Taste and Smell

CARL PFAFFMANN

Brown University

Taste, smell, and the so-called common chemical sense are frequently grouped together because agents that excite them are most readily described and classified by their chemical formulas. There is no proof, however, that stimulation depends primarily upon a chemical reaction between the ions or molecules of the stimulus and some part of the receptor concerned. In certain instances, as in the sense of taste, it is known that the stimulus substance must be in solution. Colloids are tasteless. It has been argued that odor-producing molecules dispersed in a gaseous form must first dissolve in the mucus that covers the olfactory epithelium before stimulation can occur. But efforts to stimulate the olfactory receptors of man by stimulus solutions introduced directly into the nostrils have not been conclusive. In water-inhabiting vertebrates, olfactory stimulation by substances dissolved in the water obviously takes place (Parker, 1922).

Three types of sense organ and sensitivity are included in the chemoreceptor group:

1. The *common chemical sense*, a sensitivity to mildly irritating solutions found on moist mucous membrane surfaces such as the eyeball and nasal and mouth cavities, as well as the external skin of water-inhabiting vertebrates. The nerve endings appear to be undifferentiated free nerve terminations from the nerves of general sensitivity.

2. The sense of *taste* located in man on the tongue and portions of the throat. In

certain water-inhabiting vertebrates this sensitivity may be present on barbels and other parts of the body surface. The sense organs are specialized endings called taste buds consisting of modified epithelial cells upon which gustatory afferent nerve fibers terminate.

FIG. 1. The three types of chemoreceptor. Olfactory cell (A) and free nerve endings (B) consist entirely of neural elements; gustatory receptors (C) consist of modified epithelial cells upon which the afferent nerve fibers terminate. (From Parker, 1922.)

3. The sense of *smell* which in man is located in the upper recesses of the nasal cavity and in lower animals in olfactory pits or sacs. The end organs consist of long spindle-shaped cells with fine hairs projecting from their distal ends. The proximal end of the cells tapers into fine nerve fibers to form the olfactory nerve.

Of these three classes of sensory cells, only those of the common chemical sense and olfaction are primary neural elements (Fig. 1). The sense cells of taste are modified epithelial cells. When the taste nerves are cut, the taste cells and buds degenerate. When the nerve fibers regenerate and reach

the periphery, taste cells and taste buds reform (Olmsted, 1920*a, b*).

The fact that the chemical sense organs are grouped together at the entrance to the respiratory and alimentary tracts of air-inhabiting animals means that these senses are frequently stimulated in combination. The contribution of each of these senses to the complex experience we call flavor or "taste" of food may be ascertained only by analytical study. These perceptions are further complicated by other components such as warm, cold, touch, and pressure.

For man, vision and hearing appear to be the more important senses, in spite of the fact that the chemical senses have a close relation to food getting, avoidance of certain noxious fumes, and perhaps sexual activity. Loss of taste, ageusia, although disconcerting, is nothing like the loss of vision or hearing. Perhaps taste and smell are of greater importance in animals. In fact, the relatively greater development of certain structures underlying olfaction in some species has led to the designation of these creatures as macrosmatic as opposed to man who is microsmatic.

Recent experiments have reemphasized the importance of the chemical senses in food getting. Animals rendered deficient in one constituent of the diet were found to increase the intake of the needed substance when given access to a wide variety of food substances. The capacity to make such selections seems to depend on taste. Selection of needed substances because they "taste good" may occur in human beings under certain conditions (Richter, 1942).

COMMON CHEMICAL SENSE

The existence of two classes of receptors in the nasal passages has long been recognized: (1) the true olfactory nerve endings of the olfactory cleft and (2) the common chemical sense consisting of the trigeminal nerve endings sensitive to mildly irritating vapors. True odors are typically described by such

terms as fruity, foul, fragrant, etc., whereas the trigeminal stimulants cause mild pain and frequently lead to strong reflex effects like sneezing, crying, or coughing. Many olfactory stimulants may affect both systems. Experimental studies on animals with surgical removal of one or the other set of nerves indicate that only such relatively mild agents as oil of cloves, extract of orange, etc., stimulate the sense of smell alone. Oil of wintergreen, xylo, acetic acid, or ammonia stimulate both smell and the free nerve endings (Allen, 1929).

Acids in concentrations far above those required to call out the sour taste will elicit pain from surfaces of the mouth devoid of taste buds, and, in fact, from all exposed or partially exposed mucous membrane surfaces. In lower aquatic vertebrates the whole surface of the body is sensitive to acids and other irritants.

The common chemical sensitivity is said to be distinct not only from touch, but also from pain (Crozier, 1916*a*). However, the type of afferent impulse elicited by chemical stimulation in the cutaneous nerve preparation of the frog, for example, appears to be much the same as that elicited by scraping, burning, or other injury. These impulses travel in small nerve fibers of slow conduction. Impulses initiated by tactile stimuli are of large potential and are rapidly conducted (Adrian, Cattell, and Hoagland, 1931). Crozier (1916*a*), utilizing the leg flexion of the frog as an indicator of stimulation, studied the differential effect of cocaine upon the sensitivity to pain elicited by a pinch on the foot and by immersing the foot in acid. After cocainization the acid continued to elicit a response whereas pain had become ineffective. The reaction time to the acid, however, was increased. It might be argued that, since the chemical stimulus covered a large area of the foot, spatial summation occurred to render the chemical more effective. Pain and the common chemical sensitivity appear therefore to be mediated by the same nerve endings.

On the other hand, it is quite clear that such chemical sensitivity is distinct from touch, and, in the mouth and nose, distinct from taste and smell.

Of the three types of chemically sensitive endings, the common chemical sense appears to be the least sensitive. For alcohol, which is an adequate stimulus for all three senses, the threshold values for mouth surfaces devoid of taste buds ranged from 5 to 10 mol.* The mildly sweetish taste of alcohol could be detected at 3 mol, and the odor at a concentration of 0.000125 mol (Parker and Stabler, 1913).

TASTE

Anatomy. The taste end organs consist of spindle-shaped cells grouped together in

FIG. 2. Golgi preparations of taste buds and associated nerve endings. *A.* Taste cells and a "sustentive" element. *B.* Nerve endings, sense cells not shown (after Retzius). (From Crozier, 1934.)

gobletlike clusters called taste buds. A tiny hair projects from each taste cell toward the taste pore at the open end of the bud. The nerve fibers supplying these taste cells arise from a subepithelial plexus to wind about and terminate on the surfaces of the taste cells. Certain nerve fibers may be seen to bifurcate and to end upon more than one taste cell in either the same or neighboring taste buds (Fig. 2).

On the tongue, the taste buds are primarily located on the dorsal surfaces of the mushroomlike fungiform papillae, in the grooves of the foliate papillae, and in the trenches of the circumvallate papillae at the back of the tongue (Fig. 3). The middorsal tongue region is devoid of taste buds and is

* Mol is an abbreviation for molar concentration (see footnote on p. 1148).

insensitive to taste stimuli. Taste buds are also found in somewhat lesser numbers on the palate, the anterior faucial pillars, the pharynx, and the larynx.

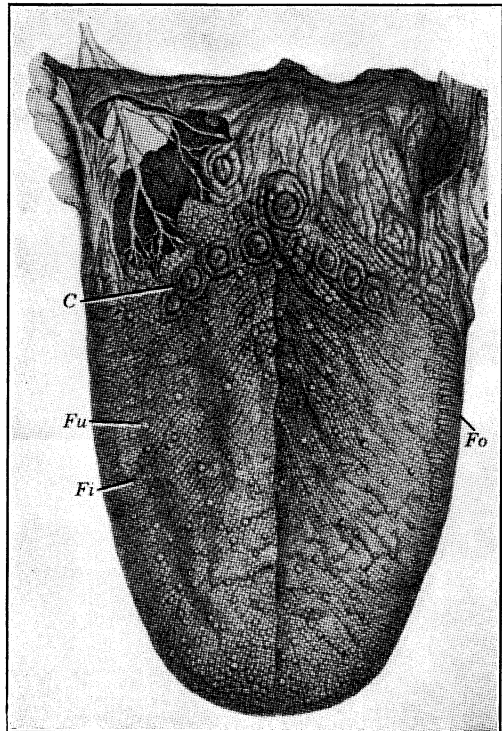

FIG. 3. Dorsal surface of the tongue partially dissected to show the nerves to the posterior part. The circumvallate (*C*), fungiform (*Fu*), and filiform (*Fi*) papillae are shown. The foliate papillae (*Fo*) are not clearly visible in this view since they are on the lateral surface of the tongue. Taste buds occur in *C*, *Fo*, and *Fu*, not in *Fi*. (From Wenzel, reproduced from Warren and Carmichael, 1930.)

The number and distribution of taste buds change with age. In children many more buds are found over the dorsal tongue surface. With increasing age, the number of taste buds decreases (Arey, Tremaine, and Monzingo, 1935). The reduced sensitivity found in older people is probably associated with this decrease in the number of sense cells (Richter and Campbell, 1940).

The nerve fibers from the taste buds do not travel in a single cranial nerve. Those

from the anterior part of the tongue travel in the lingual nerve, a mixed nerve that subserves touch, temperature, and pain sensi-

native pathway may exist (Fig. 4). (See Cushing, 1903; Lewis and Dandy, 1930; Schwartz and Weddell, 1938.) Nerve fibers

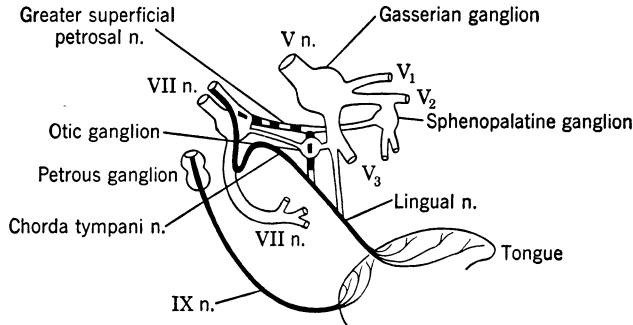

FIG. 4. The nerve supply to the tongue. The solid lines indicate the most common pathways for the taste impulses. The broken line indicates an alternative path from the chorda tympani believed to exist in a limited number of cases. (Modified from Cushing, 1903; Schwartz and Weddell, 1938.)

FIG. 5. The effect of lesions near the medial lemniscus on gustatory discrimination. The ordinate shows the percentage of total fluid intake selected from the quinine flavored bottle. Heavy solid and heavy broken lines are the pre- and postoperative threshold curves, respectively, of a rat with the lesion shown in stipple in the inset. Fine broken lines are the threshold curves of seven normal rats. ML, medial lemniscus; PC, cerebral peduncles; CG, central gray matter. (From Patton and Ruch, 1947.)

tivity. The taste fibers, however, leave the lingual nerve to form a small branch, the chorda tympani, which crosses the tympanic membrane of the ear on its way to join the seventh cranial nerve (Olmsted, 1922). This is the typical pathway, although in man clinical evidence has suggested that an alter-

native pathway may exist (Fig. 4). Nerve fibers from the larynx and pharynx may travel with the tenth (vagus) nerve. The lingual nerve supply is essentially homolateral, although there is some evidence for a dual innervation of the circumvallate papilla.

The nerve fibers carrying taste impulses are relatively small in diameter as judged by the amplitude of the action potentials following gustatory stimulation (Hoagland, 1933; Zotterman, 1935; Pfaffmann, 1941).

