioned stimulus to the effector circuit of the unconditioned response that any functional relation between the afferent and efferent circuits may well be obliterated. The effect of electroshock in obliterating or reducing previously learned habits might be a possible analogy.

Clinical and neurosurgical observations. The effect of manipulation of the hypothalamus during surgical operations on adjacent structures has been reported by several neurosurgeons and summarized by Gagel (1936) and Dott (1938). Mechanical manipulation of the hypothalamus by the neurosurgeon has been reported to produce maniacal excitement. The effects of tumors and other pathological disturbances in the general region of the hypothalamus are difficult to appraise because of pressure effects, interruption of pathways to and from other structures, etc. However, the clinical reports give

evidence of many of the symptoms that characterize patients who have frontal lobe pathology or have undergone frontal lobotomy. There is release from inhibition resulting in euphoria, accentuated flow of speech and ideas, restlessness, and lack of social inhibitions.

Alpers (1940), in summarizing the effects upon the personality of pathological lesions in the hypothalamus, emphasized four principal kinds of clinical features: emotional changes, intellectual deficits, personality disorders, and psychotic manifestations. Among the emotional changes are excitement, manic-like reactions with push of speech and ideas, swings of mood alternating between depression and excitement, emotional lability with a low threshold for uncontrolled laughter, and sometimes apathy and negativism. Since these kinds of emotional response may appear with lesions in other regions of the brain, Alpers looked upon the hypothalamus as one of a series of stations concerned with emotional expression. Similarly symptoms often referred to the cortex, such as memory loss and inability to concentrate, have been reported in connection with hypothalamic lesions. Alpers listed other personality changes such as carelessness, indifference, antisocial tendencies, lack of social restraint, and loss of appreciation of personality change. The psychotic manifestations included confusion, hallucinations, disorientation, manic excitements, and in some cases Korsakoff psychosis. Alpers claimed that the physical manifestations of excitement or mania, depression, or anxiety often are accompanied by subjective experiences characteristic of true emotional responses.

In discussing hypothalamic syndromes Kennedy (1940) stressed the fact that the hypothalamus is concerned with the control of numerous rhythmic processes. Among these he mentioned the regularity of the rhythm of breathing, constancy of the pulse, the cycle of sleep, balance of intake and output of fluid, menstrual periodicity, and exact maintenance of body temperature. Not all

of these are controlled solely by the hypothalamus-hypophysis complex, but, as he pointed out, lesions frequently bring out paradoxical and complex symptoms for which the diffusely acting sympathetic and the discretely acting parasympathetic, in combination with pituitary activation from the hypothalamus, are apparently responsible. Lesions in this area following epidemic encephalitis provide examples. He believed that the hypothalamus is concerned not only with *emotional expression* but also with *mood*.

Electroencephalographic studies. With the discovery by Berger (1929) that the brain has a recordable electrical beat, and with the further discovery by Adrian (1931) and Adrian and Buytendijk (1931) that isolated ganglia and parts of the brain give rhythmic potential oscillations independent of sensory influx, a new approach to brain function was evolved. The autonomous or self-maintained rhythmicity of various parts of the nervous system has led to new concepts of brain function and integration, but perhaps more important it has provided by its presence or absence or variations a new index of cortical activity. Reviews covering most of the early literature in this field have been presented by Jasper (1937) and Lindsley (1944). One of the earliest findings by Berger, many times confirmed by others, is the fact that in a relaxed state in the absence of special stimulation the dominant activity is a fairly rhythmic 10-per-second potential oscillation called the *alpha rhythm*. When light, sound, or other types of sensory stimulation are introduced, the alpha rhythm is blocked or markedly reduced. This has been variously explained as inhibition by a specific active area of the wider, spontaneously active region, interference by sensory influx and its irradiations with resting rhythms tending to produce desynchronization of the multicellular rhythmic beat, disruption at thalamic levels of presumed pacemakers for the several cortical rhythms, etc. However this may be, an interesting aspect

of sensory stimulation and its effect upon the alpha rhythm is that it seems to depend more upon attention or set under conditions of anticipation, or upon suddenness and unexpectedness, as in arousal by startle, than upon sensory stimulation per se.

Figure 5 illustrates the effect of a brief flash of light or a brief buzzer sound in blocking the alpha rhythm while the subject was sitting in the dark, relaxed, with eyes open. The blocking of the alpha rhythm by such sensory stimuli typically occurs about $\frac{1}{2}$ second after the onset of the stimulus; the alpha rhythm often returns 1 to 2 seconds after the cessation of the stimulus, unless the startle aspect of the stimulus has produced marked surprise, tension, and apprehension. This latter seems to be illustrated in Fig. 5 by the response to the buzzer.

Shown on the same records is a tracing of the galvanic skin response (GSR), here recorded as a change of electrical potential (Tarchanoff effect) from the palm of the hand, rather than as a resistance change (Féré effect). It will be noted that in association with both light and sound stimuli there is a GSR of moderate potential change with a latency of about 1.5 seconds. Also shown on the records is a tracing of the electrocardiogram (EKG) which provides a measure of change in heart rate, as well as other characteristics of heart action. We shall be concerned here, however, only with the changes in the EEG (electroencephalogram) and the GSR.

Since the GSR reflects the activity of the sweat glands, which are activated by sympathetic nerve impulses, it is apparent that a somatic sensory stimulation, light or sound, has activated the sympathetic branch of the autonomic system. At what level this comes about is not immediately apparent; it might be at the level of the lower brain stem, diencephalon, or cortex. The significant thing here is that any sensory stimulus that initially invokes a galvanic skin response tends, after repetition a number of times, to produce either no response or a very small

one. This is certainly true of the same auditory stimulus, although a change to a new and even weaker one may reinstate the response. Here then is a kind of adaptation or adjustment to repeated stimulation. The same is characteristic of the blocking of the alpha rhythm by auditory stimuli; visual stimuli are more resistant to this type of

perhaps suffice to show that the flux and flow of the ordinary daily environment, with its shifting sensory impressions, tends to produce continual changes in the level of autonomic activity and in the state of the brain's activity insofar as this is revealed by the electroencephalogram. This might be considered one of the lower levels of emo-

FIG. 5. Effect of unexpected light and sound stimuli upon the electroencephalogram (EEG), the galvanic skin response (GSR), and the electrocardiogram (EKG). Note that both light and sound stimuli block the alpha rhythm of the electroencephalogram after a latency of about 0.4 second; the galvanic skin response occurs after a latency of approximately 1 to 1.5 seconds. (From Lindsley, 1950.)

adaptation, although the instructions or anticipatory set may be a significant factor.

The initial effectiveness of a stimulus in blocking the alpha rhythm and in causing a galvanic skin response appears to be the "arousal aspect" of a new or unexpected stimulus. This seems to be like the situation involved in startle reactions, except that the intensity of the stimulus and the magnitude and diffuseness of the response may not be so great.

We seem to have here, in the effect of the sensory stimulus on the brain and autonomic system, an example of both central and peripheral influence. These examples will

tional responsiveness, and, if so, the organism might be described as being in a more or less continual state of emotional flux. That such activation does not have to be conscious has been suggested by the fact that subjectively subthreshold visual stimuli have been found to produce blocking of cortical alpha waves (Lindsley and J. R. Smith, unpublished observations). Likewise in records of GSR activity during auditory stimulation it appears likely that responses may be obtained to subjectively subthreshold stimuli.

To turn now to another phenomenon of the electroencephalogram, Fig. 6 illustrates in the records from a normal subject the

effect of apprehension and tension as opposed to a relaxed, nonapprehensive state. This phenomenon is familiar to all electroencephalographers, who frequently find that a normal subject or a patient brought in for an EEG is tense, worried, and generally apprehensive about the procedure. The initial ("apprehensive") record in Fig. 6

pulses, both peripheral and central, to play upon an activation mechanism, which appears to have its principal focus in the hypothalamus. This mechanism, apparently the reticular formation, extends into the thalamus and downward into the lower brain stem and permits discharge of impulses both centripetally and centrifugally. The conse-

FIG. 6. Electroencephalograms from a normal subject during initial "apprehensive" period and later "relaxed" period. Note reduction or suppression of alpha rhythm during apprehension. (From Lindsley, 1950.)

shows low-amplitude poorly developed alpha waves, and sometimes faster rhythms of low amplitude. After a few minutes of recording, the subject usually quiets down and assumes a relaxed state, with the result shown in the lower record of the figure. Here the alpha waves are well developed and of considerably greater magnitude than in the initial record. As will be shown later, this is probably an effect of "activation" or "arousal" and may be considered akin to the effects of discrete sensory stimuli in producing arousal with consequent blocking of the alpha rhythm and GSR activity. Physical tension and apprehension provide a persistent source of im-

quency of this action is to further somatic and autonomic activity peripherally, reduce alpha waves in the electroencephalogram, and substitute an activation pattern.

Cohn (1946) reports two general types of EEG patterns among patients with anxiety states characterized by excitement, depression, or general irritability. Type I shows reduced alpha-wave activity and low-amplitude beta waves; type II shows predominantly high-voltage beta waves mixed with alpha waves. In the first type the patient is generally tense, and presumably the resulting sensory influx tends to obliterate the alpha rhythm. Such a patient is said to show a more normal picture when dis-

tracted and relaxed, especially after a period of hyperventilation. The EEG of the second type is associated with increased emotionality and marked autonomic response.

The "anxiety" record shown in Fig. 7 appears to be similar to Cohn's type I EEG. It is the record of a man who broke under severe emotional strain during a wartime encounter with the enemy. The record

the effect of specific emotional arousals on the EEG seem to have confirmed these EEG changes (Williams, 1939; Thiesen, 1943; Harrison, 1946; Darrow, Pathman, and Kronenberg, 1946).

Effects of subcortical lesions and stimulation on the EEG. Some recent experiments by Lindsley, Bowden, and Magoun (1949) and by Moruzzi and Magoun (1949) con-

FIG. 7. Electroencephalograms illustrating absence of alpha waves in the records of a patient in an "anxiety" state and the well-regulated alpha rhythms of a "normal" subject. The former should not be considered pathognomonic of anxiety; furthermore the electroencephalograms of normal subjects and those of patients with anxiety cannot always be so readily differentiated. (From Lindsley, 1950.)

was taken sometime later when he had recovered, at least to the extent of appearing superficially "normal." The normal record, shown for contrast, was from a man who had shared the same battle experiences. The "anxiety" record was flat throughout and showed almost no evidence of alpha rhythm; hyperventilation did not change the picture.

The foregoing accounts of the effects on the EEG of unexpected sensory stimulation, apprehension, and anxiety all indicate some degree of emotional arousal or activation effect that tends to suppress the alpha rhythm and to increase the rapid, apparently desynchronized activity. Others who have studied

tribute to a better understanding of the electroencephalogram and seem to have explanatory value with respect to the effects of emotional arousal upon the EEG. The latter study demonstrated, among other things, that electrical stimulation of the reticular formation in the lower brain stem of the cat abolishes the large rhythmic potentials of the cortex under nembutal and replaces them with an "activation" pattern consisting of rapid low-amplitude waves. The activation pattern is not unlike the EEG pattern described above for emotional arousal and tension in human subjects. One is impressed by the fact that the increased sensory influx in these latter conditions may

feed into the reticular formation of the lower brain stem via collaterals from spinothalamic tracts and, like the effects of electrical stimulation, produce the activation pattern described.

The study by Lindsley, Bowden, and Magoun (1949) dealt with the simultaneous recording of electrical potentials from the cortex and thalamus in unanesthetized cats after transection of the spinal cord at the first cervical level, or after transection at higher brain stem levels. Transection at progressively higher levels in the brain stem permitted greater delimitation of the effects of the reticular formation on higher centers. Bilateral lesions in the hypothalamus toward the head end of the reticular system completely eliminated influx through the reticular formation. As more and more of the reticular formation was eliminated by higher transections at the level of the pons and the midbrain, the electrocortical pattern changed from one of activation with the initial cord transection to one of increased synchronization. Bilateral lesions in the hypothalamus eliminated all fast activity composing the activation pattern and introduced rhythmic synchronized large waves that occurred in "bursts" or spindlelike formations similar to those of normal sleep. Thus the removal of sensory influx via the reticular formation, which normally imposes its influence upon the hypothalamus, thalamus, and even the cortex via the diffuse projection system, permits the thalamus and cortex to beat with their own spontaneous rhythms in a waxing and waning pattern. Simultaneous recording from certain nuclei in the thalamus and from the cortex demonstrated that these rhythms occur in unison, thereby indicating that there is some form of thalamocortical linkage. The similarity of these bursts of rhythmic activity to the normal sleep spindles is of special interest, since the "waking center" appears to be in the posterior region of the hypothalamus, and, as previous experiments have shown, lesions in this area produce

somnolence and drowsiness. According to Kleitman's (1939) theory of sleep, the influx of sensory discharge into the waking center must be markedly reduced for sleep to occur. The preceding experiments suggest that this influx is via the reticular formation; lesions of the hypothalamus either destroy this center or markedly reduce the sensory influx to it.

With regard to emotion it appears that the sensory influx via the reticular formation in the intact organism may initiate autonomic reflex effects in the hypothalamus—for example, the galvanic skin response to sound stimulation, or the startle response and other visceral changes—but at the same time the cortical activation effect may induce cortical inhibition (or facilitation) of hypothalamic mechanisms. Some of these possibilities have been schematically diagrammed in Fig. 9 and will be mentioned later.

Hypothalamic recording and emotional probing. Grinker (1938) described a method presumed to make possible the recording of electrical potentials from the hypothalamus in human subjects. It consisted in inserting a special long needlelike electrode through the nasal passages to the proximity of the base of the brain and the hypothalamus. Grinker (1939), Grinker and Serota (1938, 1941), and Hoagland et al. (1938*b*) recorded what they thought were hypothalamic potentials simultaneously with those from cortical regions. In general the electrical activity in the two regions was similar: electrical stimulation of the hypothalamic region gave rise to concurrent cortical changes, and emotional probing of the patients produced changes in both the hypothalamus and the cortex. Masserman (1941) criticized the "hypothalamic" lead, pointing out that in man it is probably 3 to 6 centimeters removed from the hypothalamus and is in all probability closer to the pons and the medulla. Accordingly he felt that electrical activity recorded between this point and other reference leads on the ear lobe

or head should not necessarily be interpreted as hypothalamic in origin.

Hoagland, Cameron, and Rubin (1938a) recorded standard electroencephalograms in psychotic patients and normal subjects during probing of emotional details in the life history. Using a measure of slow waves called the "delta index," they reported that both normals and psychotics showed an increase in heart rate and delta index during strong emotional excitation. Discussion of significant emotional factors or conflicts brought out an increase in the slow waves, which was reduced with repetition of the emotionally charged questions. Since Thiesen (1943) found no increase in the delta index during emotional excitement and since other studies have not revealed evidence of slow waves during emotional states, it seems likely that the delta waves might have been artifactual or the results of skin potential changes arising from sympathetic discharges.

THEORETICAL CONSIDERATIONS

Despite the long history of emotion, going back to the Greek philosophers, there has been little discussion of emotion as theory. The modern interest and discussion have centered chiefly around the writings of James and Cannon. James' stimulating writings at the turn of the century were responsible for an increased interest in emotion, and the earlier formulated theories of James (1884) and Lange (1885) came to be a dominating influence in subsequent psychological thinking. James' position is perhaps best summarized in his *Principles of Psychology* (1890) where he states:

Our natural way of thinking about these coarser emotions [e.g. grief, fear, rage, love] is that the mental perception of some fact excites the mental affection called the emotion, and that this latter state of mind gives rise to the bodily expression. My theory, on the contrary, is that *the bodily changes follow directly the perception of the exciting*

fact, and that our feeling of the same changes as they occur IS the emotion. . . . every one of the bodily changes, whatsoever it be, is FELT acutely or obscurely, the moment it occurs.