The gustatory fibers of the seventh, ninth, and tenth nerves form a well-defined tract of the medulla, the tractus solitarius. The secondary gustatory neurons arise from its nucleus. Both histological and behavioral studies indicate that these fibers ascend in the opposite medial lemniscus (Fig. 5). Clinical, anatomical, and physiological observations have indicated that the taste fibers in the thalamus are closely allied with those of general somatic sensitivity of the face in the arcuate nucleus. In the cortex, likewise, taste is localized in relation to the somatic sensitivity of the face and not in conjunction with the olfactory sensitivity as was formerly supposed (Patton and Ruch, 1947). The region concerned lies at the inferior end of the central fissure near the sylvian fissure (Fig. 6).

Taste Qualities

Sour, salty, bitter, and sweet are the typical gustatory qualities elicited by sapid solutions applied to the taste buds. It is commonly held that these four are the primary taste qualities from which all other true tastes are compounded. Although some investigators (Hahn, Kuckulies, and Taeger, 1938) include alkaline with this group, most others believe that alkaline is a combination taste that may include nongustatory components like touch, olfaction, or pain (Oehrwall, 1891; von Frey, 1910; Kloehn and Brogden, 1948). The complex tastes of many stimuli may be duplicated by mixtures of substances that elicit the four basic qualities. The salty-sour bitter taste of potassium chloride, for example, may be matched by an appropriate mixture of sodium chloride, tartaric acid, and quinine hydrochloride (von Skramlik, 1926).

The fungiform papillae on the anterior part of the tongue can be stimulated indi-

vidually by means of very fine brushes moistened with saturated solutions of quinine sulphate, cane sugar, and sodium chlo-

FIG. 6. Schematic diagram of the central pathways of the somatic fibers of the Vth nerve and gustatory fibers of the VIIth and IXth nerves. Important parts are: SNV, spinal nucleus of the Vth nerve; TS, nucleus of the tractus solitarius; ML, medial lemniscus; LL, lateral lemniscus; IC, internal capsule; SF, sylvian fissure. (From Patton and Ruch, 1947.) The results of recent experiments (not shown in the diagram) indicate that some fibers terminate in the opercular and para-insular cortex buried in the sylvian fissure.

vide or a 0.2-per-cent solution of hydrochloric acid. Of 39 papillae tested in this manner, three reacted exclusively to salt, three to acid, seven to sweet, and none to bitter. The others reacted to all or some of these stimuli in various combinations (Oehrwall, 1891; Kiesow, 1898). Punctate stimulation

of slightly larger areas on the tongue indicates that salt sensitivity is greatest on the tip and sides, sour on the sides, sweet on the tip and bitter on the back (Kiesow, 1894; Hänig, 1901).

This suggests that the four qualities may be mediated by four different receptor mechanisms present in various combinations in each of the papillae and occurring with varying density in various parts of the tongue. The differential action of certain drugs like

gan with which the stimulus combines before stimulation can take place.

Sour. Of the stimuli for the four fundamental tastes, that for sour has been most clearly defined. The sour taste is a common property of all save the very weakest acids like phenol. The common property of all acids is that in aqueous solutions they ionize into anions and the cation hydrogen.

FIG. 7. Oscillographic record of a single nerve fiber preparation responding to acid on the cat's tongue. The large initial upward deflection signals the time of applying the stimulus. This is followed by the train of nerve impulse spikes. A. Stimulus 0.5 *N* acetic acid. B. Stimulus 0.01 *N* hydrochloric acid. Each interval mark at base of record B indicates $\frac{1}{10}$ second. (From Pfaffmann, 1941.)

gymnemic acid, which selectively reduces only sweet and bitter sensitivity, is consistent with this view (Shore, 1892; Kiesow, 1894). In a study of the action potentials in the gustatory nerve fibers of the cat, individual nerve fibers were isolated that responded only to acid and not to any other taste stimuli like sodium chloride, sucrose, or quinine (Fig. 7). (See Pfaffmann, 1941.) Two mixed types were found, one that responded to acid and salt, and a second that responded to acid and quinine. No fibers responsive to sugar were found. Since the histological evidence shows that one fiber may supply more than one taste bud, the mixed sensitivity could be accounted for by this fact. It is clear, however, that a specificity for acid stimuli has been demonstrated. Crozier (1934) has suggested that such specificity might be determined by a specific receptive substance in each end or-

In most chemical reactions the strength of an acid is determined by the degree to which this dissociation occurs. Strong acids of equal concentration have a sour taste that is proportional to the degree of dissociation. On the other hand, weak acids like acetic, which are only slightly ionized, have a sour taste greater than would be predicted from the H ion concentration. In one study the threshold for HCl was 0.00125 *N* with a pH of 2.9.* Acetic acid thresholds fell at a con-

* Chemical concentration may be stated in several different ways:

1. Percentage concentration equals the number of grams of solute dissolved in 100 grams of solvent. Where water is the solvent, this is equivalent to 100 cubic centimeters (milliliters) of water. Other ways of specifying percentage concentration are frequently used as, for example, the number of grams of solute in 100 grams of solution.

2. Molar concentration (mol) equals the number of gram molecular weights in 1 liter of solution. The number of grams of solute divided by its molecular weight equals the gram molecular

centration of 0.005 *N* with a pH of 3.5 (Richards, 1898; Kahlenberg, 1898). It has been suggested that organic acids may penetrate the receptor membranes with greater ease than do strong acids (Crozier, 1916*b*; Taylor, 1928*a*). On the other hand, the difference in taste strength of weak and strong acids has been attributed to the buffer action of saliva. A typical buffer system consists of the salt of a weak acid, such as sodium acetate, mixed with acetic acid. The salt, sodium acetate, tends to be highly dissociated, and the partially dissociated acid acts as a reservoir for H ions such that, upon the addition of other H ions, the excess is taken up by an increase in the amount of undissociated acid.

This reaction, i.e. change in undissociated acid, proceeds to the right when H ions are withdrawn. The total free H ion concentration does not change significantly in such a buffer.

Weak acids and saliva act like such a buffer so that little change in the original pH of the acid itself occurs in the mouth. Acetic acid held in the mouth for 5 seconds showed a pH change from 3.5 to 4.4. Sul-

weight. Equal volumes of equimolar solutions contain an equal number of molecules.

3. Normality *N* equals the number of gram equivalents in 1 liter of solution. The gram equivalent is usually given by the molecular weight of a compound divided by the total positive or total negative valence without regard to sign. For HCl the molar and normal concentrations are equal. For H₂SO₄, the normality is one-half the molarity because the SO₄ group has a valence of two and requires two hydrogen atoms. Solutions of a given normality always react with exactly equal volumes of any solution of the same normality.

The hydrogen ion concentration is usually stated in terms of pH, the hydrogen ion exponent:

$$\text{pH} = \log_{10} \frac{1}{[\text{H}^+]}$$

where [H⁺] is the effective H ion concentration in normality. Since the H ion concentration in pure water is 1 × 10⁻⁷ *N*, or pH 7, water neutrality is indicated by pH 7, acidity by values less, and alkalinity by values greater, than 7. (Findlay, 1933.)

phuric acid, on the other hand, changed from pH 3.5 to 6.3 (von Skramlik, 1926). It has been suggested that sourness can be predicted by the titration capacity of the acid when titrated with a buffer solution (Kennrick, 1931; Beatty and Cragg, 1935), although not all investigators believe that saliva is the buffer. If buffered solutions are employed as stimuli, it can be shown that the same degree of sourness can be elicited at different pH's (Liljestrand, 1922). The taste of the buffer solutions remains as long as the solution is held in the mouth, whereas the taste of dilute acids rapidly disappears. This is attributed to the fact that buffer solutions provide a continuous supply of H ions as they are used up. The sourness of an acid under ordinary methods of tasting depends on, but does not necessarily parallel, the strength of the acid in terms of the free H ion concentration (Harvey, 1920; Paul, 1922; Moncrieff, 1946).

On the other hand, Hahn, Kuekulies, and Taeger (1938) were able to minimize the effects of saliva by means of their Gustometer. This device consists of a U-shaped tube with a round opening at the bend of the U. Taste solutions flow through the device and over the surface of the tongue, which is held lightly against the opening. Preliminary rinsing with water is followed immediately by the acid stimulus. Under these conditions, the threshold determinations for weak acid and strong acids alike yield a value of approximately 0.003 *N*. The chemical combining capacity of the acid apparently determines the sourness.

These results suggest, therefore, that the anomalous sourness of weak acids under normal conditions of tasting may depend upon the interaction with the saliva. Where this effect is eliminated by prior removal of the saliva, the total acid, i.e. the total H ion available, determines sourness.

Salt. The most characteristic stimulus for the salty taste is sodium chloride, common table salt, which, interestingly enough, is the only agent that will elicit a pure salty taste.

Other salts like sodium bromide or potassium chloride arouse additional qualities like bitter or sweet as well as saline. That the salty taste results primarily from anions like Cl, Br, I, SO_4 , NO_3 , etc., is generally agreed (Kahlenberg, 1898), but there is less agreement on the relation of stimulating strength to ionic concentration. Some investigators find that, at threshold, the salt taste solutions are equimolecular in terms of the anion (Höber and Kiesow, 1898; Gley and Richet, 1885; Hahn, Kuckulies, and Taeger, 1938). Others, however, report that, in a common cation series like Na_2SO_4 , NaCl, NaBr, NaI, NaHCO_3 , NaNO_3 , the relative strength of these stimuli is in the order named. Since sodium is common to all these solutions, the anions must account for the differences in stimulating efficiency (von Skramlik, 1926).

That the cations play a role in the salty taste is indicated by the fact that sodium chloride, lithium chloride, and potassium chloride all have tastes that are slightly different from one another. For example, lithium chloride has a slightly sour component, and potassium chloride is slightly sour and bitter. The cations may be arranged in order of their strength of taste as follows:

This series is probably related to the mobility of the ions, for ammonium is the fastest and lithium the slowest (Frings, 1948). Both cations and anions therefore play a role in stimulating the sense of taste. Similar ionic series have been described not only for physiological action (Starling, 1933; Hopkins, 1932; Crozier, 1934) but also for certain physical reactions such as the precipitation of colloids by electrolytes (Findlay, 1933).

Sweet. Unlike the stimuli for sour and salty, those for sweet include among their more common members a number of substances that have no known common physical or chemical property. Many of these are

organic substances that, as a rule, are not ionized. Sucrose is a typical example:

Many sugars such as fructose, and glucose and others in which the CH_2OH group is repeated, have the characteristic sweet taste. On the other hand, saccharin, which is extremely sweet, has the following structural formula:

The sweet taste is presumably due to the anion, for most of the salts are sweet. Other sweet stimuli of a diverse nature are lead acetate and a number of beryllium salts. In these salts, the Be^{++} ion seems to be responsible for the sweet taste.

An attempt to bring some order into the relations among the many sweet-tasting compounds of the aliphatic series was made by Oertly and Myers (1919). They suggested that the sweet taste is due to two factors in the molecule, a glucophor and an auxogluce. A glucophor is a core grouping of atoms that forms a sweet-tasting compound when combined with a number of other atoms included in a second grouping called auxogluces. An example of their formulation is provided in Table 1.

TABLE 1

Sub- stance	Formula	Glucophor	Auxo- gluc
Glycol	CH ₂ OH—CH ₂ OH	CH ₂ OHCHOH	H
Glycerol	CH ₂ OH—CHOH—CH ₂ OH	CH ₂ OHCHOH	CH ₂ OH
Glycine	CH ₂ NH ₂ —COOH	CHNH ₂ —COOH	H

In all, they identified six glucophors and nine auxoglucs. This represents only a beginning, for many substances such as saccharin or dulcin cannot be accounted for.

In general, it may be said that homologues, i.e. substances with similar physical and chemical properties, display a similarity in taste. The homologue of a particular substance may, however, introduce an additional taste. With increasing molecular weight in a homologous series, the taste may change from sweet to bitter (Moncrieff, 1946).