Lange's theory, put forth independently, held that a stimulus object or situation gives rise immediately to vasomotor changes wherever blood vessels are found. The secondary changes occurring in the tissues were believed to give rise to the sensations that constitute the emotion. More recent interpretations of Lange's theory have recognized that the sensory impulses may arise from receptors in the blood vessels themselves.

Cannon (1931) schematized the neural basis for the James-Lange theory (see Fig. 8). Briefly this may be described as follows: an object stimulates one or more receptors (R); afferent impulses proceed to the cortex (path 1), and the object is perceived; efferent impulses immediately activate muscles and viscera (path 2); the activity of these organs stimulates receptors, causing afferent impulses to reach the cortex via paths 3 and 4. The perception of these changes in muscles and viscera, following upon the original perception of the external stimulus object, transforms the object—simply-apprehended into the object—emotionally-felt. According to James, "the feeling of the bodily changes as they occur is the emotion."

James and Lange did not attempt to portray the neural mechanisms of emotion, for the intricacies of neuroanatomy and neurophysiology were largely unknown in 1884 or 1885.

Cannon (1927) cited the following objections to the James-Lange theory: (1) Total separation of the viscera from the central nervous system does not alter emotional behavior. (2) The same visceral changes occur in very different emotional states and in nonemotional states. (3) The viscera are relatively insensitive structures. (4) Visceral changes are too slow to be a source of emo-

tional feeling. (5) Artificial induction of the visceral changes typical of strong emotions does not produce them.

Although the experiments supporting these criticisms were ingenious and apparently sound, the question remains whether they proved anything about the James-Lange theory. Rather it appears that the James-

onomic system, since efferent fibers issue from cranial nerves III, VII, and IX, and afferent fibers enter the brain stem via VII and IX; likewise sensory response of skin and proprioceptors was possible in the neck, the head, and the shoulder of Sherrington's dogs. However, much of the sensory influx from the viscera was cut off (and all of it

FIG. 8. Diagrammatic representation of the James-Lange and of the thalamic theories of emotion. Key: R—receptor; C—cerebral cortex; V—viscera; Sk M—skeletal muscle; Th—thalamus; P—pattern. The connecting lines represent nerve paths; direction of impulses is indicated by arrows. Corticothalamic path 3, on the right, is inhibitory in function. (From Cannon, 1931.)

Lange theory, by its very nature and formulation, is not a theory but an untestable hypothesis. By way of illustration, some of the evidence supporting point 1 above will be cited. Sherrington (1900) destroyed connections between brain and viscera completely, and isolated most of the skin and musculature of the body as well, by transecting the spinal cord and vagus nerves in dogs. Cannon, Lewis, and Britton (1927) removed the ganglia of the sympathetic chain in cats. As reference to Fig. 1 will show, neither procedure removed completely the possibilities of response or sensory influx from structures innervated by the auto-

from the circulatory system), and it was the perception of visceral changes upon which James had heavily relied for the object-emotionally-felt. Both Sherrington and Cannon report no diminution in the dogs' ability to express signs of various emotions such as anger, joy, fear, disgust, and rage except in the parts of the body where autonomic and somatic efferents had been eliminated.

Hebb (1946, 1949) objects to the logic of the interpretation of these experiments, pointing out that James did not say that the expression of emotional behavior would be lost by interfering with the viscera, but rather that the awareness or consciousness

of the emotional feeling would be lost. It is true that one cannot, except by unwarranted inference, assume that, because an animal responds as if angry or afraid, it has actually *felt* that way, but the same is true of a human being, despite the fact that he may have reported that he *felt* that way. An objective method cannot be expected to prove or disprove an immaterial consequence or epiphenomenon, as consciousness is often regarded. The two levels of discourse do not mix. Until the phenomena of consciousness are identified objectively the scientific study of emotion will have to be confined to emotional behavior, broadly interpreted to include all measurable organic changes. Some of these organic changes, especially the electrophysiological, already appear to be useful substitutes for the phenomenology of consciousness. They measure excitation level which seems to be, more than anything else, related to the phenomena that have been called consciousness.

Let us turn now to the Cannon-Bard thalamic theory of emotion. The thalamic theory is sometimes associated with the names of Head and Cannon, for on the basis of clinical material in neurology Head (1920) made notable contributions, some of which Cannon (1927, 1931) applied in the formulation of the *thalamic theory*. Much of the subsequent support for the theory has come from the work of Bard.

Cannon's formulation of the thalamic theory may be best understood by reference to Fig. 8. An external emotion-provoking stimulus excites receptors (R) and starts impulses toward the thalamus (path 1); at this point they may activate thalamic processes or go on to the cortex (path 1') where they may arouse conditioned responses that in turn excite thalamic processes (by release of inhibition in path 3). Thus efferent discharges are set up in path 2, either through direct activation of the thalamus over path 1 or after impulses have passed to cortex (path 1'), where they inactivate inhibition over path 3, which allows patterned motor

responses in the diencephalon to find expression in effectors via path 2. At the same time an upward discharge in path 4 carries to the cortex an appreciation of the pattern just released. Thus this *qualé* combined with the original sensory experience permits the impulses over path 4 to transform in the cortex the object-simply-apprehended to the object-emotionally-felt. The difference between this view and that of James and Lange is that for Cannon (1927) "the peculiar quality of the emotion is added to simple sensation when the thalamic processes are aroused." Bard (1934) makes it clear that this involves reactivation of the cortex via path 4. For James and Lange the object-emotionally-felt occurs only when sensory impulses from reacting effectors have reached the cortex.

In reply to a critique of his theory by Newman, Perkins, and Wheeler (1930), Cannon (1931) countered with additional evidence and made his position more explicit. Subsequent critiques by Harlow and Stagner (1932, 1933) were answered in two articles by Bard (1934). A final shot in this particular battle of critiques was the scholarly contribution of Lashley (1938), who questioned some of the thalamocortical mechanisms postulated by Dana (1921), Wilson (1924, 1929), and Head (1920), which were accepted in partial support of the thalamic theory by Cannon and Bard. Lashley doubted that there was sufficient evidence to endow the thalamus (diencephalon) with the ability to control patterns of emotional expression and provide, at the same time, for the wide range of affective states observed in normal and psychopathologic individuals. Lashley questioned the adequacy of thalamic mechanisms to serve as a reservoir of emotional tension and to account for the motivational aspects of emotional behavior upon which so much of modern dynamic psychology depends. However, in fairness to Cannon and Bard it should be emphasized that the thalamic theory did not pretend to account for all aspects of emo-

tional experience, or for drive and motivation.

Arnold (1945) criticized Cannon's views on homeostatic control and his notion that fear and anger are emergency functions. She marshaled some interesting evidence to prove that neither anger nor fear has emergency functions; that, contrary to Cannon's position, anger is associated with predominantly parasympathetic excitation, fear with predominantly sympathetic activity, and excitement or elation with moderate parasympathetic activity. Later Arnold (1950) presented "An Excitatory Theory of Emotion," in which emotion is said to be an excitatory phenomenon represented in the threefold division of fear, anger, and excitement transmitted over separate cortico-hypothalamic pathways and touching off different hypothalamic effector systems. Arnold drew upon several lines of evidence to support her theory.

Although perhaps antedated by Duffy (1934, 1941), a new wave of interest and critique concerning the general status of emotion was touched off by Leeper (1948), whose penetrating article attacked not the theories per se but the implication of many writers that emotional behavior is a disrupting and disorganizing process. Leeper considered this a fallacious interpretation of the work of Cannon and others on the physiological aspects of emotional behavior, not intended by the authors of the original experimental work. On the contrary Leeper interpreted much of emotional behavior as an organizing, mobilizing process, which he attempted to fit into a motivational framework. In this he was joined in part by Duffy (1948) and Webb (1948). On the other hand, Young (1949) took issue with Leeper and defended a position previously expressed in his book, *Emotion in Man and Animal* (1943).

Hebb (1949) has presented a theory that qualifies emotion as *emotional disturbance*, which he says is neither innate nor learned but a little of both, for some nonspecific

learning must precede the expression of a pattern that is ready-made. Emotional disturbance is basically a disruption of the timing of neuronal activity in the cerebrum, produced by conflict of phase sequences or lack of sensory support for a phase sequence. A phase sequence appears to be a molar grouping of smaller units or patterns of activity in cell assemblies, but a dynamic, constantly changing sequence. Hebb attempts to reconcile a number of seemingly diverse psychological concepts based on experimental observation in terms of neurophysiological theory.

With increasing knowledge of the central and peripheral nervous systems and their functions, it becomes apparent that previous theories of emotion (James-Lange) or of emotional behavior (thalamic theory) are inadequate to account for not only the peripheral bodily changes in emotion, but the central manifestations as revealed by electrocortical activity. The basic framework of the thalamic theory may be retained, but it must be expanded to include some newly conceived mechanisms. Some of these newly discovered facts have been touched upon in a preceding section. It now remains to consider their place in a theory of emotion. As with most theories, this attempt to integrate the facts falls far short of the goal, but a useful purpose is served if new light can be brought to focus upon the problem and if a further search for facts can be stimulated.

An Activation Theory of Emotion

As far as it may be considered a theory, the conception to be described here may be labeled an "activation theory." It is based largely upon recent findings concerning the electroencephalogram and particularly the interaction of the cerebral cortex and subcortical structures. The activation theory is not solely an explanatory concept for emotional behavior but relates also to the phenomena of sleep-wakefulness, to EEG manifestations of cortical activity, and to certain

types of abnormal behavior revealed in neurologic and psychiatric syndromes.

The theory rests mainly upon the following points, which are supported by experimental evidence:

1. The electroencephalogram in emotion presents an "activation pattern," characterized by reduction or abolition of synchronized (alpha) rhythms and the induction of low-amplitude fast activity.

2. The activation pattern in the EEG can be reproduced by electrical stimulation of the brain-stem reticular formation extending forward into the basal diencephalon through which its influence projects to the thalamus and cortex.

3. Destruction of the basal diencephalon, i.e. the rostral end of the brain-stem activating mechanism, abolishes activation of the EEG and permits restoration of synchronized rhythmic discharges in thalamus and cortex.

4. The behavioral picture associated with point 3 is the antithesis of emotional excitement or arousal, namely, apathy, lethargy, somnolence, catalepsy, hypokinesia, etc.

5. The mechanism of the basal diencephalon and lower brain-stem reticular formation, which discharges to motor outflows and causes the objective features of emotional expression, is either identical with or overlaps the EEG activating mechanism, described under point 2, which arouses the cortex.

Evidence for point 1 has been discussed in a preceding section of this chapter, and Figs. 5 to 7 illustrate the "activation effect" under conditions of moderate sensory stimulation causing emotional arousal, a condition of apprehension, and a state of anxiety. In addition it should be mentioned that Berger (1933) reported that fright abolishes the alpha rhythm, and that fear and anxiety tend to produce rapid waves. Jasper and Andrews (1938a) found that startle would block the alpha rhythm for a period of time (see effect of auditory stimulus in Fig. 5). Williams (1939) observed that embarrass-

ment and apprehension tend to abolish alpha waves. Jost (1941) found that the reaction of an unstable group of children to frustration was accompanied by reduction of alpha activity and increased autonomic responsiveness. Rheinberger and Jasper (1937), in recording electrical activity from the cortex of an unanesthetized cat, found that when the animal was alert or emotionally aroused the pattern was characteristically one of low-amplitude fast activity with an absence of synchronized waves. As the animal became more relaxed and quiescent, slower alpha-like rhythms appeared. During sleep slower waves and spindle-like bursts dominated the picture. Under barbiturate anesthesia, thought to have its principal effect on the diencephalon, similar slow waves and spindling patterns occur. Lindsley, Bowden, and Magoun (1949) found that the alert unanesthetized cat with cord transected in the upper cervical region shows a low-amplitude fast electrocortical activity, i.e. an activation pattern.

The work of Moruzzi and Magoun (1949) supplies evidence for point 2. Direct electrical stimulation of the reticular formation in the lower brain stem in the cat abolished synchronized activity in the cortex and introduced in its place fast activity of moderate amplitude. Furthermore they found that the evoked potentials resulting from stimulation of a peripheral sensory nerve were not blocked by electrical stimulation of the reticular formation, but that the rhythmic after-discharge following each evoked potential was abolished. Likewise the recruiting potentials (Dempsey and Morison, 1942) induced by thalamic stimulation were abolished.

With regard to point 3 the evidence supplied by Lindsley, Bowden, and Magoun (1949) indicates that lesions in the diencephalon, at the rostral end of the activating system, abolish the activation effect and reinstate synchronized rhythmic discharges that may be recorded diffusely over the cortex and at the same time in a limited region

of the thalamus. The simultaneity of discharges in the thalamus and the cortex suggests reverberating circuits or some form of mutual interaction of cortex and thalamus. The limited thalamic area involved seems to be a continuation of the diffuse projection system. Lesions or transections of the lower brain stem that left more and more of the reticular formation intact resulted in greater cortical activation. Lesions in the midbrain, eliminating medial and lateral lemnisci (direct sensory pathways to the thalamus and the cortex) but leaving intact the tegmentum and the reticular formation, did not abolish the activation pattern, whereas the reverse condition did abolish it and produced synchronized activity. Consequently it is evident that spinothalamic pathways projecting directly to the cortex via the thalamus do not produce the generalized activation pattern of the cortex. Rather it appears that these ascending pathways, by way of collaterals, shunt some of their impulses into the lower brain-stem reticular formation, which affects the cortex through the agency of the diffuse projection system.

Both experimental animals with hypothalamic destruction and clinical patients with pathology involving the hypothalamus (e.g. epidemic encephalitis) show symptoms that are the reverse of those due to hypothalamic stimulation (which causes emotional excitement and autonomic and motor discharge). Such animals and patients show little sign of emotion and are typically apathetic, lethargic, and somnolent. Some more limited lesions produce catalepsy, hypokinesia, and other symptoms found in neurologic and psychiatric syndromes. Additional evidence of this kind in support of point 4 has been given in a preceding section of this chapter.

The evidence reviewed by Ranson and Magoun (1939) strongly supports point 5. Electrical stimulation of the hypothalamus and of the downward extension of the reticular formation produces both somatic and visceral discharge. Emotional excitement

and arousal is part of this picture. They state:

It is probable that the active hypothalamus not only discharges downward through the brain stem, spinal cord and peripheral nervous system into the body but also upward into the thalamus and cerebral cortex. This upward discharge may well be associated with emotion as a conscious experience. This is in line with Cannon's theory (1927). But this excitation of the cerebral cortex by the hypothalamus is not essential for maintaining the waking state.

Magoun and collaborators (Sprague et al., 1948; Lindsley, Schreiner, and Magoun, 1949; Schreiner, Lindsley, and Magoun, 1949) have demonstrated that the lower brain-stem reticular formation plays a significant role in both facilitating and inhibiting spinal motor activity, depending upon the region stimulated.

Figure 9 is an attempt to represent schematically the principal structures and interconnections involved in the central regulation of emotional behavior. The diagram does not include basal ganglia of the extrapyramidal system or the cerebellum, both of which may also participate to some extent in emotional response. Reference to Figs. 4, 5, and 9 should help to make clear the extent of the hierarchical arrangement of reflex pathways involved in emotion. Most of the interconnections illustrated in Fig. 9 are supported by both anatomical and physiological evidence, although a few of them are merely inferred from suggestive data. The activation theory requires all the possible mechanisms schematized in Fig. 9, and these will be referred to in the subsequent discussion.

How is the activation theory of emotion related to sleep? Kleitman (1939) held that sleep is dependent upon a reduction in the bombardment of the waking center in the hypothalamus by afferent impulses from the various somatic and proprioceptive receptors, but particularly from the visceral receptors. It is under similar circumstances of reduction of afferent influx that the electro-

encephalogram shifts from a picture of activation and desynchronization (alert state) to one of increased synchrony with rhythmic

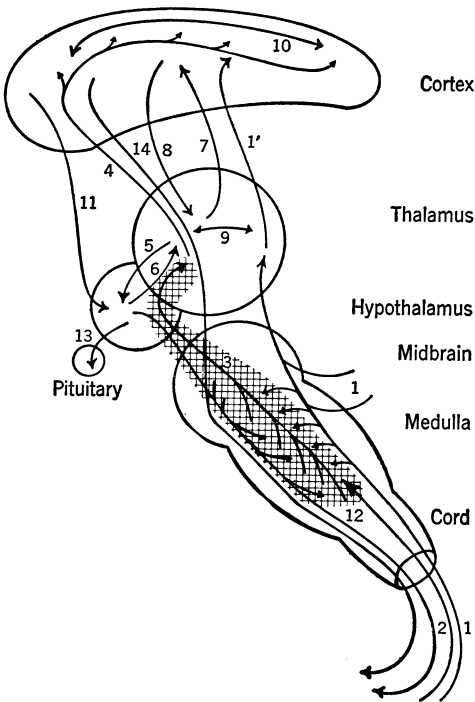

FIG. 9. Schematic representation of principal central nervous structures and probable pathways involved in emotional behavior. The diagram does not include the cerebellum and certain basal ganglia that may also participate. Key: 1—somatic and cranial afferents; 1'—direct thalamocortical projections; 2—visceral afferent pathways; 3—centripetal projections of reticular formation; 4—diffuse thalamocortical projections; 5 and 6—interconnections of hypothalamus and thalamus; 7 and 8—interconnections between thalamus and cortex; 9—intrathalamic connections; 10—intracortical connections; 11—cortico-hypothalamic pathways; 12—visceral efferent pathways; 13—hypothalamohypophyseal tract; 14—corticospinal pathways. The crosshatched area represents the reticular formation.

alpha waves (relaxed state), and finally to one of large slow waves and even greater synchronization (sleep).

The more intense, unexpected, and persistent the external stimulation, the greater is the bodily tension aroused reflexly through lower levels of the spinal cord and brain-

stem. But these afferent impulses are not necessarily limited to reflex adjustments via spinal or lower brain-stem levels; some of them undoubtedly relay upward to successively higher levels. It is believed that both visceral and somatic afferent impulses feed into the reticular formation of the lower brain stem (see Fig. 9, paths 1 and 2). In this system of forward projections to the hypothalamus and the thalamus (pathway 3) the impulses activate not only the waking center (in the rostral midbrain or the basal diencephalon) but reach the cortex via the diffuse projection system (pathway 4). The activation pattern of the entire cortex seems to attest to this fact. Whether all such afferent impulses also reach the cortex via direct relay in the thalamus is not known. It appears that some of them at least do not; for example, visceral impulses in general do not give rise to awareness, and those that are appreciated provide only a vague awareness and little or no localization and discrimination.

Homeostatic adjustments preserving constancy of the internal environment are in some instances partly organized at low reflex levels (viscerovisceral reflex) but at the same time are influenced by and participate in external adjustments via somatovisceral and viscerosomatic reflexes. These reflexes probably constitute one of the lowest orders of reflex activation in the cerebrospinal system. How much of these activities is referred to higher, central levels of integration is uncertain, but no doubt some of the impulses affect the waking center and may well involve autonomic reflex adjustments in lower-brain-stem and hypothalamic levels.

A higher order of reflex adjustment, and one we commonly accept as a form of emotional response (probably a primitive and transient form of fear), is the startle pattern described by Landis and Hunt (1939). This is apparently a somato-viscero-somatic response, since both visceral and somatic reactions occur. For example, a strong, unexpected auditory stimulus produces a gen-

eralized bodily response, predominantly of flexion. Visceral manifestations are increased blood pressure, heart rate, and galvanic skin response, to mention only a few. There is no doubt that a cortical activation occurs as well (see Fig. 5), even to an auditory stimulus of moderate intensity, and the effect is generalized over the cortex, suggesting diffuse cortical projection. But the impulses from the VIII nerve, after passing through the pons and the midbrain, make final synaptic relay in the medial geniculate body of the thalamus and proceed to the auditory cortex by direct projection. It seems likely that on their way to the thalamus these pathways contribute collaterals to the reticular formation in the lower brain stem. Activation of this system makes possible the diffuse activation of the cortex as well as the waking center and the hypothalamic centers of visceral response.

Davis (1948) has shown that the muscle tension response to strong auditory stimuli reveals *a* and *b* components in the muscle action potential record. The first of these components has a latency of 0.1 second; the second component has a latency of 1 second or more. Both components, like the galvanic skin response, show adaptation effects to stimulus repetition, and Davis believes that they are both components of the startle response. Landis and Hunt (1939) found that the latency of the eye blink accompanying startle was even less than that of the *a* response, averaging about 40 milliseconds. A significant point, so far as the hierarchy of reflex adjustments is concerned, is that here we see evidence, in terms of latency, of the differential nature of the components of the startle response. The eye blink and the *a* response appear to occur at a lower brain-stem level and with more direct reflex connections (shorter latency) than the *b* response and the galvanic skin response, which probably involve at least a diencephalic level of reflex integration. A third stage of adjustment verges on the voluntary, involving the cortical level after the significance of

the stimulus is recognized. Impulses mediating this level of response apparently reach the cortex via direct projection pathways (Fig. 9, pathway 1'). However, before discrimination at the cortical level occurs, it appears that the cortex has already been alerted via the diffuse projection system, since the alpha rhythm is blocked and the EEG activated by the auditory stimulus in about 0.3 second.

Thus it may be seen that, through the mechanisms illustrated in Fig. 9, varying degrees and complexity of activation are possible as a hierarchy of reflex responses progressively involves higher levels of the neuraxis. Beyond the relatively simple startle response, involving mainly a brain-stem level in the hierarchy of response mechanisms, the nature of the more complex emotional responses is less clear. However, as Fig. 9 shows, there is reason to believe that additional complications are involved, for there are not only intrathalamic and intracortical connections (paths 9 and 10) but thalamo-cortical connections (paths 7 and 8) and corticohypothalamic tracts (path 11).

That cortical inhibitory and facilitatory influences upon diencephalic and other sub-cortical centers are possible is revealed by the influence of frontal lobectomy, lobotomy, and topectomy in human patients (Freeman and Watts, 1942, and others). These influences are also shown in cats by the effect of bilateral removal of the neocortex, sparing rhinencephalic structures, which causes *placidity*, whereas removal of rhinencephalic structures induces *anger* and *rage* reactions (Bard and Mountcastle, 1947). Other evidences of inhibitory and facilitatory effects of the cortex upon diencephalic structures come from the results of local stimulation in the premotor and other frontal areas (see Fulton, 1949). Other indications of corticohypothalamic control and the pathways involved have been discussed above.

These mechanisms make it possible to account for emotional excitement and rage re-

sponses normally held in check by cortical inhibition, but capable of release by rhinencephalic lesion and presumably also by activation through the reticular formation and the diffuse projection system. Experimental evidence for the former is clear; but for the latter the evidence is not complete, it is merely suggestive. The cortical activation is clear, but so far only alertness and moderate excitement have been demonstrated. Apparently cortical inhibitory mechanisms must be released, or greater facilitation induced, through accessory mechanisms in the cortex before rage and other strong responses can be aroused.

What of the milder emotions, the so-called pleasant and relaxed states or mildly exciting emotions? The evidence is not yet definitive, although it suggests that the degree of activation is very much less under these conditions. The cortical activity apparently remains relatively synchronized, and the ratio of sympathetic to parasympathetic activation is probably reduced to one of only moderate sympathetic dominance. White (1940) reported that stimulation of the preoptic and anterior hypothalamus in the region of the presumed parasympathetic center seemed to inhibit sympathetic discharge and the waking center, thereby producing greater relaxation and drowsiness. A differential control of parasympathetic and sympathetic centers in the hypothalamus, through inhibitory and facilitatory effects, should make it possible to provide for the different forms of emotional behavior. However, it is not profitable on the basis of present experimental evidence to attempt to account for all the varieties of emotional expression. These explanations will have to await further research. Many of the nuances of behavior undoubtedly depend upon learning and habituation, which, reinstated through memory and ideation and operating through the complex network of intracortical connections, make possible emotional responses that represent varying gradations between maximal excitement and

its opposite — relaxation and sleep. In short, the activation theory appears to account for the extremes, but leaves intermediate and mixed states relatively unexplained as yet.

Methods and Procedures in the Study of Learning

ERNEST R. HILGARD
Stanford University

In order to bring the study of learning into the laboratory, it is necessary to discover or to invent situations in which graduated improvement may occur, so that scores may be obtained. Such situations exist in familiar tasks like typing and piano playing. In these it is possible to score success according to time required, or errors made, or repetitions needed. Rote memorizing lends itself readily to this kind of study. All that is needed is the introduction of measures of progress, such as the number of promptings needed after different amounts of study. It was natural that the earliest quantitative studies of learning made use of these familiar experiences. Ebbinghaus (1885) selected rote learning for study; Bryan and Harter (1897, 1899) chose the learning of telegraphy. Students of animal learning found it simplest to score tasks that required the animal to move about, so that it could be timed or its course of action followed. The problem box (Thorndike, 1898) and the maze (Small, 1899, 1900) can be scored in these ways.

If we can score progress, that is all we need to start a learning experiment. But we have to add more to the design of the experiments if their data are to solve the problems of learning theory. The measurements must be relevant to a conceptual scheme. For one thing, variations classified as learning must not be of a kind more ap-

propriately attributed to other psychological functions, such as maturation or motivation. Learning is always an inference, derived from changes in performance, and learning is not the only factor that can cause these changes. Performances change as organisms grow older, they change as organisms become fatigued, they change with the state of the organism (as when it is drugged), and they change with motivation. Only by appropriate controls can it be ascertained that the changes studied are surely to be classified as learning, or, more strictly, to be used to make inferences about learning. Even though we achieve this first step successfully and can distinguish learning from other influences, additional problems remain. It is a scientific truism that any given experiment can bear quantitatively on only a limited number of questions of theory. This is particularly evident in experiments on learning. Knowledge about memorization and retention derived from Ebbinghaus' experiments on nonsense syllables is valid scientific knowledge, but it does not cover all the features of remembering and forgetting, such as those to which Freud, Lewin, and others have later called attention. The Bryan and Harter experiments were appropriate to their interest in the form of learning curve, but their methods would not bear on problem solving and creative ability. Once we accept the fact that any one experiment can pro-

vide information about limited aspects of learning only, we see the need for an integrated plan of attack if comprehensive answers are to be obtained.

In this chapter primary attention is given to the problem of making learning situations quantifiable, and only secondary consideration is given to making them relevant to theory. The relevance of the experiments to generalizations about learning are more fully discussed in the chapters that follow.

A precise definition of learning is not necessary, so long as we agree that the inference to learning is made from changes in performance that are the result of training or experience, as distinguished from changes such as growth or fatigue and from changes attributable to the temporary state of the learner. The experiments themselves define the field ostensively.

TYPICAL EXPERIMENTS

A list of typical experiments may serve to remind us that methods and procedures vary widely with the situations studied. The problems that may be studied also differ within and among such situations. In the short statements that follow, typical experiments will be characterized, and a few references will be cited where additional information about such experiments may be found.

Situations Used with Both Lower Animals and Human Subjects

Throughout the history of the experimental study of learning there has been a strong emphasis upon the comparative method. Interest in animal learning has not usually been directed at animal training (as it might be in training homing pigeons or hunting dogs). Instead it has been directed at general principles of learning, applicable not only to the species studied but to the learning of other animals and to human learning as well. Nearly all the problems set for lower animals have been adapted in

one way or another for use with human infants or adults. In recognition of this tendency references are given in this part of the chapter to studies using both lower animals and man.

Negative adaptation or habituation. The classical experiment upon learning not to respond to a repeated stimulus is that of the spider studied by the Peckhams (1887). The spider dropped from its web when a tuning fork vibrated, but on successive trials it reacted less and less until finally it did not react at all. Other experiments on habituation are cited in the chapter by that title in Humphrey (1933). A typical parallel is provided in the experiments of Dodge (1923) on habituation to rotation.

Classical conditioning. The dog that learns to salivate to the sound of a tuning fork (Pavlov, 1927) serves as the prototype of one form of experiment widely copied and adapted to other species, including man. The experiments on both animals and human subjects are reviewed by Hilgard and Marquis (1940).

Instrumental or operant conditioning. The rat that learns to press a lever in order to deliver a pellet of food presents us with an example of instrumental or operant conditioning. The situation is defined by the responses of the organism that produce the reinforcing or rewarding goal object. It is the movements of the rat which bring the pellet of food. In classical conditioning, by contrast, the unconditioned stimulus appears even though the organism does nothing. The lever-pressing situation was most extensively studied by Skinner (1938), although it has become an integral part of the experimental program in Hull's laboratory (Hull, 1943). This experimental method has also been used with pigeons (Skinner, 1948).

The equivalent experiments with children were introduced by Ivanov-Smolensky (1927) and extended by others (Jackson et al., 1938).

The puzzle box or problem box. Thorndike's hungry cat trying to release the latch

on a cage in order to obtain food outside (Thorndike, 1898) illustrates a number of experiments making use of a wide variety of latch boxes, sawdust boxes, platform boxes, and other devices (Warden, Jenkins, and Warner, 1935, pp. 244-254). Although these may also be considered instrumental conditioning, they differ mechanically from the lever-pressing box in that the end state

one of which food might be found. The animal was trained to find food in the one compartment that was lighted. After this preliminary training the signal light was turned on and then off, and the animal's choice was forcibly delayed for some seconds. The aim was to find out how long the animal could delay without "forgetting" where the light had been turned on. In later experi-

FIG. 1. Puzzle box for cats (after Guthrie and Horton, 1946, p. 14). The front is of clear sheet glass. The diagonally striped pole operates the release mechanism, opening the door at front center.

usually involves release from confinement as well as access to the lure. Among the later variations of Thorndike's method with cats are those of Adams (1929) and of Guthrie and Horton (1946). (See Fig. 1.)

The corresponding experiments with human subjects are analogous without being altogether comparable. They involve discovering an appropriate movement or combination of movements in order to resolve a problematic situation, as in the solution of wire puzzles (Ruger, 1910).

Delayed-reaction experiments. The delayed-reaction experiment was introduced by Hunter (1913). He confronted an animal with a limited number of behavior choices, such as three open compartments, in

ments (Hunter, 1917) the method was modified to what has been called the "direct" method. That is, the sight of food being placed into the compartment is substituted for the indirect signal, the light. This procedure appears to place less strain upon the animal's symbolic capacities, so that much longer delays are obtained with the direct method than with the indirect ones (e.g. Tinklepaugh, 1932; Harlow, Uehling, and Maslow, 1932). The relevant experiments are reviewed by Munn (1933), Cowles (1940), and Heron (1942).