Ethylene glycol	Sweet
Trimethylene glycol	Sweet
Propylene glycol (1.2)	Sweetish
Tetramethylene glycol	Less sweet
Hexamethylene glycol	Bitter

With the increase in molecular weight, the solubility decreases and therefore the concentration available for taste stimulation may be expected to fall off.

As with many physiological reactions, stereoisomerism can be shown to affect taste quality. One of the best examples is that of asparagine

which in the dextrorotatory form is sweet but in the laevo form is tasteless. Hence the sweet taste is determined not only by the presence of certain ions or groups of atoms but by the structural arrangement of the molecules themselves.

Bitter. Typical stimuli for bitter are the alkaloids such as quinine or strychnine. As is true for sweet, no one class of chemical agents is characterized by the bitter taste. A number of electrolytes such as magnesium

or ammonium salts are bitter. It appears that an increase in the molecular weight of salts is associated with a change from salty to bitter. Bitter is often associated with the sweet taste. As noted above, many substances can be converted with relatively little change in the molecule from sweet to bitter, and many sweet substances have a bitter aftertaste. This relation has led to the theory that the taste mechanisms for bitter and sweet constitute a class distinct from those for acid and salt in which electrolytes constitute the major class of stimuli (Taylor, 1928*b*). It has even been suggested that a single receptor mechanism may be involved in the bitter-sweet sensitivity. Both are depressed by the action of gymnemic acid, although the major action is upon the sweet. Salt and sour sensitivity is relatively unaffected. Alkaloids and other toxic agents frequently have bitter tastes, as do a number of narcotic agents. Their effects are generally thought to be due to their special affinity for the lipoidal elements in the gustatory cells. The initial action is frequently excitatory followed by an inhibitory action. It is the former that may be basic to the sweet, and the latter that may be associated with the elicitation of the bitter taste.

The laws relating taste quality to chemical constitution are still highly empirical, and, except for the acids and to some extent for the salts, there is no simple rationale for the many relations that have been discovered, particularly among the organic stimuli.

Electrical stimulation. Taste is not particularly responsive to inadequate (non-chemical) stimulation except by electrical currents. When the tongue is stimulated with monopolar electrodes, a characteristic stinging sour quality is elicited at the anode, and a burning alkaline taste occurs at the cathode. Upon breaking the current, a marked sour aftertaste occurs at the cathode. According to one view, first suggested by Humboldt, the sour taste at the anode may be due to H ions, the secondary prod-

ucts of the electrolysis of saliva (von Skramlik, 1926). It is unlikely, however, that any gross change in the acidity or alkalinity of the saliva takes place. When currents of short duration are employed, the time constant of stimulation by the anode is relatively long compared with that of the cathode (Bujas and Chweitzer, 1934). This suggests that the anodal process is a slow one and that it may involve some electrolytic process acting on the sense cell. The shorter time constant of the cathode may indicate direct stimulation of the nerve. Both processes may occur under certain conditions, as in stimulation by alternating currents (Bujas and Chweitzer, 1937).

The gustatory endings of the cat's tongue can be stimulated by the anode of a constant current, as evidenced by the discharge of nerve impulses in the individual afferent nerve fibers of this preparation. Such discharges have the same general frequency and adaptation rate as those elicited by acids. Thus anodal stimulation resembles very closely the adequate stimulation by acids themselves. However, the latency of the impulse discharge is much shorter with electrical stimuli, probably owing to the rapid development of the ionic concentrations in the neighborhood of the taste cell membranes. The latency of discharge to acid stimuli probably includes the relatively slow diffusion time required for the H ions to reach the surface of the taste cells (Pfaffmann, 1941). Interestingly enough, the cathode has never been observed to stimulate the single fiber preparation. It does, however, tend to reduce any spontaneous discharge that might be under way.

Sensitivity

Measurements of threshold sensitivity by different investigators frequently show wide discrepancies. The method of applying the stimuli, the amount of solution used, the area of tongue involved, and the psychophysical procedures employed may lead to significant differences in threshold, even with

the same group of subjects (Richter and MacLean, 1939). The drop method yielded an average sodium chloride threshold of 0.19 per cent as compared with 0.08 per cent for the choice method in which the subjects were allowed to compare water and salt solutions by sipping.

In addition there are more fundamental variables that may influence sensitivity. For example, changes in the threshold in the same individual have been noted from day to day. In women, during pregnancy, the threshold is elevated particularly for sodium chloride and for acid (Hansen and Langer, 1935). Differences in sensitivity among individuals may reach such magnitudes that some individuals are said to be "taste-blind." This has been found primarily in the sensitivity to a group of substances like phenylthiocarbamide which is bitter to some and, except in the highest concentrations, tasteless to others (Fox, 1932; Blakeslee, 1932). This insensitivity appears to be an inherited characteristic. It has also been shown that the acidity of the saliva, which differs in different individuals, may influence the sourness of a weak acid, like acetic acid, when compared with hydrochloric acid (Cragg, 1937).

In spite of such effects, however, it is possible to give a typical order of magnitude for stimulation by certain characteristic taste stimuli (Table 2).

TABLE 2

ABSOLUTE THRESHOLDS

Substance	Per Cent Concentration (approx.)	Molar Concentration
Sucrose	7×10^{-1}	2×10^{-2}
Sodium chloride	2×10^{-1}	3.5×10^{-2}
Hydrochloric acid	7×10^{-3}	2×10^{-3}
Crystallose (sodium salt of saccharin)	5×10^{-4}	2×10^{-5}
Quinine sulphate	3×10^{-5}	4×10^{-7}

According to these figures the four sensitivities may be arranged in order from low to high as follows: salty, sour, sweet, and

bitter, where saccharin is used as the sweet stimulus.

For purposes of neurological examination the graded series of taste stimuli shown in Table 3 were found to be suitable (Börnstein, 1940). To the normal subject the

TABLE 3

GRAMS PER 100 CUBIC CENTIMETERS OF H₂O

	Easily Recognizable	Moderately Strong	Very Strong
Sucrose	4.0	10.0	40.0
Sodium chloride	2.5	7.5	15.0
Citric acid	1.0	5.0	10.0
Quinine monohydrochloride	0.075	0.5	1.0

three intensities shown elicited tastes that were easily recognizable, moderately strong, and very strong, respectively. Tests were carried out by applying single drops to different parts of the tongue surface so that localized impairment of taste sensitivity might be detected. The graded series is valuable because neural lesions might lead to a partial impairment of sensitivity. In mild cases only the weakest stimuli might be ineffective. In severe cases even the strongest stimuli might be without taste.

As already indicated, the gustatory receptors are spread out over a surface so that stimulation may be diffused over the whole tongue or restricted to a small area. Stimulation of small areas is associated with increased reaction times to the stimulus and with elevated thresholds (Holway and Hurvich, 1938; Bujas and Ostojcic, 1941).

Temperature. That temperature influences taste sensitivity has been recognized for a long time. The early workers, however, found little consistent effect except at the extremes (0 to 50 degrees C) (Kiesow, 1896; Chinaglia, 1916). Others reported effects in the intermediate range between 10 and 40 degrees C (Komuro, 1921; Goudriaan, 1930). Hahn and Günther (1932) carried out a systematic temperature analysis by means of the Gustometer. With this device it is possible to bring the tongue

area to the temperature of the taste solution prior to stimulation and to maintain the temperature of the taste solution relatively constant throughout the course of stimulation. Temperature has a typically different effect upon each of the four basic qualities (Fig. 8). But not all stimuli for any one quality are affected in the same

FIG. 8. The effect of temperature on taste thresholds for sodium chloride, quinine sulphate, dulcin, and hydrochloric acid. The ordinate gives the thresholds in arbitrary units. The value of one unit on the ordinate differs for each of the four substances, as shown by the key in the figure. For example, one unit for NaCl equals 0.0005 per cent. (From Hahn, 1936.)

way. The sensitivity for some sweet substances shown in Fig. 8 may rise with a rise in temperature and then decrease above 37 degrees C. Others like glycol may show no change in threshold, and still others may show intermediate effects.

These relatively complex temperature effects suggest that stimulation cannot be a simple chemical reaction between stimulus and taste cell. Most chemical reactions are enhanced by a rise in temperature. Only for sweet does such a relation appear to exist, and even in this case there are many exceptions, depending upon the substance and the subject.

Internal factors. Particular interest has been aroused by the possibility that changes in the blood stream and body fluids affect, by some direct chemical action, the sensitivity of the taste cells. The intravenous injection of certain drugs (Hartridge, 1945) gives rise to taste sensations after a latent period attributed to circulation time. Pre-

1947; Young and Chaplin, 1949). In order to determine whether a lowering of the gustatory threshold occurs in adrenalectomized rats, a direct physiological study of afferent impulses in the chorda tympani nerve was made when salt solutions were applied to the tongue. The minimal concentration of salt that would just elicit a dis-

FIG. 9. Adaptation and recovery curves for sodium chloride. The ordinate indicates the threshold concentrations. The course of adaptation to three concentrations of sodium chloride, 5, 10, and 15 per cent, is shown for an adaptation period of 30 seconds and a recovery period of 30 seconds. The unadapted threshold is 0.24 per cent. (From Hahn, 1934.)

sumably these sensations arise from stimulation by the substance circulating in the blood. The further possibility has been advanced that a decrease in the body supply of a specific substance like NaCl may lower the gustatory threshold for that substance. Animals rendered salt deficient by adrenalectomy display an increased preference for salt such that they voluntarily ingest enough extra salt to counteract the usually fatal results of adrenal insufficiency (Richter, 1942). Actually, normal rats prefer weak salt solutions to water when both are available in a free choice situation (Bare, 1949; Chaplin,

charge of afferent impulses was essentially the same in normal and salt-hungry (adrenalectomized) rats. In fact the average threshold for both groups equaled approximately the concentration at which the adrenalectomized animals first displayed a preference for salt. This suggests not only that both groups are equally sensitive but that the salt-needy animals show the preference as soon as they can taste the salt. The normal animals do not (Pfaflmann and Bare, 1949). It seems likely, therefore, that the physiological changes induced by adrenalectomy have relatively little effect on the

taste bud. Some change more central in locus must account for the enhanced salt hunger displayed by these animals.

On the other hand, Mayer-Gross and Walker (1946) have shown that the hypoglycemia following the injection of insulin apparently leads to a reduced sensitivity for

Adaptation. It has long been recognized that the intensity of taste decreases as the taste substance is held in the mouth. Such adaptation may be complete (Abrahams, Krakauer, and Dallenbach, 1937; Krakauer and Dallenbach, 1937) or partial (Mayer, 1927; Hahn, 1934). With the aid of the

FIG. 10. Adaptation and recovery curves for three substances. The NaCl curve is similar to that labeled 5 per cent in Fig. 9; the adapting solution of cane sugar had a concentration of 10 per cent, and that of glycocol, 1 per cent. The ordinate units are arbitrary; 10 units is equal to the adapting concentration. This makes all three curves more nearly comparable. The adaptation curve for sodium chloride is negatively accelerated; that for sugar, positively accelerated; and that for glycocol, linear. (Modified from Hahn, Kuckulies, and Taeger, 1938.)

sugar. Reduction of the blood-sugar level below 50 milligrams per cent* appeared to render the sense of taste specifically less sensitive to sugar. Sensitivity to other substances was not affected. Subjects in a hypoglycemic condition preferred 30 per cent sucrose solutions, whereas at normal blood-sugar levels this solution was usually rejected as too sweet. These results suggest that a reduction in blood-sugar level may be associated with a decreased taste sensitivity.