The delayed-reaction experiment is readily adapted for use with human infants. Hunter performed some preliminary experiments himself (Hunter, 1913, 1917), and later ex-

perimenters have gone on with the method (Skalet, 1931; Bühler and Hetzer, 1935).*

The discrimination experiment. The discrimination experiment was originally devised to test the discriminatory capacities of animals. Training problems were a necessary nuisance which had to be disposed of before the animal could exhibit its sensory capabilities. Each sense modality presents its own problems. Because we are here concerned with learning rather than with sensory discrimination, our discussion will be limited to the learning of discriminations within one modality, vision. An elaborate apparatus was designed by Yerkes and Watson (1911) chiefly to control the visual stimulus. The problem required the use of visual cues for turning to the right or to the left to find food at the end of the runways. A simple form had been used successfully by Yerkes (1907) in his study of the dancing mouse. Some of the difficulties encountered in the use of the discrimination box led other experimenters to become more interested in the learning problems as such. They have found that the directness of the relation between the visual cue and the reward determines the ease with which the discrimination can be made. This is consistent with the fact that the direct method in the delayed-reaction experiment is easier than the indirect method. An important advance was achieved in the case of teaching rats to discriminate by the invention of the jumping apparatus (Lashley, 1930), which requires the rats to jump directly at the stimuli which are used as signals for the location of food (see Fig. 2). If the rat jumps toward and strikes the correct card, the card drops down and the rat finds itself

* The delayed-reaction experiment is to be distinguished from the delayed-reward experiment, with which it may be verbally confused. In the delayed-reaction experiment the response is delayed, but the reward follows the successful response immediately; in the delayed reward experiment the correct response may be made promptly, but time elapses before the reward is delivered. As illustration of delayed reward, see Wolfe (1934).

on the feeding platform behind the open window. If it jumps to the wrong card, it finds the window locked and falls into the net below. Other methods are described in some detail by Kreezer (1942). Because the learning problems have turned out to be as

FIG. 2. Discrimination apparatus (after Lashley, 1930, as redrawn by Munn, 1946, p. 253). The positive ("correct") card falls over when the rat jumps against it, giving access to the food table. The negative card is locked, and after jumping to it the animal falls into the net.

perplexing as the problems of sensory discrimination, the discrimination method has proved useful for studying a number of problems within learning. It has been used, for example, by Muenzinger and his associates (e.g. Muenzinger, Bernstone, and Richards, 1938) to study motivation in learning.

A variation of the discrimination box consists in a series of discriminatory choices arranged along a pathway, as in a maze, with the reward obtained only at the end of a series of choices (Stone, 1928). This per-

mits the study of serial problems not possible with a single discrimination.

Other variations of the discrimination experiment include the presentation of several stimulus patterns from among which the choice has to be made. The selection of an odd stimulus from a number of similar stimuli has been studied with chimpanzees (Nissen and McCulloch, 1937); matching from samples, originally done by Kohts (1928), has been used extensively by Harlow and his associates (e.g. Harlow, 1942).

The equivalence method, developed by Klüver (1933), requires the organism to at-

tempt with many blind alleys. The first step of simplification made each choice that between two alternatives. With retracing prevented by valvelike doors, the animal progressed from one choice-point to another. Only fairly recently has it been realized that there are real advantages in studying single choice-point mazes (e.g. Tolman, 1938) and some things to be learned from single alley mazes with no choice-points whatever (e.g. Hull, 1934).

Mazes have been constructed in great variety. In experiments with rats the pathways are either enclosed or raised from the

FIG. 3. Warner-Warden maze—linear pattern (after Warden, 1929). The symmetrical pathway permits an analysis of serial learning problems.

tend to the stimuli that are mounted upon platforms pulled in by the animal. A correct choice is rewarded by food on the platform.

The discrimination experiment can be applied to young children by methods quite similar to those used with animals. One method requires a choice between boxes on the basis of stimuli upon their lids. The correct choice finds the lid unlocked and the reward inside. If the wrong card is chosen, the child finds the lid locked and is deprived of the reward (Gellerman, 1933a).

The alley maze. An alley maze provides a learning situation in which the obstacle interposed between the organism and the satisfaction of an aroused appetite is a path that has to be traversed before the goal can be reached. As so often happens in the course of scientific progress, the maze has evolved from complexity to simplicity. The earlier mazes were often bewildering affairs

floor so that the maze is a trestlelike structure. Most two-dimensional mazes are built in a horizontal plane, although some are built vertically. There are also three-dimensional mazes (e.g. Hunter, 1929). In addition to the recent trends toward unit mazes, with each unit a single choice, there is also some trend toward a linear arrangement of these units (Fig. 3), so that an animal makes all choices from the mid-line between start and food box (e.g. Warden, 1929). Earlier mazes were often constructed for the convenience of the experimenter, returning the rat to a food box near its starting point. This imposed either a clockwise or counterclockwise trend to the correct path and biased the entrances into blind alleys at different choice-points (Ballachey and Buel, 1934).

The patterns of mazes used with animals have been duplicated for human subjects, either full-scale or as stylus mazes in which

the path is a slot to be followed manually (e.g. Warden, 1924). The raised wire path is another form of finger maze (Miles, 1928). The human subject is usually blindfolded when he 'runs' such mazes. Direct comparative studies between man and lower animals are complicated by verbal factors in human maze learning and by the difficulty of equating the pretraining given animals with instructions given the human subject.

Another variation of the maze is worthy of mention here: the maze with multiple paths. The choice is not between true path and blind alley, but must be made on some other basis. There may be paths of different length, to study the preference for shorter paths (Yoshioka, 1929), or one fixed path and one variable path, to study the preference for variety (Krechevsky, 1937). In the Dashiell checkerboard maze (Dashiell, 1925) the paths form a grid like the streets of a city laid out in blocks with streets at right angles. The goal is placed diagonally opposite the entrance, and all possible paths in the goal-ward direction are the same length. Hence the maze is useful for studying the degree of fixity of successive runs from start to goal.

The temporal maze. Maze relations need not be spatial only. A longer alley requires a longer running time, and the discrimination between long and short alleys could conceivably be based upon differences in time. This conjecture can be put to the test by introducing time as a variable either through interposing delays or through requiring that turns within the same alleys be made in a fixed temporal order.

Study of time discrimination through the use of delay boxes in alternative paths has been done by Sams and Tolman (1925) and by Anderson (1932).

What is more commonly referred to as a temporal maze is that used by Hunter (1928) in the study of double alternation. The animal is required to run around two adjacent squares, in the order twice around the right, then twice around the left. This requires

that the run down the common path between the two squares shall end twice in turns to the right, then twice in turns to the left. According to simple association theory, the two occasions upon which the run down the path has terminated in turning to the right should make it difficult for a subsequent run down the path to become the cue for turning to the left. Hunter believes the mediation of a symbolic process to be necessary. The problem is, indeed, a difficult one for an animal at the level of the rat, although it can be solved by the raccoon.

Linear mazes can be constructed with multiple units requiring for solution repeated double alternation in the form rr-ll-rr-ll, etc. (Buel, 1934).

The double alternation problem can readily be presented to the human subject in the form of a stylus maze.

Multiple choice. In the effort to find an instrument appropriate to the study of the differences in higher mental capacities among different species of animals, Yerkes early invented the multiple-choice experiment (Yerkes, 1917), developing an apparatus previously used by Hamilton (1916). The apparatus consists of a number of compartments entered by doors arranged fan-shaped, equidistant from the starting point. Several adjacent doors may be opened at once, in any section of the bank of doors. Food is to be found in one of the compartments, located according to a relation among the open doors. An easier sort of problem is to react to the door at the extreme left of the bank of open doors. A harder problem is to react always to the middle one of an odd number of open doors.

For the human subject an arrangement of telegraph keys is used, the exposed keys corresponding to the open doors. More complicated relations may be used with the human subjects, such as the problem: "If an odd number, the first left of the middle; if an even number, the right end." Probably no animal below man can master a prob-

lem of this order of difficulty. The many experiments with species as different as birds, rats, pigs, cats, monkeys, and chimpanzees are reviewed by Warden, Jenkins, and Warner (1936) and by Munn (1938).

Detour ("insight") problems. The detour problems have been so named by Köhler (1925) because the path toward solution of the animal's problem is not direct but calls for the circumventing of some sort of obstacle. Either the animal must literally go around an obstacle (perhaps first of all by moving away from the goal), or it must make some use of tools or their equivalents. In any case it is necessary for a time to divert attention away from the goal and toward the means by which the goal can be reached. The problems that Köhler popularized by his experiments with chimpanzees involved tool using, as in obtaining a banana from outside the cage by means of a stick, and box stacking, in which a lure suspended from the ceiling could be reached only by building some kind of structure beneath it. These experiments have been extended by others, e.g. Bingham (1929) and Jackson (1942).

Comparable insight experiments have been done with children (Alpert, 1928). In the string-pulling experiment some strings lead directly to the object to be drawn in, and others, although open to observation, are placed in misleading positions. This procedure has been used with monkeys (Harlow and Settlage, 1934), with chimpanzees (Finch, 1941), and with children (Richardson, 1932).

By an appropriate modification, mazes have been used to study behavior in rats somewhat like the detour behavior of primates. Thus Tolman and Honzik (1930) arranged a multiple-path maze with some common segments. Their problem was to determine whether or not, following a block of the common segment of two paths, the rat would follow the remaining open path, even though it was the least preferred of the three possible paths. They believed that

their results proved the rat's capacity for insight.

Reasoning problems. Closely related to the detour problems are those on reasoning. Experiments have been done with rats (Maier, 1929), with children (Maier, 1936), and with human adults (Duncker, 1926; Maier, 1930).

The method consists essentially in teaching segments of behavior in isolation, then setting a problem in which the segments have to be combined in novel ways. In the typical experiment with rats, the rat is fed briefly on one platform and then required to return to this platform either by a route not used before or by a route that, though familiar, has to be selected appropriately as against alternative familiar routes. In the experiments with human adults, a number of ingenious situations have been arranged in which familiar objects must be used in unfamiliar ways. Thus a pair of pliers may be used as a pendulum bob, a metal clamp as a coathanger, a Bunsen burner tube as a blowpipe. Although Maier prefers to think of the reasoning task as involving functions other than those employed in learning, it is difficult to defend a sharp distinction between learning and reasoning.

Social learning. The influence of one learner upon another has been a matter of recurrent interest, in part because of the importance of imitation as one of the possible modes of learning. It was inferred from the earlier studies (e.g. Thorndike, 1911; Haggerty, 1909) that little imitation occurred, although later studies have been more friendly to the claims of imitation (Warden and Jackson, 1935; Yerkes, 1943). One method of studying the problem is to have animals in neighboring cages subjected to similar problems. The question is whether an untrained animal can learn from one that has solved the problem. Another method is to expose several animals at once to the problem, to see whether and under what conditions copying behavior occurs (Miller and Dollard, 1941).

Other problems studied with animals include competition and cooperation, dominance and submission, and the like (e.g. Crawford, 1937; Maslow, 1940).

The field of human learning is readily extended to the learning of social attitudes, as, for example, by way of movies (Thurstone, 1931).

Situations Used Primarily or Exclusively in the Study of Human Learning

Despite the lighthness and agility of lower animals, it is man who is the past master in the art of motion. His laryngeal and manual skills, under control of his superior nervous system, permit him to achieve performances unmatched by other animals. Hence there

FIG. 4. Duplicate-cage imitation apparatus (after Warden, as reproduced by Warden, Jenkins, and Warner, 1935, p. 258). Other devices may be substituted for the double-latch problem shown in the panels.

Behavior in the clinical situation where symptoms are either developed or relinquished is important as learning, but clinical observations have done little to further our knowledge about learning. Some of the studies by students of Kurt Lewin on the forgetting of an intention, on the recall of interrupted tasks, on task resumption, and the like, have about them much of the flavor of the clinic, although they are strictly experimental studies. Some of the animal studies on fixation, regression, experimental neuroses, etc., are also relevant (Sears, 1943).

are skills, both verbal and nonverbal, little represented in studies of animals below man. These include studies of rote memorization and retention of verbal materials, studies of verbal reasoning and concept formation, and studies of skilled performances of the perceptual-motor type.

Rote memorization and retention. Ebbinghaus (1885) introduced the nonsense-syllable experiment which has since served as the basis for countless experiments. The literature has been well summarized by McGeoch (1942).

The pattern of the nonsense-syllable experiment can be followed with other verbal materials, such as adjectives or related discourse. With appropriate changes the methods may be used for the study of memory for objects or pictures or tasks. The study of testimony, as originated by Münsterberg (1909), is one such variation.

Verbal reasoning and concept formation. Although some reasoning experiments with children (Maier, 1936) have been designed parallel to animal experiments, and although some work has been done on concept formation in animals (Fields, 1932), studies of syllogistic reasoning and concept formation in man cannot be paralleled in any precise manner by work with animals.

The method of concept formation, named by James "the dissociation of varying concomitants," was put to test by Hull (1920) through the use of Chinese symbols identified by a concept sign that had to be discovered as the common element among symbols bearing the same name. Work along somewhat the same lines was continued by Smoke (1932). The experiments are reviewed in Woodworth (1938).

Motor skills. Motor skills, or, more accurately, perceptual-motor skills, have been studied in a variety of forms since the pioneer work of Bryan and Harter on telegraphy. Ball tossing, dart throwing, archery, typewriting, digit-symbol substitution, spool packing, mirror star tracing, and many other tasks have been made use of. One of the tasks used widely enough to justify theoretical analyses is that of rotary pursuit learning (Fig. 5). A number of devices have been used, but most extensively that introduced by Koerth (cf. Seashore, 1928). This consists of a small brass target near the edge of a revolving turntable. The subject is required to keep the point of a hinged stylus on the target, and receives a score according to the amount of time that he is able to keep the stylus in contact with the target as the turntable revolves.

There is no special reason why motor skills should not be studied among animals. They can be taught acts of balancing, tightrope walking, jumping, and running. Some studies of individual differences in motor skills have appeared, but these have not been treated primarily as studies of learning, e.g. the running abilities of horses

FIG. 5. Pursuit rotor. The subject attempts to keep the hinged stylus in contact with a small brass target which revolves with the phonograph turntable. The electric clock registers the amount of time that the stylus is in contact (photograph courtesy Stanford Psychological Laboratory).

(Stone, 1935), handedness in rats (Wentworth, 1942), and in chimpanzees (Finch, 1941).

The foregoing list gives an introductory overview of the kinds of situations that have been brought into the laboratory for study. The problems studied can in part be inferred from the situations, although their listing would require additional dimensions. There are the problems of part-whole learning, of distribution of practice, of transfer of training, of motivational control of learning, and many others—each of which can be studied in several of the situations previously listed.

CLASSICAL CONDITIONED RESPONSE EXPERIMENTS

Once we decide to do an experiment on the conditioned response, we face a number of additional decisions. Among these are:

The kind of subject, lower animal, child, or adult, to be used.

The response that is to serve as the unconditioned response.

The unconditioned stimulus to be used (including the range of intensities).

The conditioned stimulus to be used (including the range of intensities).

The duration of stimuli and intervals between them.

The number of trials per session, with the intervals between them.

Many of these decisions can be made only after some preliminary experimentation. Supplementary decisions arise concerning the experimental room (soundproofing, etc.), the animal holder or other arrangement for fitting the subject to the apparatus, the methods of producing the stimuli and of recording their occurrence, the registration of the response, etc. The most helpful reference on the Pavlov procedures is that of Podkopaev (1926). Other suggestions may be found in Hull (1934), Hilgard and Marquis (1940), and Liddell (1942). Animal holders and recording equipment are described by Wendt (1938) and Wendt and Dodge (1938).

Controls against Irrelevant Responses

The conditioned response, like any other response, is recorded as a movement or a secretion. It has to be defined by its functional relations within a total stimulus-response situation. It is often difficult to distinguish between conditioned responses and the other kinds of responses that occur.

Original responses and pseudoconditioned responses. Conditioned stimuli are seldom completely neutral. They may evoke slight reactions at the beginning of experimentation. These responses may decrease if the conditioned stimulus is repeated in isola-

tion. Hence preliminary habituation trials commonly precede conditioning. New responses may appear, however, without the introduction of the unconditioned stimulus. These are pseudoconditioned responses (Grether, 1938), and sufficient trials need to be run with the conditioned stimulus alone, either to permit them to appear or to assure that they are unlikely to appear. In human eyelid conditioning, they have been shown to be more likely to appear in response to visual stimuli if the subject is dark adapted (Grant and Norris, 1946).

Although pseudoconditioned responses may appear when the conditioned stimulus is presented alone, they are more likely to appear if trials with the unconditioned stimulus alone are interspersed among trials with the conditioned stimulus. Presentation of the unconditioned stimulus appears to raise the excitability in some manner. Pseudoconditioning of this sort is prevalent enough to require controls. If such controls are not run, changes may be attributed to the paired stimulation when they are not actually a function of the pairing.

If conditioning is conducted in daily sessions, usually at least one daily session should be devoted to these controls, prior to the undertaking of conditioning proper.

Responses to extraneous stimuli. Within conditioning proper there are three kinds of control trials: those with the conditioned stimulus alone, those with the unconditioned stimulus alone, and those without either of the stimuli. In trials without either stimulus, as much of the background as possible remains the same as during paired stimulation, except that the stimuli do not reach the subject. Responses that are the result of time relations or noisy switches or of other cues may be detected on these control trials. The matter of extraneous cues is especially important when thresholds are being determined. The controls recommended by Pavlov are probably excessive; we can obtain quantifiable conditioned responses without building elaborate soundproof labora-

tories. When the intended cues are sufficiently prominent, animals do not tend to react to marginal cues. This is, of course, a relative matter, but few experimenters have found it a handicap to be without specially constructed laboratories.

Some Favorable Arrangements

Instructions. It has been shown that instructions are important in human conditioning (Miller, 1939; Hilgard and Humphreys, 1938). If the experimenter tries to avoid giving instructions, the subject becomes self-instructed. The experiment is under better control if the experimenter sets the stage through his own instructions and then reports these instructions in his account of the experiment. One finding of some interest is that the usual instructions, supposedly producing a neutral attitude toward the stimuli, tend to produce a set not to respond (Miller, 1939).

Nonreinforced trials. Some experimenters have been wary of introducing nonreinforced trials in the midst of paired stimulations, lest extinction be introduced and conditioning delayed. The alternative, if a record is to be kept of the rate of conditioning, is to measure conditioning according to the prevalence of anticipatory conditioned responses within reinforced trials. Such responses are not unusual; they are the rule in conditioning experiments done with the more favorable intervals between conditioned and unconditioned stimuli.

Intervals too short for anticipatory responses to appear within paired stimulation tend to be unfavorable for conditioning, but in order to find this out we have to do experiments with such unfavorable intervals. To test for conditioning it is then necessary to intersperse test trials to the conditioned stimulus alone. According to present evidence, we need not fear that such nonreinforced trials will delay conditioning, for in experiments with partial or intermittent reinforcement there is no slowing up of conditioning even though reinforcement is

omitted on half or more of the trials (Brogden, 1939; Humphreys, 1939).

Nonreinforced trials within paired stimulation may in fact produce resistance to extinction when nonreinforcement becomes the rule (Humphreys, 1939). It is essential that all procedures be carefully thought out and fully reported if one study is to be made

FIG. 6. Effect of stimulus separation upon simple eyelid conditioning. The interval plotted is that between the conditioned stimulus (light or sound) and the unconditioned stimulus (an air-puff to the eye) with human adult subjects. The most favorable interval appears to be at or near 0.5 second. Backward intervals, in which the conditioned stimulus follows the unconditioned, are not shown.

comparable to another, for many unexpected relations are found to hold.

Stimulus intervals. Although for phasic responses, like finger withdrawal or eyelid reactions, the most favorable stimulus interval appears to be about half a second between conditioned and unconditioned stimulus (Reynolds, 1945; Kimble, 1947), it is quite possible that smooth muscle responses may call for longer intervals. The practice in conditioning salivation, galvanic skin responses, and pupillary reactions has been to use somewhat longer intervals, but the critical experiments on time interval have not been done. It appears to be a fairly safe rule of thumb to expect the most favorable interval to be somewhat longer than the

latent time of the conditioned response to the conditioned stimulus, so that this response may appear prior to the onset of the unconditioned stimulus and response. In the arrangement he called simultaneous conditioning, Pavlov had the conditioned stimulus precede the unconditioned stimulus by an interval from a fraction of a second to 5 seconds.

Trial intervals. Most experimenters have found it best to run but a few trials per day, in banks of not more than 10 trials, although several banks are sometimes run in a day. Overcrowding of trials, either through having them too close together or too many in one period, appears disadvantageous (Calvin, 1939).

Favorable arrangements for conditioned discrimination. The usual method of obtaining conditioned discrimination is the method of contrasts, in which one of a pair of stimuli is reinforced, the other not reinforced. The stimuli are presented one at a time in a random order. It is somewhat more satisfactory to establish the response to the positive stimulus first, before the discrimination is undertaken. This has the advantage that generalization or induction effects are less complicated, and discrimination proceeds more smoothly when the negative stimulus is later introduced. When both stimuli are present from the start, the situation parallels that of partial or intermittent reinforcement, and both stimuli share for a time in the reinforcement. This may delay discrimination.

Measures of Conditioning

Types of score. Provided accurate records of response are obtained, the progress of conditioning (or of extinction or discrimination) may be scored according to amplitude of responses, latency of responses, or relative frequency of responses. If all these measures are obtained, it is desirable to make frequency and amplitude as independent as possible by scoring amplitude only

for obtained responses. Then frequency will refer to the number of conditioned responses relative to the possible number, and amplitude and latency will both be descriptive of the obtained conditioned responses. Humphreys (1943a) has proposed using the term *magnitude* to refer to amplitude scores that are computed on the basis of all responses, including those of zero amplitude, reserving *amplitude* for scores derived from responses of measurable size.

It is extremely difficult to avoid some artificiality in scores because of inadequacies of recording. Thus the reliability of amplitude measures will be spuriously high if the measures are taken within a single period. Then the method of attaching the recording system to the subject may introduce a constant error. Frequency measures will depend upon the amplitude of response necessary before a response is recorded (Lumsdaine, 1941). If there is no inertia in the recording system, latency can be recorded accurately, except for the difficulty of determining when a response of small amplitude departs from its baseline.

Reliability of conditioning scores. Humphreys (1943a) has summarized data for the eyelid reaction which show what is to be expected in the scoring of conditioning according to the several movement characteristics. The reliabilities are given in Table 1. The acquisition-extinction correlations

TABLE 1

RELIABILITIES OF MEASURES OF STRENGTH OF
CONDITIONED EYELID RESPONSES (AFTER
HUMPHREYS, 1943a)

	Acquisition- Extinction		Segment- Segment		Odd-Even	
	N	r	N	r	N	r
Frequency	188	0.61	188	0.86	82	0.94
Amplitude	128	0.68	188	0.87	82	0.92
Magnitude	82	0.65	82	0.93	82	0.97
Latency	128	0.54	188	0.73	82	0.87

show to what extent we may use resistance to extinction as a measure of response

strength during conditioning. The segment-segment correlation was used earlier by Campbell and Hilgard (1936) and Campbell (1938) in order to avoid correlated errors of measurement which make odd-even reliabilities too high. Trials were divided into fourths, and the totals of the first and last fourths are compared with the totals of the middle fourths. The odd-even correlations are presented for comparison. Humphreys believes the 'true' reliabilities to lie somewhere between the segment-segment correlations and the odd-even estimates.

Intercorrelations of measures of conditioning. In Table 2 are presented some inter-

TABLE 2

INTERCORRELATIONS OF MEASURES OF REFLEX SENSITIVITY AND OF CONDITIONED EYELID RESPONSES (AFTER HUMPHREYS, 1943*a*)

	Light					
	Reflex	Crit.	Freq.	Mag.	Amp.	Lat.
Reflex to puff	0.35	-0.30	0.40	0.30	0.43	-0.09
Reflex to light		-0.42	0.45	0.35	0.30	-0.09
Criterion			-0.88	-0.63	-0.43	0.40
Frequency				0.71	0.47	-0.48
Magnitude					0.89	-0.25
Amplitude						-0.15

correlations of measures of reflex sensitivity and of conditioned eyelid responses. Reflex sensitivity to puff refers to the magnitude of eyelid responses to an air-puff on the cornea, the puff being alike for all subjects. Reflex sensitivity to light refers to the magnitude of reflex lid closure to a sudden illumination change, at a latency much shorter than that of the conditioned response. The criterion score is a special type of frequency score. It refers to the number of the trial upon which the fifth conditioned response occurred.

These tables indicate the sorts of information it would be desirable to have in relation to other responses used in conditioning experiments. Unfortunately only fragmentary additional data are available (e.g. Kellogg and Walker, 1938).

EXPERIMENTS ON OPERANT OR INSTRUMENTAL CONDITIONING

The experiments introduced by Skinner (1938) with the rat and later with the pigeon (Skinner, 1948) permit the study of a number of learning processes according to units of measurement unfamiliar in other situations. Therefore some of these arrangements will be described in detail.

The rat has usually been studied in a dark and soundproof box which contains a lever and a food receptacle. When the rat presses the lever a food pellet is dropped into the food receptacle. The rat, which has been maintained on a standard diet and rigid feeding schedule, responds and eats and responds again without leaving the box. A record is kept of its responses to the lever, plotted against time. Skinner prefers a cumulative record, so that each response raises the record line one notch. An extinction curve is obtained by disconnecting the food magazine so that food no longer is delivered when the lever is pressed.

Arrangements within Operant Conditioning

The most important arrangements besides those of regular reinforcement and extinction with nonreinforcement are those of periodic reconditioning, reinforcement at a fixed ratio, discrimination, and differentiation.

Periodic reconditioning refers to an arrangement under which food is delivered on a regular schedule, independent of the rate of lever pressing by the rat. That is, a pellet appears every 3 minutes or 6 minutes or 9 minutes, as the case may be. Under these circumstances uniform rates of responding tend to appear. The number of responses per reinforcement is described as the *extinction ratio*, e.g. 18:1. Pigeons trained under the arrangements of periodic reconditioning have been shown to develop highly stereotyped or ritualistic ("superstitious") behavior (Skinner, 1948).

Reinforcement at a fixed ratio consists of delivering food after a predetermined number of responses, e.g. every fifth or tenth response. By gradually increasing the ratio very rapid rates of responding can be obtained. Once established, the rule is that the rate will be higher, the fewer the reinforcements. After each reinforcement there is a delay followed by an accelerated increase in rate of responding.

Discrimination is set up in this situation by presenting food following the lever pressing only in the presence of a discriminatory stimulus, such as a light. The discrimination is established if the animal responds only when the light is on. The choice is between response and no response, not between alternative responses.

Differentiation of response refers to the situation in which lever pressing of a given force or producing a given excursion is rewarded. The animal then learns to restrict the range of its response to the limits set by the experimenter.

The method of approximation. Because the food appears in the same space where the animal is working, it is possible to train animals in the Skinner box to do what the experimenter wishes (within limits set by the animal's response repertory) by rewarding approach reactions. This makes possible fairly rapid teaching of responses otherwise difficult to elicit, such as visual discriminations. One of Skinner's demonstration experiments with the pigeon will be described, as illustrative of the method.*

A tame pigeon, about 1 year old, is reduced to about 80 per cent of its well-fed weight and fed once a day. On this schedule it is active as an experimental animal. A small food tray is arranged to swing into its wire cage by activation of a solenoid, and to swing out again when the current is shut

off. The pigeon readily learns to come to the food tray at the sound of the solenoid. A pigeon thus prepared, and kept without food for 24 hours, is ready for experimentation. A white cardboard with a black spot is placed in the cage, and the pigeon is to be taught to peck at the spot. The pigeon may be activated by preliminary feeding with the mechanical tray. The hungry bird, in moving about the cage, eventually faces in the direction of the card. It is again fed. After it pecks five or six times the food is removed. Now the pigeon tends to return to the place where it was when the solenoid sounded. If it again faces the card it is again reinforced and again returns to where it was. The experimenter waits until it takes a step toward the card, then again reinforces. The fact that the behavior is disrupted by the pigeon's returning each time to the food tray does not matter. Presently it will be nearly against the card, each approach response being reinforced. Against the card it may attempt to fly up or do something else, but if always brought back by reinforcing it will eventually peck at the card. If the pecking is reinforced, it will be repeated. If the pigeon did not begin by pecking the spot, delay in reinforcement will cause it to vary its pecking somewhat, so that finally only pecks on the spot need be reinforced. The whole process requires about 3 to 5 minutes and may be demonstrated before a class, despite all the confusion of an interested audience. The same method makes possible very rapid teaching of discrimination, as between a black and white spot, or between a large and small spot, or between vertical and horizontal lines.

The method of approximation is the laboratory equivalent of what animal trainers have long done in order to achieve the remarkable performances of hunting dogs and circus animals. Although the illustrative experiment has been done with the pigeon, the method would undoubtedly work well with other animals. Some of the arrangements used by

* Acknowledgment is made of a private communication from Dr. Skinner explaining his method, which was tried out successfully with the aid of Dr. Roger B. Loucks at the University of Washington during the summer of 1947.

Masserman (1943) in the development and cure of neuroses in cats are dynamically very similar.

Measures of Operant Conditioning

Because the animal remains in the apparatus, in the presence of the response mechanism, how often it responds depends upon itself rather than upon the experimenter. New types of scores are required in this situation, because a single trial does not have its conventional meaning.

Rate of response becomes a useful score. This may be defined as so many responses per unit of time, or as so many responses per reinforcement. This latter score, used by Skinner in reporting results of periodic reconditioning, is called an "extinction ratio" because it shows the number of nonreinforced responses (extinction responses) for each reinforcement.

When reinforcement ceases entirely, the total number of responses yielded before the animal ceases to respond provides a measure of resistance to extinction. This is used by Hull (1943) as one measure of strength. Skinner sometimes speaks of this total number of responses as making up a "reflex reserve."

Reliabilities of scores in the Skinner box experiment have not been reported, but there are studies of the variability of several types of extinction score (Humphreys, 1940; Walker, 1948).

MAZE AND DISCRIMINATION EXPERIMENTS

The procedures and methods used in the study of animal learning have been well summarized by Warden, Jenkins, and Warner (1935), Munn (1933), Kreezer (1942), and Yerkes (1943). On the maintenance of laboratory animals, the manual by Warden, Ross, and Klein (1942) is useful. At this point only some general methodological considerations will be discussed and some precautions suggested.

Considerations Prior to Experimentation

Strains of animals. The albino rat differs in some situations from the rat with pigmented eyes. The wild rat differs from the laboratory rat. Mixed strains, because of their greater range of individual differences, may yield higher coefficients of reliability in standard learning situations than more homogeneous strains—without necessarily being more suitable than selected strains for the purposes intended. For some purposes, of course, homozygous strains are desirable. If the ideal of perfect homogeneity in both inheritance and training were obtained, reliability coefficients as ordinarily computed would reduce to zero. It is to some extent an absurd situation that we value the very coefficients that we do our best to reduce by careful inbreeding of experimental animals.

Feeding and maintenance schedule. In the course of long-continued experimentation, rats get older and larger. If they are on a reduced diet it is necessary that they be fed enough to increase in weight while growing, or their hunger motivation will be disturbed through inanition. Preferred motivational levels can be maintained by permitting young rats to gain weight and older rats to lose weight during the experimentation period (Stone, 1929a). Under these circumstances there is little change in learning ability with age over the period from 100 days to 2 years, so far as it has been studied in mazes, serial discrimination, and simple escape boxes.