* Milligrams per cent equals the number of milligrams per 100 cubic centimeters of solvent.

Gustometer it has been possible to adapt a particular region of the tongue for controlled periods of time and to determine thresholds during and after adaptation. Adaptation is proportional to the strength of the adapting solution (Fig. 9), but the form of the adaptation curve is not always the same (Fig. 10). The adaptation curves within the same quality may be quite different for two chemically different substances. This suggests that the locus of the adaptation process, in part at least, is at the point where the stimulus and the taste cell interact. The recovery curves all have the same

general shape and can be fitted with equations that resemble those typical of unimolecular reactions, i.e. where the rate of reaction is proportional to the concentration of only one reactant that is gradually used up. The initial adaptation curves do not all conform to such a model.

The use of such adaptation curves as the basis for a theory of stimulation in terms of some unimolecular chemical model (e.g. as in Lasareff's theory, 1922) is open to question in the light of further results on cross adaptation (Hahn, Kuckulies, and Bissar, 1940). The effect of chemically different substances that aroused the same taste quality was examined. With 24 different salts studied, such as NaCl, NaBr, KCl, CaCl₂, etc., adaptation to any one salt did not affect the threshold for any other salt. There was no cross adaptation. On the other hand, all acids would adapt the sour taste for all other acids. Some bitter and sweet stimuli showed cross adaptation; others did not.

Since it does not appear reasonable to assume that there are as many as 24 different receptors for salt, it has been suggested that so-called gustatory adaptation is due to a change in the permeability of the taste cell for the specific agent bathing the cell. The receptor can still respond when another adequate stimulus is applied. This has been characterized as a kind of inhibitory process rather than adaptation. If this conclusion is accepted, the kinetics of gustatory stimulation cannot be inferred from adaptation curves, for adaptation and stimulation are two different processes.

Adaptation has been observed to influence the threshold for stimuli of other qualities. Sensitivity for all qualities was enhanced by prior adaptation to sucrose or sodium chloride. Quinine raised the sensitivity to all qualities but sweet, on which variable results were obtained. Hydrochloric acid adaptation did not affect the other qualities (Mayer, 1927; Dallenbach and Dallenbach, 1943).

Relative sensitivity. Intensity discrimination in taste, according to some investigators, shows the same general relations as in the other senses: relative sensitivity is approximately constant only in the middle ranges (Lemberger, 1908; Holway and Hurvich, 1937). Other workers report that $\Delta I/I$ is nearly constant over the entire range (Saidullah, 1927; Kopera, 1931; Bujas, 1937). The approximate average value of $\Delta I/I$ found for all qualities by most investigators is $\frac{1}{6}$.

In one study this function was determined for two different substances, sucrose and crystallose, both of which produce a sweet taste. Since the value of ΔI was obtained for each jnd directly, it was possible to specify for both substances the concentrations that fell at an equal number of discriminable steps above threshold. In addition, equal-sweetness concentrations were independently determined. Concentrations at equal numbers of jnd steps above threshold were not equally sweet. A crystallose solution 9 jnd's above threshold equaled in sweetness a sucrose solution 6 jnd's above threshold (Lemberger, 1908).

The relative sweetness of crystallose and sucrose changes with concentration as shown

TABLE 4
EQUALLY SWEET CONCENTRATIONS (CF.
LEMBERGER)

Sucrose	Crystallose	Ratio, Crystallose/Sucrose
0.041 mol	0.00085 mol	1:482
0.053	0.000161	1:330
0.102	0.000273	1:300
0.140	0.00045	1:311
0.164	0.00062	1:265

in Table 4. Crystallose becomes relatively less sweet than sucrose, measured both in jnd's and in physical units of concentration. Certain other substances behave in a similar manner. Figure 11 shows the concentration of different substances that taste as sweet as various concentrations of sucrose (Cameron, 1947). Most of the curves turn upward

(slight positive acceleration) which indicates that these substances become relatively more sweet as the concentration increases. Not all sweetness matches follow this rule, however.

Efforts to apply subjective scaling methods to the sense of taste have proved successful (Lewis, 1948; Beebe-Center and Waddell, 1948; MacLeod, 1950). Such studies show, as is true for other senses, that

Exceptions to these trends are occasionally noted. For example, two subjects found sugar in the higher concentrations to be predominantly unpleasant. They reported a dislike for sweet which may have been determined by excessive consumption of sweets in their youth.

It is possible that other factors, such as physiological changes, may affect the pleasantness of various taste stimuli (Beebe-

FIG. 11. Curves showing the concentrations at which different substances taste as sweet at various concentrations of sucrose. Gram-mol per cent is $\frac{1}{10}$ the value of the molar concentration. (From Cameron, 1947.)

the size of the Jnd increases as the intensity of the stimulus increases. Cross quality matching, that is, matching salty with sweet for magnitude of sensation, indicates that the ratio units of taste are more valid than Jnd units (Bujas, 1937).

Affective value. It is of interest that both odors and tastes usually have more affective value than most other sensations except pain. There is almost general agreement that strong bitter is unpleasant and that sweet is pleasant. The degree of pleasantness depends upon the intensity of the stimulus, and, particularly for salty and sour, intensity determines whether the taste is pleasant or unpleasant (Saidullah, 1927; Engel, 1928). Weak concentrations of salt or acid may be definitely pleasant but become unpleasant as the concentration in-

Center, 1932). In fact, change in this aspect of taste rather than change in threshold seems to be a more likely explanation of the craving for salt discussed above. Just how past experience and physiological variables contribute to this pleasantness of taste and how this relates to the needs of the organism for such substances is a problem demanding further investigation.

Theory

Theories of gustatory function may be concerned with either of two aspects: the mechanism of excitation, whether physical or chemical, or the nature of the receptors that underlie different taste qualities. For sour and salty tastes the adequate stimulus appears to have been delineated. The evidence for bitter and sweet is less clear. In

order to account for the similarity in the effects of two such chemically diverse agents as saccharin and sucrose, simplicity of theory would suggest that there is some as yet unrecognized physical property, other than chemical structure, that determines the sweet taste. On the other hand, some unique property of the sensory endings for sweet might account for the fact that these diverse agents give rise to the same quality, if the same endings are concerned in both instances.

Although some writers have stressed the importance of a physical process like adsorption of the taste substance on the surface of the taste cell (Renqvist, 1919) and others have argued for a chemical mechanism (Lasareff, 1922), the present evidence suggests that taste stimulation is not solely one or the other. The fact that stereoisomers have quite different tastes argues against a simple chemical mechanism. Nor can the temperature and adaptation effects previously described be interpreted in this way. Certain additional physicochemical processes, involving the membrane of the taste cell, as well as a chemical reaction with some

substance of the taste cell itself may well be involved (Hahn, Kuckulies, and Bissar, 1940).

The view that there are four basic taste qualities, salty, sour, bitter, and sweet, has been generally accounted for on the grounds that there are four different types of specifically sensitive receptors. Any taste is the result of stimulation of one or more of these basic receptors to a greater or less extent. Efforts to show that there are taste receptors that are specifically sensitive to different chemical agents have been successful (Pffaffmann, 1941). However, whether these receptor types correspond directly with the types postulated from the basic qualities seems doubtful. The details of this specificity remain to be elaborated.

SMELL

The olfactory receptors are located in a small patch (2.5 square centimeters) of yellowish brown pigmented mucous membrane covering the medial wall of the superior concha and the adjacent lateral wall of the nasal septum (Fig. 12). The two receptor

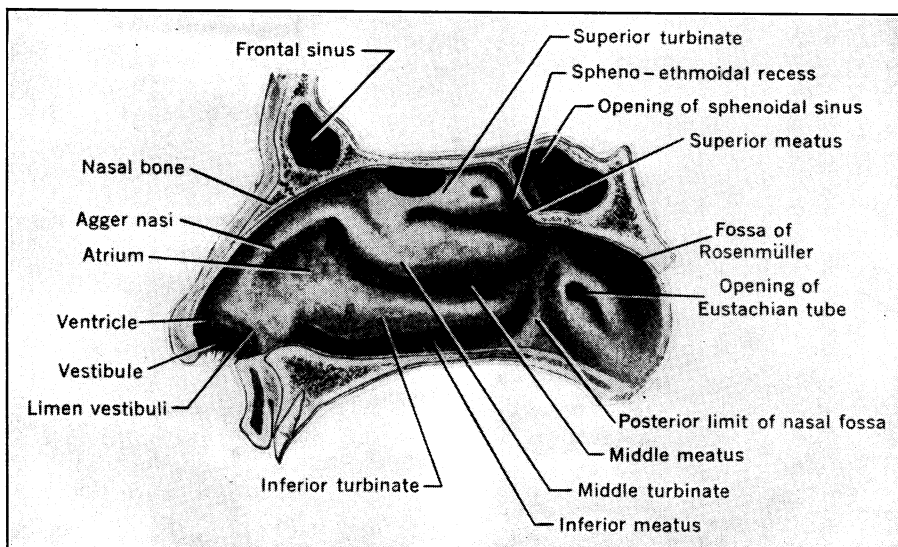

FIG. 12. Lateral wall of the right nasal cavity. The darkened area marks the approximate limits of the olfactory region. (Modified from Piersol, 1923.)

areas, one in each nasal cavity, are anatomically distinct, being separated from each other by the nasal septum. The olfactory epithelium is made up of basemant and columnar cells which support the long, ovoid olfactory cells. The distal end of each olfactory cell terminates in several delicate hairs

route, especially during eating. Sniffing or vigorous inhalation produces a surge or turbulence in the olfactory cleft itself. It is obvious that the impairment of odor sensitivity can result from simple mechanical block of these air passages. Closure of the anterior nares will effectively eliminate olfaction. Congestion of the mucous membranes during an attack of the common cold may have a similar effect.

The olfactory nerve fibers enter the olfactory bulb to end in a series of intricate,

FIG. 13. Olfactory and sustentacular cells from the olfactory epithelium of man. (From Parker, 1922.)

that project out into the mucus covering the nasal epithelium. The fine, unmyelinated proximal ends of the cells form the olfactory nerve fibers which enter the olfactory bulb of the brain directly after piercing the cribriform plate. The sense cells therefore subserve the functions of both reception and conduction (Fig. 13).

During quiet breathing, odorous particles may be carried to the olfactory cleft by slight eddy currents as the air enters the nostrils during inspiration or the posterior nares during expiration. Much odor stimulation takes place by way of the latter

FIG. 14. Section of the olfactory bulb of a kitten. Golgi method. A, layer of glomeruli; C, layer of mitral cells; I, J, granule cells; a, b, glomeruli showing the terminations of the olfactory nerve fibers; c, glomerulus showing the terminal arborization of a dendrite of a mitral cell; d, tufted cells; e, mitral cell; h, recurrent collateral from an axon of a mitral cell. (From Ranson and Clark, 1947.)

basketlike terminations called glomeruli (Fig. 14). At this point in the olfactory pathway occur the first synapses of two different types of cells: the large mitral cells and the tufted cells. Axons from both types form the olfactory tract which then passes

caudally along the base of the frontal lobe. In the olfactory bulb the arrangement of cells and axons provides a convergence of pathways and a return route back to the glomerulus itself by way of collaterals, so that a kind of closed reverberating circuit is formed. It is this "feedback" that accounts in part for the great sensitivity of the sense of smell.