For purposes of maintaining weight control it is desirable to have age-weight norms available for comparison. Although there are marked individual differences in well-fed weight, the norms are useful in showing age-weight trends for the two sexes. Representative values are given in Table 3. Because these norms are inappropriate with different stocks and different diets, it is preferable to have norms for the local colony. The Stanford colony, for example, falls below the King norm after 60 days.

TABLE 3
AGE-WEIGHT NORMS FOR ALBINO RATS
(AFTER KING, 1915)

Age in Days	Average Body Weight in Grams	
	Males	Females
13	17	16
30	49	46
60	123	107
90	185	148
120	223	173
151	245	186
182	258	197
212	268	197
243	280	210
273	281	211
304	296	219
334	301	222
365	306	223
395	314	221
425	312	216
455	324	220
485	326	235

Taming and pretraining. The handling of the animals prior to the experimentation proper undoubtedly makes a difference in their later performances. Therefore it is important to specify as precisely as possible what this prehistory has been. Animals raised in isolation may differ in some respects from animals raised in a cage with other animals. Those animals that are frightened by handling approach the experimental situation differently from those accustomed to being handled. Pretraining corresponds in animal training to instructions in human learning, and for purposes of comparative study careful controls of pretraining are essential. An animal that has been taught to run down a straight alley to receive food in a box at the end is already to some extent a "maze-wise" rat when placed at the start of an alley maze. The study by Jackson (1932) on transfer presents much relevant material. Karn and Porter (1946) have shown the influence of different kinds of pretraining on the latent learning experiment.

Natural Propensities Affecting Experimental Design

We can save time in the training of animals and obtain performances more nearly representative of the animal's capacity if we arrange the experiment in a way that is psychologically natural, that is, in accordance with behavior that is characteristic of the organism being studied. The rat has evolved as a good maze-running animal. Birds may prove to be superior to the rat in their ease of learning visual discriminations. Animal trainers do not expect the same sorts of performances from cats as from dogs, from sea lions as from monkeys. Even within performances that are readily obtainable there are types of bias that affect the design of experiments. Such natural biases have been most fully studied in the rat maze situation, although we know a good deal about other forms, such as the chimpanzee (Yerkes, 1943).

Position preferences. One of the most common tendencies found in rat learning is that of turning one way at a choice-point (either right or left) beyond chance expectancy. Because the maze is a series of such choices and because the discrimination experiment depends upon such choices, the apparatus and stimulus presentation sequences must be so arranged that an animal with a right-going or a left-going tendency will not achieve a score above chance. Since these tendencies may be strengthened by frustration, care must be taken that the problem set is not too difficult.

Stimulus preferences. In discrimination experiments there is often an initial preference for one of a pair of stimuli. If this happens to be the positive stimulus, the discrimination may appear to be easy. If this happens to be the negative stimulus, the discrimination may appear to be difficult. Seeing rats, for example, tend to prefer darker to lighter visual stimuli, whereas rats with cerebral lesions may reverse this preference (Krechevsky, 1936).

It is important to test for such initial preferences before discrimination experiments are undertaken. Half the animals should be run against their original preferences, half in accordance with their original preferences. The reason for dividing the group in this way is that the effects of frustration are not completely understood. It is not known whether training in line with original preferences is more or less satisfactory than training against original preferences. Maier, Glaser, and Klee (1940) suggest that animals that have learned in accordance with original preferences transfer more easily to new situations (including reversal of the discrimination) than animals that have learned against original preferences.

Sequence preferences. In addition to position habits, in which the same direction of turn is preferred, there are both single and double alternation habits. In simple alternation the rat tends to turn now right, now left. On a simple T-maze the commonest response on trial 2 is to choose opposite to trial 1. Double alternation, a less common sequence preference, is twice to the right followed by twice to the left. Gellerman has provided a table of stimulus sequences that prevent scores above chance from occurring by position habits, simple alternation, or double alternation. These sequences are reproduced in Table 4.

Centrifugal swing. The inertia of running produces a tendency for the rat to run off at a tangent when the choice-point is so arranged that one path (either true path or blind alley) more nearly continues the directional set already present. Ballachey and Buel (1934), extending Schneirla's earlier observations on ants (Schneirla, 1929), were able to predict which blinds in a multiple-T maze would be entered most frequently by the rat on the early runs. The tendency shows even on the first run, before any learning of the maze pattern can have taken place. This is one reason for preferring mazes of the linear type, as earlier described.

22	RLLRRLRRL	44	LLLRLRRLRL

Clarity of relation between reward and rewarded behavior. Experience with direct and indirect methods of delayed reaction and with the various methods of setting up discrimination experiments shows the importance of structuring carefully the relation between the behavior to be encouraged and discouraged and the rewards (or punishments) used. What such structuring means will be described differently according to one's psychological theory, but the practical consequence is the same. The situation must be clear to the learner. This means that the figure-ground structure should be adequate, that secondary reinforcements should enhance the discriminations required, that reward and punishment should be prompt. Between the experiments of Hull (1933a) and of Leeper (1935) there were great differences in the ease of teaching rats to go one way when hungry, the other way when thirsty. What was a relatively slight change in the experimental arrangement

made an enormous change in difficulty. The difference is to be attributed to the clarity of the situation (or the differential nature of the secondary reinforcements).

A distinction hard to state satisfactorily is that between something simple for the learner and something clear to the learner. In a mechanically easy but psychologically unclear situation, a learner may achieve the correct performance promptly, but the learning may be highly stereotyped and show little transfer to new situations. This kind of learning is easy, but unclear. On the other hand, in some insight experiments the solution may be obtained with great difficulty, but once the principle is mastered it is clear and readily used in new situations. This kind of situation is difficult, but eventually clear. Improvement of experimental controls, following the warnings of the Clever Hans experiment (Pfungst, 1911), have tended to overmechanize experimental arrangements, and only in later years have we recognized the importance of making a more careful psychological analysis of the situation confronting the animal learner.

Other factors. Animal behavior in the maze situation is a very complicated affair. In his attempt to predict the precise behavior of blind alley entrance and elimination, Tryon has worked out a quantitative theory of ten components: direction sets, food pointing, short-cut, counter tendency, centrifugal swing, adaptation, lassitude, exit gradient, inertia, and conflict (Tryon, 1940a, b).

Measures of Maze and Discrimination Learning

Types of score. In the maze the most obvious scores are the amounts of time required to run the maze on successive trials, and the number of blind alleys entered per trial. More analytical scores show which blind alleys were entered on which trial and give added information such as the depth of blind alley entrance, the tendency to run along the outer or inner wall, the nature of

retracings, and so on. Some criterion of mastery is commonly chosen, usually one or more errorless runs. It is necessary to make some decision about the first run through the maze, because some animals may not complete the run in a reasonable time. In such a case an arbitrary maximum time is often allowed. Pretraining that results in a successful maze run on the first trial is more satisfactory, because arbitrary scores prevent adequate statistical treatment.

In the discrimination experiment the usually reported scores are the proportion of correct choices, or the number of trials required to reach a criterion. An important statistical characteristic of the criterion in discrimination learning has been reported by Grant (1946, 1947). Because in a choice between two things repeated choices of one of the pair are likely to occur by chance, a criterion has to be selected such that it would be unlikely to be reached in the number of trials required for the discrimination. Thus, if an animal requires 200 trials to learn a discrimination, a criterion of 5 successive correct choices would not do, for that criterion would be reached by chance too frequently in 200 trials. Merely tossing coins, in other words, would lead to this kind of evidence of discrimination. Only a longer run would be statistically improbable. Table 5 is useful in determining how long a run is needed for significance. Additional tables are provided by Grant (1947), covering other standards of significance.

Reliability of maze scores. Many studies have been made of the reliability of maze scores. Representative coefficients have been assembled by Kreezer (1942) and by Tryon (1942). The most common measure of reliability is determined by correlating the errors made on odd and even trials, then correcting the correlation by the Spearman-Brown formula. Under favorable circumstances the reliabilities of mazes such as the multiple-T maze reach 0.99. These circumstances include a large number of choice-points (17 to 20), heterogeneous rats (mixed

TABLE 5

CRITERIA FOR DETERMINING LENGTH OF RUN
REQUIRED FOR STATISTICAL SIGNIFICANCE WITH
DIFFERENT NUMBERS OF TOTAL TRIALS (AFTER
GRANT, 1947)

S (Length of Run of Successes)	Largest Number of Total Trials for Which Probability of a Run of at Least S Suc- cesses is Below 0.05			
	$p = \frac{1}{2}$	$p = \frac{1}{3}$	$p = \frac{1}{4}$	$p = \frac{1}{5}$
2				2
3			5	9
4		8	19	42
5	6	21	73	203
6	10	60	284	1006
7	17	173	1125	5014
8	31	510	4486	
9	59	1521		
10	112	4551		
11	218			
12	429			
13	850			
14	1692			
15	3374			

Note: p refers to the proportion that successful choices bear by chance to total alternatives. In the usual discrimination experiment $p = \frac{1}{2}$. The experimenter decides in advance how many trials are to be run. Suppose in a discrimination experiment the decision is to run 429 trials. The table shows that a subject may be said to have learned by the chosen criterion if it makes 12 consecutive successful responses by its 429th trial. The end of one day and the beginning of the next must be permitted to count as part of a run.

strains of pigmented and nonpigmented rats), doors to prevent retracing, automatic recording, uniformity of handling, and other conditions. Representative experiments obtaining such high reliability coefficients are those of Tryon (1930) and Brown and Ghiselli (1938). Provided similar favorable conditions hold, multiple-U and multiple-Y mazes may also yield high reliabilities.

Other methods of computing reliability fall into two general classes: first, those using data from a single learning series; second, those

using data from two learning series. Within a single learning it is possible to use time scores instead of error scores, segments of learning instead of odd-even trials, odd-even blinds instead of odd-even trials, and so on. Comparisons of various methods have been made by Leeper (1932) and by Spence (1932). When repeated learnings are used there are still more possibilities. One method is that of learning another maze of a form comparable to the one first learned. Another is to relearn the same maze after an interval of time. Obviously these different measures of reliability imply different definitions, and the correlations obtained depend upon somewhat different sorts of consistencies. The only generalization that can be made is that these methods all yield lower reliability coefficients than those obtained by correlating errors on odd and even trials. Representative relearning coefficients over intervals of time up to 230 days run from 0.75 to 0.89 (Leeper, 1932; Tryon, 1931*b*; McNemar and Stone, 1931); alternate forms yield somewhat lower coefficients, a representative range being 0.56 to 0.81 (Commins, McNemar, and Stone, 1932; Tryon, 1931*a*).

Reliability of visual discrimination learning. Stone (1928) found that a relatively high coefficient (0.94) could be obtained in a five-unit multiple light-dark discrimination box, provided the first 10 of 40 trials were omitted. Brown and Ghiselli (1934) report a reliability coefficient of 0.98 for their multiple visual-discrimination apparatus. Williams (1929) found a coefficient of 0.96 for errors on 24 trials of a one-chamber box. Apparently consistent measures of individual differences may be obtained for such tasks.

Reliabilities and interrelations of other measures of animal learning. A great many measures of animal drive and learning have been reported in studies making factorial analyses of animal behavior. Among these are studies by Anderson (1938), Thorndike (1935), and Vaughn (1937). In general, even though reliabilities of the separate instru-

ments may be high, intercorrelations between tasks using unlike apparatus are quite low.

EXPERIMENTS ON MOTOR SKILLS

A great variety of materials have been used in the study of the learning of motor skills, among them ball tossing, dart throwing, telegraphy, archery, spool packing, digit-symbol substitution, mirror star tracing, and pursuit learning. The maze is sometimes included as a skill, but its motor aspects are in fact subordinate to the serial learning of choices, often learned verbally. These tasks are commonly used as tests of motor proficiency, in which case the problem of learning is subordinated to that of individual differences. The two problems are related in that a measure of individual differences obtained in a learning situation can be truly reliable only if there is some prediction made about ultimate level of skill with practice.

Determining Effects of Conditions of Practice

Skills lend themselves well to studies of the most efficient means of practicing — by wholes or parts, with massed or distributed repetitions, with or without manual guidance, and so on. There are two chief arrangements for conducting such experiments. One makes use of a new group of subjects for each new condition studied. This is the familiar control-group method, and its logical and statistical comparisons are best understood. The second arrangement makes use of the same subjects over again under the various conditions being tested. This has the advantage of assuring that the background learning abilities are really alike throughout, so that smaller groups may be used. The disadvantage is that the different conditions are used at different stages in practice (at different stages in “learning how to learn”), and controls are necessary, which introduces statistical difficulties. The arrangement of counterbalanced practice effects is sometimes referred to as the method

of equal average order (Robinson, 1929). The methods of the control group and of equal average order both require some further comments.

Method of the control group. The main problem in establishing a control group and an experimental group is to ascertain that both groups are representative samples of a single population, so that the groups may be considered alike, within the limits of sampling errors, at the beginning of practice. Only then can differences under two or more conditions of practice be attributed to the experimental variable or variables. From a sampling point of view, the simplest procedure is to draw the two samples independently in some unbiased way. The initial scores of the two samples may then be compared to demonstrate that such matching was indeed satisfactory.

An alternative is to pair the subjects in experimental and control groups on the basis of some variable correlated with the experimental variable. Such pairing cannot assure that the groups are representative of the whole population, but it can improve the probability that they are matched for the purposes of the experimental comparison. Economy is introduced, provided the matching method results in correlated scores between the matched pairs on the experimental variable.

The correlational term that enters into computations of significance of differences is not always between the same pair of measures. The correlational term most commonly used is that between the scores whose differences are being tested. This requires that the subjects of the control and experimental groups be individually matched, and that the experimental and control groups be of the same size. Another possibility is that the correlation is between scores on the matching variable (obtained prior to practice) and the scores whose differences are being tested. In this case subjects need not be matched individually, and the two groups (experimental and control) need not be of the same

size. All that is required is that experimental and control groups have the same initial mean and standard deviation in the matching variable. One control group may thus serve for several different experimental comparisons in which a correlational term enters, thereby introducing considerable saving in experimental time and subjects. The appropriate formulas to be used in the two methods, and considerations affecting their use, may be found in McNemar (1940).

The logic of the control group is somewhat modified in the experimental designs, made familiar by Fisher (1938), which are appropriate for treatment through analysis of variance. Instead of holding all background factors alike at a single value and changing one variable at a time, the one variable is studied against a background in which other variables represent different values, but in randomized fashion. The two methods lead to similar experimental arrangements when each condition of practice studied in the design for the analysis of variance makes use of a representative sample of subjects drawn from the same population. Economy is introduced by analysis of variance because all subjects of all groups enter into all comparisons. Suppose, for example, there are sixteen conditions of practice, representing different combinations of the experimental variables. Then, with but a single subject in each condition, the effect of any variable in the design is tested in relation to the performance of all sixteen subjects.

Factorial design does more than provide economy: it permits analyses otherwise impossible. For example, Grant and Schneider (1948) by means of such a design solved the baffling problem of distinguishing at once between strength of response and strength of association as functions of stimulus intensity.

Method of equal average order (counter-balanced order). When it is not feasible to use separate experimental and control groups (as in the extreme case when one subject alone is available for testing, e.g. after brain surgery), practice effects may be equalized

by presenting two conditions of practice in an A-B-B-A order. That is, the first test is under condition A; then there are two tests under condition B; then another under A. Whatever initial advantage condition A has because of freshness is counterbalanced by the disadvantage of fatigue (or boredom) in the final position; whatever initial disadvantage it has because of novelty is compensated for by its final advantage after the intervening practice on B. If such changes progressed uniformly throughout learning, the A-B-B-A order would provide perfect balancing. Because the changes are not actually linear, the means obtained by averaging A-scores and B-scores are not strictly comparable. An additional objection, however, is that variability may not be controlled even though the means are. This arises because some A-scores are obtained early and others late in practice. A correction can be introduced by considering the average of a subject's scores from the first and final quarter to be a single score, representing A-scores, and the average for the second and third quarter to be a single score, representing B-scores. Such scores will make the distributions of A-scores and B-scores from a number of subjects as much alike as the experimental arrangements permit, although some distortion persists.*

More complete rotations of conditions may be used when there are several conditions, such as:

ABC-CBA
BCA-ACB
CAB-BAC

When several conditions enter, as in the arrangement above, some statistical difficulties arise because the controlled orders do not permit the use of statistical formulas

* The point is that, if there were no differences in conditions A and B, A-scores and B-scores should turn up with the same means and standard deviations. This is the ideal of the method of equal average order. This can be tested by running in the order A-A-A-A, then comparing the scores in first and fourth quarter with those in the second and third.

that assume chance variations. The problem has been discussed in some detail by Melton (1936). If chance orders replace systematic ones, a better estimate of the reliability of the means may be obtained, but the price paid is that the means are, in fact, less reliable. The statistical problems are too complex to be discussed here. When the analysis-of-variance technique is used in any situation in which the same subject is used more than once, it is necessary to adapt the usual formulas so that a distinction is made between the variables and interactions that involve correlated means and those that do not. A specimen computational procedure in learning situations is given by Humphreys (1943b).

Measures in Experiments on Motor Skills

Time scores versus work scores. Most of the tasks used in the study of skill permit an arbitrary definition of a trial, and a choice between time scores (time per unit amount) and work scores (amount per unit time) becomes necessary. When both scores produce symmetrical distributions about means representing similar performances, the scores are equally reliable and essentially interchangeable (McNemar, 1934). There are, however, conveniences of use that in many situations favor work scores. These conveniences of scores in terms of amount per unit time include: (1) scores can be obtained for the poorest learners (who receive a score of zero if they do not achieve anything measurable*); (2) improvement is shown by a rising curve, which produces divergences of scores later in practice when small differences are of greater theoretical interest; and (3) the experiment is easily conducted in groups because trials are of

uniform length for all learners throughout the learning.

Work scores are not feasible when the nature of the material is such as to have a natural completion point, as in the assembling of an object from its parts or in the running of a maze. In general, it is desirable to present the data in the form obtained, and not to attempt conversion in any manner that will distort their meaning. Thus it is mathematically possible to convert scores in time per unit amount to scores in amount per unit time. This conversion will not always yield the same scores that would have been obtained had the experimental arrangements been altered to make the units of the converted scores directly appropriate. Thus the actual time to type exactly 100 words is different from what the average time to type 100 words is if derived from an assignment to see how many words can be typed in 15 minutes. The latter method would tend to result in longer times per 100 words.

Many other kinds of scores are possible. Direct measures closely analogous to time scores and work scores are to be preferred — scores such as errors per trial or per task. Derived scores are to be avoided, especially those that attempt to weight speed and accuracy, or those that make use of ratios computed with variable denominators. These seldom increase reliability, and they make difficult the comparison of results with those of other studies done by slightly altered methods.

Reliabilities of scores obtained in experiments on motor skills. Because individual differences in motor skills are both great and relatively persistent, high reliabilities may be obtained. Some representative reliabilities are given in Table 6. It should be emphasized that these coefficients are useful chiefly to determine how successfully the learning task can be used as a measure of relatively stable individual differences. In themselves they do not tell anything about how representative the task is of learning,

* This does not solve the problem of absolute zero of performance, because an achievement not scorable is not necessarily no achievement. Scores in terms of time per unit amount are still at a disadvantage in that the score for a learner who cannot complete the assigned task must be entered either as requiring infinite time or as of some arbitrary value.

TABLE 6

SOME RELIABILITY COEFFICIENTS OBTAINED IN MOTOR SKILLS EXPERIMENTS

Type of Task	Reported by	Nature of Coefficient	N	r
Spool packing	McNemar (1934)	Work scores vs time scores	50	0.925
		Work scores vs work scores	50	0.945
Card sorting	McNemar (1934)	Work scores vs time scores	50	0.954
		Work scores vs work scores	50	0.934
	Hilgard and Sait (1941)	Odd-even time scores	50	0.99
Pursuit rotor	Hilgard and Sait (1941)	Odd-even discrepancy scores ("aspiration")	50	0.86
		Odd-even work scores	50	0.99
		Odd-even discrepancy scores ("aspiration")	50	0.95
Punchboard maze	Hall (1936)	Odd-even errors	100	0.955
		Gain, trials 1-13 vs trials 2-14	100	0.67
Stylus maze	Hall (1936)	Odd-even errors	100	0.927
		Gain, trials 1-13 vs trials 2-14	100	0.44

or how useful it is in relation to any of the special problems of learning, such as the determination of the form of the practice curve. A task may yield overall reliability of high order and yet yield unreliable gains, as in the maze tasks reported in the table. The low reliabilities for gains in this case are due chiefly to the unreliability of the first trial in a maze experiment; the coefficients would undoubtedly have been higher if the comparisons had been made, for example between trials 2 to 14 and 3 to 15.

If the primary interest is in some measure of improvement, rather than in sustained level of performance, the usual reliability coefficient should be replaced by one based upon the stability of trends. The method of trend analysis proposed by Alexander (1946) has possibilities in this direction. In any event a reliability coefficient always has to be computed in relation to the problem at hand, and a task reliable for one purpose may or may not be reliable for another.

EXPERIMENTS ON MEMORIZATION AND RETENTION

Although experiments upon skill may also become experiments upon retention, verbal

or perceptual materials have more often been used in conventional memory experiments. What materials were used reflected in part the contemporary theoretical interest in memory. When the problem of memory was that of the decay of the memory image, it was natural to use pictures or objects, which could be recalled in imagery. When the problem was that of associative strength, it was easy to see the importance of verbal materials to be committed to memory. With the shift to more dynamic problems, materials with more personal reference became important. If amnesia or repression or other forms of motivational distortion are to be studied, the materials have to be appropriate to the hypotheses being tested.

Materials for the Study of Memorization and Retention

Nonsense verbal materials. Ebbinghaus (1885) used both meaningful and relatively nonsense materials in his pioneer studies. He invented the nonsense syllable (a vowel between two consonants, not found as a word in the dictionary). The English language makes pronunciation of many such combinations difficult, so that Luh (1922), while retaining the Ebbinghaus syllable, in-

roduced the practice of spelling out the syllables during memorization. This practice has been followed since by those trained in the Chicago tradition, under Carr, Robinson, McGeoch, and Melton. If syllables were to be spelled out, Witmer (1935) argued that more combinations would be available if three consonants were used, omitting vowels entirely, and she provided a list of consonant groups graded according to the extent to which they suggested words. Three-place numerals have also been used parallel to nonsense syllables and to consonant units. Other artificial materials have been proposed, such as four-letter nonsense syllables (more pronounceable in English than three-letter ones), and dissyllabic items, constructed of three consonants and two vowels (Woodworth, 1938).

Sets of rules for the construction of nonsense syllable lists have been proposed from time to time. The following rules are typical: *

1. A consonant appears as the first letter of a syllable only once within a list.
2. A consonant appears as the third letter of a syllable only once within a list.
3. No vowel occurs more than once within any four consecutive syllables.
4. No consonant appears more than once in any four consecutive syllables.
5. No two letters of a syllable in a list are the same as two letters of another syllable in the same list.
6. In so far as possible the list is considered as a circular series, so that the rules apply if the first syllables of the list are considered to follow the end of the list.
7. Alphabetical sequences of consonants from syllable to syllable and within a syllable are avoided as far as possible, e.g.

* These rules represent extensions of Luh's (1922) list as suggested by Melton (unpublished). The rules cannot always be followed strictly, and additional rules need to be provided concerning similarities and differences between lists to be used in retroactive and proactive inhibition experiments. See, for example, Melton and Irwin (1940).

avoiding the sequences POK-LEJ, or a syllable like LEM.

8. The syllables are chosen in reference to their degree of association value.

Six lists constructed according to these rules are presented in Table 7.

TABLE 7

* Prepared by Melton and Malmo (unpublished).

The calibration of nonsense syllables according to their association values, that is, according to the ease with which they suggest words, was first undertaken by Glaze (1928), whose published list of syllables was used in determining the association values of the syllables presented in Table 7. Hull (1933b) used a somewhat superior method, in that the associated items were called for in a situation more nearly approximating that of the usual memory experiment, but he did not calibrate as many syllables as Glaze. Krueger (1934) extended Glaze's list. Witmer (1935) calibrated 4,534 consonant groups by a method similar to that of Glaze.

The Glaze list, with deletion of duplications and of syllables in which "y" was used as a vowel, is reproduced in Table 8. A list of syllables of low association values, making use of information from the studies of Glaze, Hull, and Krueger, has been prepared by Melton (unpublished) and is reproduced in Table 9. A selection of Witmer consonant groups is given in Table 10.

* Units containing "V" and "W" have been eliminated. The others represent a selection from Witmer's published lists.

That degree of association value affects the ease with which nonsense syllables can be learned and retained has been shown by McGeoch (1930). When 10-item lists were studied for 2 minutes, the immediate recall varied directly with the associative value. Recall was highest for three-letter words (9.1), next for 100 per cent syllables (7.4), next for 53 per cent syllables (6.4), lowest for the 0 per cent syllables (5.1). It is of interest that the gap between the 100 per

cent syllables and meaningful words is greater than that between adjacent steps of associative value for nonsense syllables.

Meaningful verbal materials. The discovery that nonsense syllables can be classified according to association value both justifies their use (because they are not so remote as might be supposed from the kinds of materials more practically important) and denies some of the unique value attributed to them. There is, in fact, some trend away from the

use of nonsense materials in memorization experiments. This is in part because the motivational value of meaningful materials is much higher, and some of the supposed advantages of nonsense syllables do not exist (Davis, 1930; Sauer, 1930). In addition, there are problems, such as the effects of meaningful similarity, for which the nonsense syllable is inappropriate. Three-letter words have been used in experiments designed like those with nonsense syllables, and two-syllable adjectives have become increasingly popular. Melton and Safer (unpublished study) have rated 300 adjectives for degree of similarity (Table 11). Other meaningful materials include those with patterns of

stimuli, all have been the subject of study in experiments concerned with memorization, recognition, and recall. Such materials, like the verbal ones, vary from meaningless items (e.g. asymmetrical line patterns) to items rich in personal association, as in testimony experiments. Often the cue item is nonverbal and the response item verbal, so that the distinction between a verbal and a nonverbal task is not a sharp one. Satisfactory attempts to standardize nonverbal materials are lacking.

Methods for the Study of Memorization

Immediate memory span. Related to what has sometimes been called the span of at-

FIG. 7. Memory drum (University of Missouri model). The material to be memorized appears in the small aperture as the drum revolves. A number of lists may be mounted on the drum at once, the list to be exposed being selected by the position of the aperture (photograph courtesy Stanford Psychological Laboratory).

meaning, as in prose or poetry. Standardization has seldom been attempted. There is usually an assumption that the author of a long poem or treatise maintains about the same difficulty throughout. This assumption is subject to test, through the use of word counts or difficulty scores on the pattern suggested by Flesch (1945).

Nonverbal materials. Objects, pictures, observed activities, assigned tasks, sensory

attention or the span of apprehension is the immediate memory span—the number of items that can be learned in one trial when they are presented serially at a controlled rate. Digits, words, pictures, or objects may be used, although the verbal items are the more common. The method is an adaptation of threshold methods used in psychophysics. Lists of 4 to 12 items are commonly used. Several scores are possible.

The longest list successfully recalled is often taken as the measure of span, although alternative scores may be used. The one recommended by Woodworth (1938) is the average of two tests, the score for each being the length of longest list recalled without error.

The serial-anticipation method. The chief laboratory method for the study of lists of items to be learned by rote memorization is that known as the serial-anticipation method, developed by Finkenbinder (1913) from Ebbinghaus' method of prompting. Items are presented one after the other, only one exposed at a time. The exposed item serves as the cue to the one that follows. It also serves to confirm or to correct the subject's anticipations. Because the subject announces his anticipation for each item, the experimenter can record the exact response and obtain not only the rate of memorization but also the nature and number of the errors made. By the use of a voice key and supplementary apparatus the latency of response may be recorded as well as the accuracy. This is probably the most used method in American laboratories during the last twenty-five years.

Among the problems of procedure that have to be settled are the following:

1. The nature of the material to be learned, and the rules to be followed in list construction.
2. The subjects to be selected for the experiment.
3. The instructions to be given the subjects.
4. The preliminary training to be given the subjects before the experimental study proper begins.
5. The interval between serially presented items, and the exposure time for the item.
6. The interval between repeated trials through the list.
7. The scores to be recorded.
8. The criterion for mastery.

It is not unreasonable to expect experimenters in different laboratories to adopt standardized procedures for many of the conventional aspects of their experiments and then to introduce such changes as are necessary in order to test whatever new hypothesis interests them. By introducing essential novelties in procedure many experiments that ought to be brought into relation

are made so different that comparative appraisal is impossible.

The subject must be told either to pronounce or to spell the syllables. McGeoch (1942), following Luh (1922), recommended spelling, because of the confusion in the pronunciation of syllables like XED and ZEQ. If pronunciation is not required, unpronounceable syllables like XOQ may be used. Most of the work in Hull's laboratory (e.g. Hovland, 1938) was done with syllables that were pronounced rather than spelled. One disadvantage of the method of spelling out syllables is its artificiality when meaningful words are used. In the comparative studies of Davis (1930) and Sauer (1930), syllables were spelled out and words were not, thereby introducing an additional variable of unknown influence.

The importance of preliminary training is emphasized in studies that show the rapidity with which subjects "learn how to learn." The results of Ward (1937) are presented in Fig. 8, showing the rapid decrease in the number of trials required for learning each of the first six lists, with gradual improvement thereafter. This is an average curve. Subjects do not all follow the same pattern, and, unless some preliminary practice lists are given before experimentation proper, there is no way of telling where the subject is in the course of his changes in speed of learning.

The most common intervals between serially presented items are 2 seconds and 3 seconds. Because different types of mechanical presentation have been used, some experiments using the same interval have had different amounts of time used in changing from one item to the next and hence different proportions of the interval during which the item was exposed. It is desirable to minimize the time used in changing the items, so that for practical purposes the stated interval is also the exposure time for each item.

The interval between trials becomes a variable in experiments on distributed prac-

tice. Occasionally the lists have been run as a circular series, with the same time between the last and the first items as between the first and second items. A common practice for base conditions has been to make the time between trials three times as long as the presentation interval.

Because each item within the list is both a stimulus and a response, the first and last items are somewhat unique. The first is not

FIG. 8. Changes in rate of learning successive lists of 12 nonsense syllables (after Ward, 1937, as reproduced by McGeoch, 1942, p. 400).

a response item; the last is not a stimulus item. A decision is required about the use of the first item, because some signal is needed to inform the subject to begin recall. Two practices are used. One uses an indifferent item, such as 000, which tells the subject to attempt to recall the first nonsense syllable of the list. This makes the first syllable a response as well as a cue, which is important in some kinds of experiments, such as those on remote association. The other practice makes use of a cue item that is in all respects like other members of the list, but is not itself used as a response. In that case, if the subject is asked to learn a 10-item list, the list is actually constructed with 11 items, the first serving merely as a starting signal. The argument in favor of the latter method is that throughout the learning a nonsense syllable is used as a cue.