The central connections of the olfactory fibers are still to be clearly delineated. Brodal's (1947) review of the evidence concludes, in opposition to the common view, that the hippocampus and cingular gyrus are *not* particularly concerned with olfaction. The fibers from the olfactory bulb travel in two main tracts, the lateral and the medial olfactory tracts. The lateral tract (lateral olfactory gyrus) is continuous with the hippocampal gyrus, and the two together form the pyriform area or lobe (Fig. 15). The fibers from the olfactory bulb, partly with a relay in the anterior olfactory nucleus, are distributed to the nucleus of the lateral olfactory tract, the olfactory tubercle, the anterior part of the pyriform lobe, and certain nuclei of the amygdaloid complex. The anterior olfactory nucleus, situated in the posterior part of the bulb, connects with the corresponding nucleus of the opposite side by means of the anterior commissure. Nuclei of the septal areas probably do not receive primary olfactory fibers. The relation of the hippocampus, the mammillary bodies, the anterior thalamic nuclei, and the cingular gyrus with olfaction is thought to be indirect and slight.

Electrical activity in the pyriform lobe following olfactory stimulation has been recorded in several different species (Hasama, 1934; Allen, 1943; Adrian, 1942). Electrical stimulation of the olfactory bulbs produced definite alterations in the electrical activity of the olfactory tract, the prepyriform cortex, the pyriform area, the anterior perforated space, and parts of the hippocampal gyrus (Rose and Woolsey, 1943; Fox, McKinley, and Magoun, 1944). Potentials

could not be detected in the amygdaloid nucleus or hippocampus.

Experiments in which parts of the CNS were removed have yielded few instances where habits based on olfactory discrimination were disrupted. Neither destruction of the rat cortex up to 85 per cent, nor section of the cortical projection fibers from the anterior thalamic nuclei, impaired olfactory discrimination. Only transection of the rat's olfactory tract has been found to disrupt

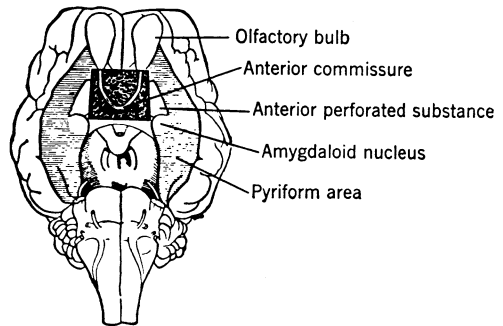

FIG. 15. Ventral view of sheep's brain, pyriform area shaded, and anterior commissure exposed. (From Ranson and Clark, 1947.)

such a habit (Swann, 1935; Lashley and Sperry, 1943). A conditioned leg flexion to odors was not impaired after bilateral temporal lobectomy, removal of the hippocampus, or destruction of the pyriform amygdaloid complex in the dog. A more complex situation where discrimination between cloves and asafetida was required, however, was abolished with bilateral destruction of the pyriform-amygdaloid complex (Allen, 1940, 1941).

Olfactory Qualities

Numerous attempts to describe odor experiences and to reduce them to some orderly arrangement have been made. Since the particular physicochemical property that does the stimulating has not been discovered, all such classifications are primarily psychological. The earliest attempts were largely odor catalogues. Since many odor stimuli also stimulate other sensory endings, like

those of the trigeminal and taste, the problem of description is rendered even more difficult.

One of the best-known classifications is that of Henning (1924), who used over 400 scents. In some experiments subjects were instructed to describe and identify the odor. In other experiments odors were to be arranged according to similarity of quality. Henning concluded that there were six basic odor qualities: *fruity*, *etherial*, *resinous*, *spicy*, *foul*, and *burnt*. The relations among

FIG. 16. The smell prism, according to Henning.

these olfactory qualities are indicated by the smell prism (Fig. 16). Although Henning attempted to show that certain chemical structures were related to the FERS face, the prism was designed mainly to show the interrelations among odor sensations. Subsequent studies by other investigators showed that, although this schema describes the general relations among odors, it is far from precise (Dimmick, 1927; Findley, 1924; MacDonald, 1922; Hazzard, 1930). These six basic odors are not to be thought of as corresponding to six different basic receptors, although that interpretation has been made.

More recently, another scheme involving only four basic components, *fragrant*, *acid*, *burnt*, and *caprylic*, has been developed, including a semiquantitative treatment of the component intensity (Crocker and Henderson, 1927). The value of each component is indicated on a scale from 0 to 8. Thus, acetic acid may be characterized as 3803

where 3 describes the odor as moderately fragrant, the acid value is 8, the burnt value 0, and the caprylic 3. Each component can be evaluated by comparing a sample with a set of odor standards for which the odor values have been determined. Each standard has a value for each of the four components, but it is used chiefly to characterize the one indicated. The standard for 8 on the fragrant scale is methyl salicylate, but its complete formula is 8453. This system can be used reliably by unpracticed subjects and has proved useful in certain practical applications (Boring, 1928).

Stimulus correlates. It is generally believed that odor depends upon particles or molecules volatilized from odorous substances or liquids. Since these particles must enter the nose to be transported to the olfactory epithelium a necessary condition for olfactory stimulation appears to be volatility. For some substances only a relatively small number of molecules may be required. For example, musk and civetone are relatively involatile; yet they are two of the most potent olfactory stimulants known. For a given odorous substance, increase in volatility will affect the strength of the odor, presumably by increasing the number of molecules impinging on the nose.

In a homologous series such as the saturated fatty hydrocarbons with the general formula C_nH_{2n+2} , there is an increase in odor from the lower to the higher members. Methane, CH_4 , is odorless; pentane, C_5H_{12} , has an indistinct odor; decane, $C_{10}H_{22}$, has a strong gasoline odor; whereas the still higher members have less strong odors owing largely to the lower volatility of the large molecules (Moncrieff, 1946).

Although many relations between chemical constitution and odor have been described, it is not possible to predict the odor of a substance from its constitution. Compounds of quite different constitution may have similar odors, and compounds of very similar constitution may have quite different odors. Seven basic chemical elements are odorous.

These are fluorine, chlorine, bromine, iodine, phosphorus, arsenic, and oxygen (as ozone). These elements occur in the high valence groups 5, 6, and 7 of the periodic table. None of the elements occurring free in nature are odorous under normal conditions. Odorous inorganic compounds are largely those made up of the nonmetallic elements. Water and carbon dioxide are odorless, but these substances are normally present in the atmosphere surrounding the sense cells. When sulphur is substituted for oxygen, a strongly odorous substance is formed, H_2S for H_2O .

Organic compounds make up the greatest class of odorous substances. Both total molecular structure and the presence of osmophoric groups and arrangements within the molecule appear to influence odor. Different forms of the same compound, stereoisomers, which have different spatial arrangements of the molecule may have different odors. On the other hand, a series of benzene derivatives all have very similar odors. Substitution of groups in the ring cannot entirely overcome the osmophoric effect of the benzene ring itself. It is of historical interest that the first compounds occurring in nature with the benzenoid structure were found in association with pleasant-smelling compounds like oil of wintergreen, oil of anise, and oil of bergamot, to name but a few. As a consequence these compounds were labeled "aromatic" to distinguish them from the fatty substances.

The natural scent of flowers and fruits depends upon the presence of minute quantities of such highly odorous oils as those named above. These are known as essential oils, for they contain the essence of the flower or fruit. These oils themselves are complex mixtures. Upon chemical analysis they are found to contain a few major constituents of known chemical structure, which are largely responsible for the odor of the essence. The production of synthetic perfumes by mixtures of the pure chemicals is possible. However, the natural essence is

usually so complex that its odor can be matched only if a small amount of the natural product is added to the synthetic mixture in order to produce just the right blend (Poucher, 1932).

Sensitivity

In spite of the relative inaccessibility of the olfactory end organs, odorous materials can be detected at extremely low concentrations. Of the chemical senses smell is the most acute. In terms of concentrations of molecules it has been estimated that olfaction is 10,000 times as sensitive as taste (Moncrieff, 1946). Differential sensitivity, on the other hand, is not so great.

Measurement of the physical concentration of odorous vapor present at threshold is not possible by direct methods because the amounts are so small. Threshold values are therefore obtained by the dilution technique. For example, a known quantity of odorous substance may be evaporated in a room of known dimensions and the concentration computed. It was by this method that the oft cited threshold concentration for ethyl mercaptan of 4×10^{-8} milligram per liter of air or 7×10^{-13} mol was found (cf. Moncrieff, 1946). The small glass olfactory chambers (camera inodorata) in which small amounts of odorous material may be evaporated operate on the same principle. More elaborate devices have been employed, with flowmeters to measure the flow of pure air through a chamber containing odorous materials. The concentration in milligrams per liter can be computed from the weight lost to a known volume of air. In other devices the concentration of the odorant has been calculated from the known vapor pressure relations for different substances as streams of air passed through saturating chambers at different temperatures. Comparative tables of threshold values show major discrepancies among the results of different investigators, depending on the methods of dilution, the method of sniffing by the subject, and a number of other

variables. However, the relative stimulating efficiency within a series of substances is often independent of the method. The values obtained when the odorants were diluted in alcohol (Passy, 1892) were greater, by a factor of approximately 150, than those found by Allison and Katz (1919) with a flowmeter type of odorimeter (see Table 5).

TABLE 5

THRESHOLD CONCENTRATIONS OF VARIOUS ODOROUS MATERIALS (CF. ALLISON AND KATZ, 1919)

Substance	Boiling Point, degrees C	Milligrams per Liter of Air	Molar Concentration *
Ethyl ether	35	5.83	7.8×10^{-5}
Carbon tetrachloride	76.7	4.53	3.0×10^{-5}
Chloroform	62	3.30	2.8×10^{-5}
Ethyl acetate	77.4	0.69	7.8×10^{-6}
Amyl alcohol	137.8	0.225	2.6×10^{-6}
Nitrobenzene	209.4	0.146	1.2×10^{-6}
Ethyl mercaptan	37	0.046	7.4×10^{-7}
Methyl salicylate	222.2	0.100	6.6×10^{-7}
Pyridine	115.2	0.032	4.0×10^{-7}
Amyl acetate	148	0.039	3.0×10^{-7}
Valeric acid	186.4	0.029	2.9×10^{-7}
Methyl isothiocyanate	119	0.015	2.1×10^{-7}
Butyric acid	162.3	0.009	1.0×10^{-7}
Isobutyl mercaptan	88	0.008	8.9×10^{-8}
Allyl isothiocyanate	151	0.008	8.0×10^{-8}
Propyl mercaptan	67	0.006	7.9×10^{-8}
Phenyl isocyanide	165	0.002	2.0×10^{-8}
Amyl thioether	95-98	0.001	5.8×10^{-9}
Artificial musk	0.00004

* Computed as the number of gram molecules in a liter of diluent or, more properly, in a liter of solution, but the concentrations are so low that a negligible error results from considering only the diluent.

In all these studies, thresholds were determined in reasonably odorless environments, but no specific air conditioning was employed. Since the presence of odor in the surroundings would affect threshold values, some of the discrepancies in the results of different investigators might be attributed to the failure to reach "zero" adaptation prior to each threshold determination (Foster and Dallenbach, 1948).

Relative measures can be used for investigating the comparative strength of different agents, the magnitude of individual differences, or the effect of adaptation and other

experimental variables. Values obtained with such devices avoid the problem of computing minimal concentrations, since the instruments are calibrated in terms of norms. The best known of these instruments is the olfactometer of Zwaardemaker, which, in its simplest form, consists of a glass tube that slips into a larger odorous tube (Fig. 17). One end of the glass tube is inserted into

FIG. 17. Zwaardemaker's olfactometer. The bent-up end of the tube is inserted into the nostril. Over the other end of the smaller tube fits the larger stimulus tube made of odorous material. As the subject sniffs, air is drawn through the odor-bearing larger tube and then through the smaller tube to the nostrils. The amount of odor is determined and measured by the length in centimeters of the odor tube exposed to the current of air. This device also exists in the double form to permit dirhnic stimulation.

the subject's nostril. The other is open and exposed to various amounts of the inner surface of the odor-bearing tube. The larger the extent of the odor-bearing tube exposed to the current of air drawn through the device by the subject's inhalation, the stronger the concentration of odorous material. A standard unit, the olfactie, is defined as the length of odor tube in centimeters exposed at threshold. One olfactie of India rubber equals 0.7 centimeter. A number of similar methods have been devised, but in all of them we encounter the difficulty that the subject determines the amount of odorous stimulation by the rate and force of his inhalation.

The blast injection technique overcomes this objection (Elsberg and Levy, 1935). A bottle containing odorous liquid or solid is connected by an outlet tube to a nosepiece inserted in the subject's nostrils (Fig. 18). Various amounts of air may be forced into the bottle by a syringe attached to the inlet

FIG. 18. Elsberg's blast injection device. The bottle contains odorous fluid or solid. The pressure in the bottle can be raised by introducing different volumes of air by means of the hypodermic syringe. Upon release of the pinch clamp on the outlet tube, odorous vapor is injected into the nostrils.

tube. This raises the pressure in the bottle so that, upon release of a pinch clamp, odorous vapor is injected into the nostrils by a sudden pressure pulse. The threshold is given by the volume of odorous vapor injected, although the pressure of injection rather than the volume appears to be the significant factor (Jerome, 1942). Highly volatile substances have smaller thresholds than do involatile substances (Elsberg, Brewer, and Levy, 1935). Volatility, however, is a factor that influences the transport of molecules from an odorous substance to the olfactory epithelium. The blast method

appears to maximize this factor so that the more basic aspects of olfactory stimulation may be masked. The method has been modified so that, during any one stimulating blast, pressure is held constant. However, even with these modifications pressure effects still appear to complicate the results obtained with the blast technique (Wenzel, 1948).

Stimulus variables that might have a direct effect on olfactory sensitivity are difficult to investigate because the stimulation pathway is so indirect and devious. Temperature and humidity influence the strength of odors largely because these factors influence volatility or transport of odorous particles from the source to the observer. In a study of the effect of temperature changes in the odorous gas, as measured at the entrance to the nostrils, the lowest values occurred between 25 and 30 degrees C. An increase of 5 degrees raised the threshold appreciably, a change opposite to what occurs when temperature affects the source itself (Morimura, 1934).

By restricting the stimulus to one nostril (monorhinal stimulation) it is possible to stimulate one patch of olfactory epithelium at a time. Thresholds determined in this way are higher than those determined dirhinally (Henning, 1926; Elsberg, 1936). Differences in the sensitivity of the right and left nostrils may reflect differences in the physical contours of the two nasal passages as well as in their intrinsic sensitivity.

The most common deviation encountered in olfactory acuity is acquired hyposmia as a result of nasal infection. Such hyposmia may be differential; that is to say, the sensitivity for certain substances only may be impaired. A change or distortion in the quality of an odor (parosmia) may also occur.

Normal variations in sensitivity may occur from day to day. In women, hyperosmia occurs just before and during the menstrual period (Elsberg, Brewer, and Levy, 1935). Pregnancy is said to be associated with

changes in odor sensitivity. Actual olfactometric tests (Hansen and Glass, 1936) indicate a reduced sensitivity. The presumed hypersensitivity of pregnancy appears to be due to changes in the affective tone of odors. More subtle and less well-recognized differences in sensitivity are thought to occur among normal individuals. Certain floral odors, for example, can be detected only by certain observers. This may be analogous to the taste blindness described above (Blakeslee, 1918).

The existence of a daily cycle in olfactory acuity has been demonstrated by Goetzl and Stone (1947). This cycle appears to bear some relation to hunger and appetite. Olfactory acuity increases from morning until just before lunch. If food is ingested, the threshold becomes elevated, to be followed by a second decline during the afternoon. If lunch is withheld there is no midday rise in the threshold. The administration of amphetamine sulphate in lieu of lunch also produces a midday elevation of the olfactory threshold. This drug reduces both the sensations of appetite and the free caloric intake (Goetzl and Stone, 1948).

Adaptation. Perhaps the best-known physiological process affecting olfactory sensitivity is adaptation to the continued presentation of an odor stimulus. The apparent disappearance of odor soon after we enter a malodorous atmosphere is a common experience. Figure 19 shows how this adaptation proceeds for two different intensities of two different substances. For any one substance, it has been shown that the time required for total adaptation is directly proportional to the vapor pressure exerted by an odorous gas (Woodrow and Karpman, 1917). High vapor pressures are equivalent to large numbers of molecules in the air entering the nose. The degree of adaptation therefore appears to be proportional to the molecular concentrations in the nasal passage.

Qualitative changes in certain odors during the adaptation process were given much

consideration by the earlier workers, for it was thought that some clue to the nature of the olfactory receptor might be provided by this information. For example, the odor of nitrobenzol changes from one of bitter almonds to that of tar or pitch. The unpleasant odor of mercaptan changes to a pleasant ethereal quality (von Skramlik,

FIG. 19. Olfactory adaptation curves. Increasing adaptation is measured by the increase of the olfactory threshold (in olfactics). Adaptation occurs faster for benzoin than for rubber. With each substance the adaptation is faster for the more intense stimulus. (After Zwaardemaker, 1925.)

1926). Such changes were thought to depend on the differential exhaustion rate of different components of the receptor mosaic. Further evidence along the same line is provided by the classical experiments of Nagel (1897) in which two chemically inert substances were mixed in such proportions that one, vanillin, masked the scent of the other, cumarine. Adaptation to vanillin alone unmasked the cumarine odor of the mixture.

Adaptation to one substance may affect the sensitivity to other stimuli (cross adaptation). Exposure to camphor elevates the threshold for eucalyptol and eugenol. In fact, each of these three substances affects

the threshold for the others. There is, therefore, a mutual adaptation effect. This is not simply a generalized fatigue, because the threshold for benzaldehyde is not greatly changed. Benzaldehyde in turn has little effect on the thresholds for the other three (see Fig. 20). Such effects suggest a receptor mosaic made up of groups of sensitive units, each of which is sensitive to different groups of chemical stimuli. Whether such

difficult. When many components are present, analysis becomes even more difficult. Training, however, may markedly influence the ability to analyze odors. The professional perfume chemist is particularly adept at distinguishing many components.

Masking of one odor by another occurs regularly when the intensity of one surpasses that of the other. Concerning another interaction effect, "compensation,"

FIG. 20. The selective character of olfactory adaptation. The ordinate indicates the threshold change in olfactics after adaptation by each of four substances (camphor, eucalyptol, eugenol and benzaldehyde) in turn. Self-adaptation is indicated by the solid figure; threshold changes for the other substances, by crosshatching. The threshold for each substance is most influenced by itself. In addition, camphor, eucalyptol, and eugenol all appear to show reciprocal adaptation effects. The sensitivity to benzaldehyde is little affected by these substances. Benzaldehyde has little effect upon their thresholds. (Based on data of Ohma in von Skramlik, 1926.)

adaptation experiments can provide the basis for a theory of the olfactory receptor, however, may be open to question in view of the adaptation experiments described in the section on taste.

Stimulus mixtures. The mixture of odors in certain instances produces effects that agree with the mosaic concept. When two quite different odors are presented simultaneously, the components may be readily identified. The components may appear distinct and unrelated. The more the components resemble each other, the greater the tendency for blending to occur. A unitary blend or fusion may result which, however, resembles the odors of the components. Attention to one or the other of the components individually then becomes extremely

there is less agreement. As first described, the simultaneous presentation of two odors was said to lead to cancelation, so that no olfactory experience occurred. The odor of paraffin and India rubber canceled each other. That this was due to a physiological process was suggested by the fact that compensation could be demonstrated when each odor was presented to each nostril separately (dichorhinal stimulation) (Zwaardemaker, 1925). Since these early observations there has been increasing doubt of the generality of this phenomenon. Numerous examples have been cited of the reduction in strength of an odor with physical mixture of the odorous gases in a chamber prior to inhalation (von Skramlik, 1926). In such instances physical or chemical interaction be-

tween the two substances can occur. This, according to Henning (1924), accounts for all cases of so-called compensation.

Differential sensitivity. Although the absolute threshold of olfactory discrimination indicates a reasonably high order of sensitivity, the differential sensitivity is relatively poor. Gamble (1898) found that the Weber fraction for different substances varied between $\frac{1}{6}$ and $\frac{1}{2}$, with the average ratio around 38 per cent. Over a wide range of I values the $\Delta I/I$ value was found to be largest at low intensities and to decrease gradually to a minimum of 10 per cent at about 200 olfactics and above (Zigler and Holway, 1935).

Theory

Theories accounting for olfactory function exhibit two aspects. The first deals with the physical nature of the adequate stimulus, whether chemical or physical. The second deals with the nature of the receptor, whether it consists of many specialized different endings or of only a few basic types. Some theories, of course, consider both aspects of the problem.

The more fundamental problem at the present stage of knowledge is the nature of the essential stimulus for smell. Until the essential stimulus has been described in terms of its basic invariances there can be no adequate psychophysics of odor (cf. Chapter 1). It is very probable that no one physical property alone is involved. In man and animals, where the olfactory organ is tucked away in the upper part of the olfactory passage, the penetration of odor particles into this tortuous passage is required. Odorous particles appear to be governed by the gas laws. An increase in the vapor pressure of any one substance increases the intensity of the olfactory stimulation, presumably by increasing the number of molecules of odorous substance. But volatility alone does not determine odor.

Other physical properties, such as solubility in water or lipid, may be additional

important factors in determining the ease with which odor particles are dissolved or absorbed or otherwise brought into contact with the mucosa of the olfactory cleft. All these may be considered transport factors influencing preliminary stages of stimulation (Zwaardemaker, 1926).

Theories that point to such molecular effects as infrared absorption, ultraviolet absorption, Raman effect, etc., to account for the essential step in stimulation have been presented ever since Faraday first noted that many odorous materials strongly absorb radiation in the infrared region of the spectrum. Dyson (1938) placed particular emphasis upon the Raman effect. When monochromatic light shines through pure substances, spectroscopic analysis reveals scattering into the longer and shorter wavelength regions. The difference between the wavelengths of incident and reflected light is the Raman shift. It is independent of the light used and is a unique characteristic of any one substance. Raman shifts between 140 and 350 millimicrons, according to the theory, are odorous. Mercaptan and allied substances have a Raman shift of 250 millimicrons. Even stereoisomers may have different Raman shifts. Such substances frequently have different odors. Many suggestive correlations of this sort have been made; but disturbing exceptions have been found. Glycerin, which has a Raman shift in the critical region, is odorless.

The infrared theory of olfactory stimulation has been restated in a new form in which the absorption of heat in particular wavelength bands is the essential step (Beck and Miles, 1947). Only the infrared band in the range from 4 to 20 microns is considered significant, for this corresponds to the range emitted by the human body. Absorption in this range is said to produce local cooling of certain receptor elements. In a later version of the theory, Beck (1950) introduced additional factors such as water and lipid solubility, particle size, and infrared scattering. These additions, he believes,

will account for different odors of certain optical isomers with the same infrared spectra (Young, Fletcher, and Wright, 1948) and for the fact that some odorous substances like paraffin and carbon disulphide have no infrared absorption. It is well to point out, however, that a correlation between odor and infrared absorption of odorous substances, if established, does not necessarily indicate that stimulation involves cooling.