In the studying of such factors as serial position effect, it is desirable to have the cue conditions as like as possible for all items.

The data to be recorded depend upon the purposes of the experiment. The minimum is a score of hits and misses throughout memorization. In addition, actual responses may be recorded in order to study partial recall, place-skipping tendencies, intrusions from other lists, etc. Latency of response may also provide data of interest.

The experimenter must decide what criterion of mastery to employ. If all subjects practice memorization for a given number of trials, they will reach the end stage at different degrees of underlearning or overlearning. The more usual practice is to continue the trials until the subject has learned some standard proportion of the items (say 75-per-cent correct), or has yielded one perfect recitation, or two or three consecutive perfect recitations. What shall be considered mastery is arbitrary. Ideally the choice should be made in favor of the most reliable criterion. More severe criteria are not necessarily more reliable. There is a statistical problem with criterial scores which is sometimes overlooked. Any criterion that depends upon the first reaching of some high level of performance capitalizes on chance fluctuations in the direction of good scores. The mean of scores just after the criterion will tend to fall below the criterion trial.* Unless these artifacts are understood, misinterpretation of score values around the criterion are likely to arise. How serious these factors are may be illustrated by some data from Ward (1937). He found that on the trial following the criterion of one perfect recitation for a 12-unit list the number of syllables recalled was only 9.75. The "true" learning, which should serve as the

base for studying retention, was not the artificially high 12 units (which depended on the peaks of fluctuation in memorization) but was actually 2.25 syllables less. For partial mastery, in which the subject had learned 7 of the 12 items, the next trial yielded an average of 7 items. This might seem to negate the generalization that the trial beyond the criterion is invariably too low. If we remember that the memorization curve is rising rapidly at the point at which 7 of 12 items are being learned, we would predict that the trial beyond that on which 7 items are correct would be somewhat above 7. Hence the fact that only 7 correct responses are found shows that the principle of this following trial's being too low is not violated.

The method of paired associates. The task presented the subject in the method of paired associates is that of learning a series of discrete pairs so that the first member of the pair (stimulus member) will come to elicit the second member of the pair (response member). The learning of which pair follows which is not called for, and, in fact, the order is varied in the preferred experimental arrangement so that serial position effects are counteracted. That this makes a difference is clear, for it is easier to learn paired associates if the order remains constant than if the order is varied (McGeoch and McKinney, 1937). In order to obtain scores from the learning of paired associates similar to those from the serial-anticipation method, the memory drum is so arranged that the stimulus item appears in the aperture for a time before the response item appears. This permits the subject to announce the response item before it comes, so that the response may be recorded exactly as in the other method. The simplest way to do this with an ordinary memory drum is to have the stimulus item appear alone in the aperture and then in the next turn of the drum to have it appear again with its associated item. This uses two turns per item instead of the one turn used in

* In the case of more severe criteria, such as two consecutive perfect trials, the trial just preceding the criterion tends to average too low because of the exclusion of all perfect scores. Perfect scores may be made on all trials *except* that just preceding the criterial trials.

the serial-anticipation method, and the time intervals are changed to that extent. A more complex method is to use a supplementary shutter that conceals the response item when the stimulus item is first exposed, but then opens and exposes both members of the pair before the drum turns to the next pair.

Comparison of the methods. Although a number of other methods of studying acquisition have been used, the three mentioned are the best standardized. Since the memory-span method is somewhat specialized, interest centers in the similarities and differences between the serial-anticipation method and the paired-associates method. The serial method is the natural one for studying connected passages of meaningful material, like poetry or prose, and its use with artificial material provides analogies with such rote memorizing. The paired-associates method is equally natural, in that it parallels what goes on in connecting the names of objects or persons with their appearance, and in learning the equivalence between familiar and foreign words.* The processes are somewhat different, and it is appropriate to have standardized laboratory methods which may be used in studying them. A number of features such as serial-position effects and remote associations may be studied only in the serial-anticipation method, although for some purposes the paired-associates method may serve as control. The methods may complement each other in the test of certain hypotheses, as, for example, the nature of reminiscence. If reminiscence depends upon intraserial interferences, it should be found

* A variant of the paired-associates method is the word-number experiment made familiar by Thorndike in his experiments on spread of effect. The subject is required to guess the correct associate. If the guess is correct it is rewarded by being called "right" (Thorndike, 1933). Earlier experimenters working with the phenomena of spread of effect have made a number of errors in experimental design and in treatment of data, so that the principle as enunciated by Thorndike is of dubious validity. Some critical experiments are summarized by Hilgard (1948). Additional criticisms appear in Smith (1947).

with the serial method, not with the paired-associates method (Hovland, 1938).

Overlearning. The problem of the criterion of mastery has already been discussed. A related problem is that of a measure of learning beyond simple mastery.

Faced with the problem of defining overlearning, Luh (1922) assumed that the number of trials to mastery could serve as the base for 100-per-cent learning. Any additional trials could be counted as so much overlearning, expressed as a ratio to this base. Thus, if 20 trials were required to mastery, an additional 20 trials would add 100 per cent, or would be counted as 200 per cent of learning. The same definition has been used by Krueger (1929, 1930). This method is clear enough, but it exaggerates whatever chance factors led to the attainment of the original criterion of mastery, and it lacks a theoretical justification for the units of the overlearning scale.

It would be desirable to express overlearning in a manner that can be checked internally to see whether its meaning is similar from subject to subject. One method might be to describe learning according to the average number of successful responses per item. This implies that overlearning really begins when an item has been learned, and is proportional to the number of times that item has been given correctly in attempted recall. The value obtained by this method will tend to be higher for the slow learner than for the rapid learner, because the slow learner is often troubled by a few syllables while greatly overresponding to the others. In approaching some standard amount of overlearning, Luh's method would provide many more trials for this slow learner who may have already overlearned more prior to mastery than the rapid learner. If the proposed method were adopted, different stages of overlearning could be expressed by the same type of score:

Degree of learning

$$= 100 \frac{\text{Total correct anticipations}}{\text{Total opportunities to respond}}$$

Such a score would have to be given empirical standardization, for it is not known what its values would be at different criteria of mastery or at different stages of over-learning as described by Luh's method. Unfortunately such standardizing has not been done.

Methods for the Study of Retention

The problem of memorization, of committing to memory, is but the beginning of a cycle of activities in which the student of the acquisition-retention process is interested. What happens after memorization constitutes the problem of retention. Retention is measured by retesting following a lapse of time after memorization. There are a number of methods, of which the five made familiar by Luh (1922) may be taken as typical.

Recognition. All that is asked of memory in recognition is that a situation that recurs be recognized as familiar. Because the original situation is again present to the senses, cues to reinstatement are fully present and the task is relatively easy. The problem of the experimenter is to distinguish between false recognition and true recognition, because even a fully cooperative subject may be inaccurate in what is seen as familiar as well as in what is seen as unfamiliar. The usual experimental method is to present an equal number of familiar and unfamiliar items in random order. The subject is asked to select those familiar, those unfamiliar. A doubtful category may also be used. Success is scored as in a true-false examination.

$$\text{Score} = \frac{100(R - W)}{T}$$

where R = number right, correctly sorted.

W = number wrong, incorrectly sorted.

T = total number of items, including doubtful ones.

This score ranges from zero at chance level to 100 per cent at perfect recognition.

Reconstruction of series. To test retention of arrangement rather than of substance, the

subject is given cards on which are printed the items that were learned in serial order. He is asked to arrange them in the correct order. This kind of test is difficult to score in a manner symmetrical with that employed in other tests of recognition and recall. One possibility is to use a rank difference correlation between the rearranged order and the original order. This score will vary between zero at chance and 100 at perfect reconstruction. The possibility of negative values exists, as indeed it does in the method of recognition described above.

Unaided reproduction. The subject attempts to write out the material without prompting of any sort. This is the test of memory with the minimum of cues. The instructions are simply: "Try to reproduce what you learned." Because partial recall aids further recall, it is often desirable to separate the recall record so that material immediately recalled can be distinguished from material subsequently recalled. In some experiments (e.g. Zeigarnik, 1927) the results depend upon this distinction.

Recall score. In the anticipation method the first relearning trial serves as a test of recall. The score is the percentage of items correctly anticipated. Because of the artificiality of mastery defined by a criterion, the base for 100-per-cent recall should be a control trial following that on which the arbitrary criterion is reached. In the paired-associates method, the score is the percentage of right associates in the first trial. In both cases there are somewhat more cues ('promptings') than in the method of unaided reproduction.

Saving score. If there is any residue whatever from an earlier learning, it should reduce the time required to remaster the material. A poem learned in childhood, apparently forgotten, might still show some residue under this relearning method. The saving score is computed as the ratio of the trials saved in relearning to the trials required in original learning, expressed as a percentage.

There is an ambiguity in saving scores that arises because of the use of criterial trials in learning and relearning. In order for scores to extend from 0 to 100 per cent, it is necessary to make allowance for the fact that even with perfect retention it is still necessary to meet the criterion in order to demonstrate this retention. The correction is to subtract the criterion trials from all the items entering into the saving score formula (Hilgard, 1934):

$$\begin{aligned} \text{Saving score} &= \frac{100[(OL - C) - (RL - C)]}{(OL - C)} \\ &= \frac{100(OL - RL)}{(OL - C)} \end{aligned}$$

where *OL* = trials required for original learning.

RL = trials required for relearning.

C = trials required to meet the criterion of mastery.

The simplest test of the appropriateness of a score of this kind is to use it with artificial data for the conditions of 100-per-cent saving and 0-per-cent saving. If 100 per cent and 0 per cent are not yielded by the formula, values are being inappropriately entered.

There is a further correction needed in order to interpret saving scores (Bunch, 1941). Because "learning how to learn" is going on, a saving score should be tested against control learning of a new but equivalent set of materials. Thus if a poem learned in 30 repetitions in early childhood can be learned several years later in 20 repetitions, the difference cannot be attributed to retention unless an equivalent poem, learned at the later time, requires the original 30 repetitions. Perhaps memorization skill has gone up in the meantime.

Curves of retention. In plotting curves of retention, it is customary to have a learning session and a retention session for each interval to be studied. This avoids a progressive effect that would be encountered if after a single learning several successive

retests were used.* It requires that the learning groups be matched or equated in some manner, not only in learning scores but in the amount of prior practice. This can be achieved either by using a new group of subjects for each interval studied or by a fairly elaborate rotation of conditions. In any case, precise determination of the form of the curve of retention is a laborious process.

Retroactive and proactive inhibition. One of the favorite fields of study within memory has been that of retroactive inhibition: the negative transfer whereby the learning of new material makes it increasingly difficult to retain items learned earlier.

The standard arrangement is as follows:

	ORIGINAL LEARNING	INTERPOLATED ACTIVITY	RECALL OR RE- LEARNING	POSTEXPERIMENTAL TRAINING
Experimental group	Learn A _e	Learn B	Test A _e	Test B
Control group	Learn A _c	(Rest)	Test A _c	Learn B

If the experimental and control groups are comparable in their learning of A_e and A_c, then the amount of retroactive inhibition is the amount by which test A_e lies below test A_c.

McGeoch (1942, p. 459n) points out that it is desirable to keep all the subjects at the same level of practice, and hence to follow the test for the control group by the learning of material B. Similarly, if subjects are to be used in further cycles of the experiment, a retest for at least two relearning trials of material B is given the experimental group, lest the learning of material B (interpolated activity) be not taken as seriously as the learning of the other lists.

Proactive inhibition refers to the interference with new learning because of prior learning. The paradigm is:

	ORIGINAL LEARNING	TEST SITUATION
Experimental group	Learn A _E	Learn B _E
Control group	(Rest)	Learn B _C

* Hebb and Foord (1945) have made this objection to many of the earlier studies on changes in the reproduction of perceived forms, following Wulf (1922).

If the learning of B_E takes longer than the learning of B_C , proactive inhibition may be said to have occurred.

Motivational Factors in Forgetting

The clinical facts of amnesia, a memory loss from which there is later recovery, are supported by experimental studies in hypnosis. The facts are interpreted by the Freudian theory of repression. Problems are set for the experimental study of memory by these facts, but the results of such studies have thus far been rather meager (Rapaport, 1942; Sears, 1943).

Memory for pleasant and unpleasant items. Subjects are asked to rate items later to be used in memorization experiments for their degree of pleasantness or unpleasantness. Usual memorization and retention experiments are then conducted to determine which type of item is more rapidly committed to memory and which is more permanently retained. Summaries of the literature may be found in Gilbert (1938) and Rapaport (1942).

Memory for pleasant and unpleasant experiences. Because the personal involvement of the subject is important in experiments that stress motives, subjects have been asked to recall pleasant and unpleasant experiences, e.g. those had during a vacation period. Later recall is then used to determine whether there is a progressive forgetting of the unpleasant compared with the pleasant experiences. Although these experiments are designed to test the dynamic features of Freud's theory, their procedural difficulties are very great. Not only does the change in number of items reported occur, but changes occur in the hedonic appraisal of these same items on two different recalls (Meltzer, 1930).

A variation of the experiment, which holds some promise, was introduced by Sharp (1938), who examined the case histories of neurotic patients for items that would presumably arouse guilt or anxiety, and used these as the basis for retention studies. An

attempt to repeat Sharp's experiment has unfortunately been unsuccessful (Heathers and Sears, as reported in Sears, 1943).

Hypnotically induced complexes. The method of Huston, Shakow, and Erickson (1934) can undoubtedly be extended in the study of the dynamics of memorial distortion. The problems of control in hypnotic experiments are many (e.g. Hull, 1933c), but that does not mean that the experiments are to be avoided.

Memory for completed and uncompleted tasks. An experiment first undertaken by Zeigarnik (1927), since repeated and extended by others, shows a differential effect upon retention when tasks are interrupted or completed. With some twenty tasks done in a single period, subjects recall only about half (immediate unaided recall), and, under some circumstances, many more of the unfinished tasks are recalled than of the finished ones. The differential effect appears to be quite temporary, being lost over 24 hours, but the whole matter requires further study.

Word-association experiments. Although word-association experiments are not ordinarily thought of as tests of retention, they serve in fact to exhibit the conditions under which one rather than another of possible associates is aroused. Familiar in guilt-detection studies and in personality investigations, they also hold some promise in the study of the circumstances of recall.

Word-association experiments have been used in formal memory studies chiefly in the investigation of remote associations, following Wolgemuth (1913). These studies (McGeoch, 1936; Raskin and Cook, 1937) suffice to show that the method might be adapted to other studies of the dynamics of retention.

Reliabilities of Memorization Scores

It has not been customary in memorization experiments, as it has in maze experiments, to report reliability coefficients. Much remains to be done to determine the

dependability and reproducibility of such scores as reflecting individual differences.

A set of reliability coefficients is available from the study by Stroud, Lehman, and McCue (1934). These are reproduced in Table 12. Nonsense syllables were memorized by 76 college students. The serial anticipation method was used, with a 3-second presentation interval. Learning was to a

TABLE 12

TRIALS TO LEARN AND RELIABILITY COEFFICIENTS FOR LEARNING OF NONSENSE SYLLABLE LISTS BY THE ANTICIPATION METHOD (AFTER STROUD, LEHMAN, AND MCCUE, 1934)

	6-Syllable List	12-Syllable List	18-Syllable List
Trials to learn			
Mean and S.D. (1)	5.90 ± 1.97	10.5 ± 3.74	14.9 ± 3.95
Mean and S.D. (2)	5.60 ± 2.06	10.1 ± 3.56	13.8 ± 4.20
Reliability coefficients			
Scores on odd-even trials	0.65	0.95	0.96