Infrared spectroscopy is a powerful technique for the analysis of molecular structure. Infrared absorption and the Raman effect both depend on the oscillation of the atoms in the molecule around their mean positions. Because the masses and distances involved in molecular structure are so small, frequencies of oscillation are of the order of 10^{13} to 10^{14} cycles per second. It is this frequency range that determines the infrared absorption. Every organic substance has a unique infrared absorption spectrum which cannot be matched by any other substance. Odorous materials as well as many others have marked infrared absorption (Barnes, Liddell and Williams, 1943). The fact that infrared absorption, Raman shift, and other properties seem to occur largely in odorous materials is suggestive that some property related to the molecular oscillation is concerned in olfaction. But to account entirely for the nature of olfaction, due consideration probably will have to be given to the so-called "transport" factors.

Theories concerning the nature of the olfactory receptor have been based largely upon such indirect evidence as the observations on differential anosmia, differential adaptation, and odor mixture. A direct approach by means of electrophysiological methods has not proved fruitful because of the relative inaccessibility of the primary afferent neurons. Such techniques as punctate or localized stimulation, which in the sense of taste provide some of the strongest evidence for the specificity of receptors, are not applicable because of the relative inaccessi-

bility of the receptor surface itself. The indirect evidence that is available, then, points to a multiplicity of receptor units rather than to a few basic types. Olfaction tends to follow the auditory analogue, where complex tones can be subjected to an analysis by the ear alone. The remarkable ability of the trained perfume chemist to identify the components of odor provides a dramatic illustration of the analytical character of the olfactory receptor mechanism.

Somesthesia

WILLIAM LEROY JENKINS

Lehigh University

In some ways the somesthetic senses are biologically of greater importance than the special senses of sight, hearing, taste, and smell. Helen Keller provides an example of a useful life without sight and hearing, and no doubt she could have managed without taste and smell. But it is hard to imagine how anyone could survive, let alone act like a human being, if totally devoid of kinaesthesia for the control of position and movement, of pain for protection against injury, and of the temperature senses which aid in the thermostatic regulation of the blood stream. This chapter attempts to bring into perspective what we know about somesthesia and to highlight the gaps that remain for further research. The cutaneous senses will be considered first, then subcutaneous sensitivity, kinaesthesia, and internal sensitivity.

CUTANEOUS SENSITIVITY IN GENERAL

It is commonly assumed that there are four cutaneous senses: touch, pain, warm, and cold. However, this fourfold division has never been universally accepted and is still under attack today. Of only historical interest now is the older view that pain is merely the result of overstimulating other senses. Also abandoned for the lack of experimental confirmation are Head's proposal of a dual system of four epicritic and four protopathic skin senses (Walshe, 1942*)

* Walshe's critical review discusses Head's experiments and other similar investigations and

and Katz's suggestion of a separate vibration sense (Geldard, 1940). However, Nafe believes that warm and cold are merely kinesthetic sensations from dilating and constricting blood vessels (Nafe and Wagoner, 1936), and Gilmer tentatively suggests that both cold and touch may be mediated by vascular units (Gilmer, 1942*a, b*). Furthermore there is some evidence that the terms, touch, pain, warm, and cold, might be written as plurals. There may be as many as three touches, two pains, and just possibly two warm and two colds.

Sensory spots. Since 1883 it has been recognized that the skin is not uniformly sensitive. For example, if an area is mapped with a small stimulator at low temperature, some points are found that respond with a clear cold, whereas the major portion of the area does not. Similarly a stimulator at high temperature reveals warm spots, a sharp needle pain spots, and a fine hair touch spots. Although the number of spots varies with the conditions of mapping (Heiser, 1932), those of high intensity appear to remain stable over long periods of time (Gilmer, 1942*b*, p. 315). Caution demands that the sensory spots should be defined in a purely *operational* way — as points of high sensitivity appearing under certain conditions of mapping. The assumption that any map of spots corresponds point for point with individual receptors is entirely un-

gives an overall view of the whole history of the controversy.

cessary — and probably incorrect, as a study of the histology of the skin will show.

Histology of the skin. The skin consists of two layers: an outer epidermis and an inner dermis. The epidermis in turn is stratified into two parts: an outer corneal layer of dead cells containing neither nerves nor blood vessels, and an inner Malpighian layer having many free nerve endings but no

have been discovered in many different skin regions, but their full distribution has never been systematically investigated.

Of the specialized endings, shown on the right of Fig. 1, no one type is found in all parts of the skin. Basket endings around the hair bulb are associated with practically all hairs but are absent in the hairless parts of the body. Meissner corpuscles are abun-

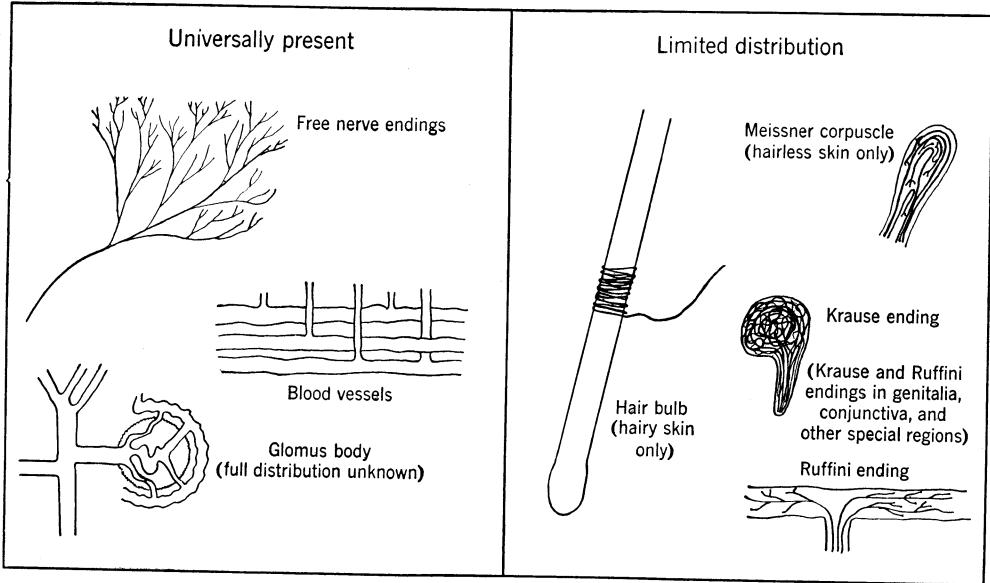

FIG. 1. End organs of the skin.

blood vessels. The dermis, on the other hand, is richly supplied with both nerve endings and blood vessels. It merges without definite boundary into the subcutaneous tissues.

The main types of nerve endings and vascular units are shown diagrammatically in Fig. 1. Note that only free nerve endings and blood vessels are widely distributed. Free nerve endings are abundantly present in the dermis and in the Malpighian layer of the epidermis, and even in the cornea of the eye, which is nonvascular. Blood vessels of varying size and shape are found throughout the dermis but not in the epidermis. Glomus bodies, which are direct arteriovenous connections of larger caliber than capillaries,

are abundant on the palms of the hands and soles of the feet but are not present in the hairy regions. Krause endings appear only in limited regions such as the conjunctiva of the eye, the nipple, and the genitalia, but not throughout the major portions of the skin. Ruffini cylinders are even scarcer than Krause endings. Indeed, so many intermediate forms of capsulated endings exist that any strict division into types is of dubious merit.

The neural basis. By piecing together information derived from histological, clinical, and physiological studies, we can derive an approximate idea of the neurological scheme underlying cutaneous sensitivity. Any given skin area appears to be innervated by a

great number of fibers approaching it from all directions. Each of these fibers, furthermore, branches and rebranches so that the distribution of a single neuron typically spreads over an area of several hundred square millimeters. The result is a complex system of overlapping supply from a multiplicity of fibers.

For example, a single hair bulb is found to have basket endings derived from two or more separate myelinated fibers. Other branches from these same fibers go to form basket endings about other hair bulbs. In addition, around the hair bulb is an accessory innervation of fine unmyelinated fibers, each a branch from a neuron supplying accessory innervation to other hair bulbs. As another instance, the free nerve endings in the Malpighian layer of the epidermis are arranged in extensive nerve nets, each covering an area of several hundred square millimeters and overlapping repeatedly with other similar nets. Nowhere do we find evidence of an isolated receptor serving a limited area and having a private line to the central nervous system—such as we might expect if sensory spots actually corresponded to single receptors. Instead it seems that mapped spots are nothing more than points of functionally high sensitivity, perhaps where the concentration of receptors is greatest.

The older idea of specific and separate fiber types in the peripheral nerve trunks has had to be discarded. Neurons are found to vary in a continuous spectrum of sizes and degrees of myelination, with corresponding conduction rates. The supposed types are merely modes in a continuous frequency distribution. Nevertheless there is a crude relation between size and sensory function. Starting with the larger myelinated fibers we find in descending order: kinesthesia, cutaneous touch, subcutaneous pressure, pain, warm, cold, and pain again in the smallest unmyelinated fibers. There is considerable overlapping, particularly through the pain-warm-cold region.

Note that pain comes in twice, first in myelinated fibers slightly larger than those for warm and cold, and again in the smallest unmyelinated fibers. The assigned relations between size and function are based on indirect evidence, from the piecing together of the results of studies on human subjects and animals. Direct evidence would require comprehensive action-current records from nerves in conscious human subjects who could simultaneously report their awareness. Such direct studies are as yet beyond the bounds of our technical skill.

In the spinal cord some degree of separation according to function is maintained. The dorsal columns contain fibers mediating kinesthesia and some of those for subcutaneous pressure and cutaneous touch. The spinothalamic tracts carry the balance of the pressure and touch fibers (mostly in the ventral portion) and the neurons for pain, warm, and cold (mostly in the lateral part).

At the level of the thalamus, division according to function is lost and only a topographical representation remains. The posteroventral nucleus of the thalamus shows three distinct regions from the head, the trunk, and the legs. Again, at the level of the cortex, the representation is topographical. Electrophysiological studies on the monkey indicate a considerable degree of point-for-point projection analogous to that of the motor cortex (Marshall, Woolsey, and Bard, 1937). But no study of the cortex has revealed evidence of separate touch areas, pain areas, warm areas, or cold areas. Whatever it is that distinguishes centrally between pain and touch, warm and cold, etc., has so far escaped our research techniques.

Identity of receptors. Returning to the skin, let us examine the problem of the possible receptors for touch, pain, warm, and cold. In cutaneous touch it appears that three different types of receptors are involved. These are the basket endings around hair bulbs, the Meissner corpuscles, and some of the free nerve endings. The basket endings are thought to be touch receptors, be-

cause even the light flicking of a single hair can be sensed, and because touch spots on hairy skin are typically found slightly to the windward of the hairs, that is, right over the basket endings. For Meissner corpuscles the evidence is less direct—simply that they are present in densest concentration where touch sensitivity is greatest. That some free nerve endings are involved is indicated by two facts: first, that the cornea has touch sensitivity, but only free nerve endings; second, that touch spots are sometimes found on the hairy parts of the body in positions not related to hair bulbs.

For cutaneous pain, it is almost universally agreed that free nerve endings must be responsible. Throughout the skin only free nerve endings are present in sufficient abundance to account for the great density of pain spots. Also, the cornea shows extreme pain sensitivity and has free nerve endings. Some pain, as Nafe suggests, may arise from the spastic constriction of blood vessels, but even then the free nerve endings associated with the blood vessels are probably directly responsible.

Concerning the receptors for warm and cold our ignorance is profound. Following von Frey's suggestion, some textbooks still proclaim Ruffini cylinders as the receptors for warmth and Krause endings as the receptors for cold. There has never been the slightest evidence connecting Ruffini cylinders with warmth, except that the Ruffini endings are very scarce and warm spots were once thought to be few and far between. In fairness to von Frey, it should be recalled that he was careful to preface his suggestion with a cautious "perhaps" which has too often been lost in reprinting.

The case for the Krause endings as cold receptors appears more plausible at first sight. Krause endings are abundant in the nipple where there is strong sensitivity to cold (Belonoschkin, 1933). The number of Krause endings per square centimeter on the prepuce agrees with the number of mapped cold spots (Bazett et al., 1932). But any

correlation of numbers might be purely accidental. More directly, Strughold and Karbe (1925) reported a topographical coincidence of Krause endings and mapped cold spots in the conjunctiva of an eye vitally stained with methylene blue. Careful examination of the data from this dramatic experiment, however, reveals that there were some cold spots without corresponding Krause endings, and some Krause endings without corresponding cold spots. Weddell, examining the tissue beneath a single excised cold spot from the forearm, found "... two groups of endings resembling Krause's and bulbs" (Weddell, 1941, p. 355).

In contrast to these scattered positive indications stands a wealth of negative findings. At least six independent studies of numerous excised cold spots have failed to reveal any capsulated endings whatsoever (Dallenbach, 1929). In fact, a systematic histological examination of sections of skin from various hairy regions failed to show any capsulated endings, although the same technique readily revealed Meissner corpuscles on the hairless skin (Gilbert, 1929). Apparently the best that can be said for the Krause ending is that it may be a cold receptor in certain limited regions, but it cannot be *the* cold receptor in the major portion of the skin.

Nor is anything known with certainty about the relative depth of warm and cold receptors. Dubious calculations based on reaction times and supposed rates of thermal conduction have generally placed warm receptors at a greater depth than cold (Bazett et al., 1932), although one calculator arrived at the conclusion that they are equidistant from the surface (Hahn, 1927). In an attempt at direct study Endres (1930) punctured the skin to a known depth and placed a drop of anesthetic on the puncture. He found that the skin had to be pierced to a greater depth on a warm spot than on a cold spot in order to destroy the sensitivity of the spot. On the other hand, Woollard (1935) found three cold spots remaining after successive slicing away of the skin had re-

moved all but the lowest portion of the dermis. This shows, at least, that cold sensitivity must extend to a considerable depth. Other evidence indicates that some warm receptors must be quite superficial. For example, Oppel and Hardy (1937) discovered that nonpenetrating infrared is more effective than penetrating radiation in arousing warmth. Also, Windisch (1931) showed that dry diathermy, which warms principally the skin surface, is far more effective than wet diathermy, which penetrates.

Dissociation as evidence. Although we must admit failure to identify fully the cutaneous receptors, there is considerable evidence that at least four functionally separate systems exist, because they can be dissociated in a variety of ways. The detailed reports are sometimes confusing and contradictory, but the essential fact of dissociation stands forth in study after study. The following paragraphs summarize the chief methods of producing dissociation.

1. Local anesthesia of a section of skin can best be controlled by driving the anesthetic into the skin electrically (Cummings, 1938). The exact order of disappearance and re-appearance of sensitivities varies, but generally warm and cold go out first and come back last.

2. Complete loss of sensitivity followed by long-delayed recovery is the outcome of cutting or crushing a nerve branch or of injecting it with alcohol (Lanier, Carney, and Wilson, 1935). Figure 2 shows an example of the dissociation of touch and warmth in one subject. Effects of shorter duration may be obtained by injecting novocaine around a nerve (Bishop, 1944a), by blocking the nerve with pressure (Raffel, 1936), or by cutting off the blood supply (Lewis, 1942). The order of disappearance and re-appearance of the specific sensitivities varies considerably with the method, but some dissociation is always found. Dissociation is likewise typical during the recovery of sensitivity in skin grafts (Kredel and Evans, 1933).

3. Dissociation has also been produced by slicing off successive thin layers of skin (Woollard, 1935) and by destroying the outer layers chemically (Bishop, 1944b). In these instances, cutaneous touch in response to stimulation seems the first to go.

4. Statistically significant differences in sensory chronaxy for warm, cold, pain, and touch have been reported (Jones and Jones, 1941). (Sensory chronaxy is the duration of an electrical stimulus of twice threshold

FIG. 2. Dissociation of warmth and touch. The maps show the state of recovery following nerve block by alcohol injection. (Adapted from Lanier, Carney, and Wilson, 1935.)

strength required to arouse the appropriate sensory experience from a mapped spot.) In studies of chronaxy, all four sensations are produced by the same type of stimulus applied to different spots.

5. Injection of a spinal anesthetic causes some dissociation (Heinbecker, Bishop, and O'Leary, 1934). Nicking the spinal cord can stop pain without interfering with touch from the same area.

6. Pathological conditions also provide striking evidence. At least one case of congenital pure analgesia has been reported, with the senses other than pain intact (Dearborn, 1932). In syringomyelia, a disease that begins in the spinal gray and moves outward, pain is usually lost first, with little or no impairment of the other senses. Then warm and cold disappear, and finally touch.

The overwhelming weight of evidence from dissociation studies provides a basis, other than mere convenience, for the separate dis-

cussions of touch, pain, warm, and cold in the following sections.

CUTANEOUS TOUCH

Touch may be aroused without direct contact on the skin simply by moving a hair. Movement of the hair apparently has a dual stimulating action, because destroying the hair root endings reduces but does not obliterate the sensitivity (Stetson, 1923). The movement must directly disturb the basket endings, and must also distort the surface of the skin, which indirectly affects other touch receptors.

Purely cutaneous touch from direct contact with the skin requires the use of very light weights or weak hair stimulators (to avoid the simultaneous stimulation of subcutaneous pressure sensitivity). The adequate stimulus for cutaneous touch is clearly a deformation gradient, and not contact as such. For example, if a finger is inserted in a vessel of mercury, there is contact all over the submerged finger, but touch is felt only at the surface of the liquid where there is a deformation gradient on the skin. The deformation gradient may be produced either by pressure or by pulling. If a small stimulator is glued securely to the skin and lightly pulled and lightly pressed, the average subject cannot distinguish between the two directions.

The *rate* at which the skin is deformed is important. Grindley (1936) showed that the minimal detectable weight is less when the stimulus is applied rapidly than when it is applied slowly. Nafe and Wagoner (1942) found that, when a light stimulator was allowed to sink into the skin, the touch sensation disappeared just when the rate of movement fell close to zero. The exact minimum rate of deformation at which touch was felt varied somewhat with the weight, but it was independent of the area of the stimulator. Using a uniform rate of application von Bagh (1935) found that the threshold was related to the depth of defor-

mation of the skin but that it was independent of the area. Holway and Crozier (1937) thought they had demonstrated that area as such (and not the distortion gradient at the perimeter) was the significant variable in discriminating differences among weights resting on the skin. Their results are inconclusive, however, because they determined difference limens by *gradually* adding weight, and they disregarded the crucial factor of the rate of application of the stimulus. Unless applied pressures are strong enough to stimulate deep pressure sensibility, it appears that the distortion of skin produced at the perimeter of a stimulator is the critical factor.

Vibratory stimulation. Separate touches can be sensed as discrete up to a frequency of about 20 per second—the exact value depending somewhat on the individual subject. Above this frequency, the touches melt into a smooth sense of vibration, which shows characteristics roughly analogous to those of hearing. Maximum sensitivity is in the region of 250 cycles per second, but the upper limit is not known with any certainty because of the technical difficulties of moving the skin at high frequencies (Geldard, 1940, p. 282). Differences between vibration frequencies can be discriminated, but much less adequately than in pitch discrimination by hearing. Thresholds in terms of amplitude of movement of the skin (not the vibrator) can be measured accurately with a binocular microscope, using a slightly mistuned stroboscopic light to slow down the apparent movement. Thresholds thus determined are much lower for touch spots than for areas insensitive to touch, indicating that the same receptors mediate both touch and vibration (Geldard, 1940, p. 279). An artifact in vibration studies is the tendency of the vibration to spread from the stimulated spot to other regions. By using a lightweight phonograph pickup rested on the skin, Weitz (1939) has shown that the vibration may spread a considerable distance from the point of origin.

CUTANEOUS PAIN

For all the vast literature on the subject of pain, relatively little is known for certain about cutaneous pain and how it is aroused. The view seems to be widely held that pain results from direct nerve stimulation of "bare" free nerve endings. It is true that the same excitants arouse pain when applied to the skin and when applied directly to exposed nerves (Lewis, 1942, p. 108). But this merely indicates that pain *might* result from direct nerve excitation, not that it necessarily does. As a matter of fact, the available evidence seems to indicate that pain receptors are just as specific as any others. There are distinct pain spots, and the prick of a needle between them does not arouse pain. Pain can be dissociated from the other skin senses. Later we shall see that some visceral pains cannot be aroused except by tension, indicating that these pain receptors must be specific even to their manner of arousal.

Pain is ordinarily associated with intense stimulation. But under conditions of hyperalgesia a mild temperature or even a light touch may cause excruciating pain. Pain is also commonly connected with tissue damage, but damage is certainly not sufficient and probably not necessary for pain. It is possible for X-rays and certain kinds of freezing to damage the skin severely without causing the slightest pain; so injury is not sufficient. Pain spots may be stimulated by mild electric shocks without any sign of damage to the tissues; so injury is probably not necessary.

Pain has often been considered the opposite of pleasure, and this idea has crept into the psychological literature. But pain is not necessarily unpleasant. Some people derive pleasure from the consumption of hot spices, horseradish, etc., which appear to obtain their distinctive effects by the stimulation of pain receptors.

Bishop (1943) suggests that mild stimulation of pain spots may not be painful at all.

In response to single electric shocks of threshold intensity applied to pain spots, his subjects reported only a vague sense of stimulation too weak to be clearly discriminated. At higher intensities there was a "painless prick." "True pain" was reported only when repeated or strong shocks were employed. Thus Bishop concludes: "Increases in total stimulation of any pattern may have both quantitative and qualitative effects" (Bishop, 1946, p. 95).

Are there two pains? It has been mentioned above that there is some justification for believing that there are two cutaneous pains. The evidence is a number of suggestive but as yet not fully coordinated facts. Various investigators have reported the subjective differentiation of "pricking pain" from "burning pain," although Lewis believes them to differ not in quality but only in latency and duration. A needle prick or a brief contact with a high-temperature stimulator arouses first a brief sting, and is followed after an appreciable interval by a flash of pain of greater intensity. According to Lewis (1942, p. 51) the average lag of the second response is 1.9 seconds at the toe, 1.3 seconds at the knee, and 0.9 second at the top of the thigh. These changes in lag, he points out, correlate with the differences in conduction rate of the two groups of pain nerves disclosed by electrophysiological study (Gasser, 1935). Furthermore, cocaineization abolishes the second pain while leaving the first intact, and cocaine is known to affect the small unmyelinated nerves first (Lewis, 1942, p. 51). Lewis believes, therefore, that the two pains are mediated by two sets of fibers, one myelinated and moderately rapid in conduction, the other unmyelinated and slow.

Possibly not connected at all with the foregoing are two other sets of puzzling facts. Schumacher et al. (1940) found the pain threshold for radiant heat to be remarkably uniform in 150 subjects. Yet Lanier (1943) discovered that the pain threshold for electric shock varied greatly in a group of 15

subjects. Whether this discrepancy is related in any way to the two sets of pain fibers is an interesting topic for future research.

CUTANEOUS WARM AND COLD

Warm and cold are almost certainly two separate forms of skin sensitivity: they can be dissociated and their two distributions on the skin show little correlation (Jenkins, 1941*b*). However, warm and cold can be conveniently discussed together, since they display so many phenomena in common.

Adequate stimulation. The nature of the adequate stimulus for the temperature senses is still a matter of speculation. Normally there is a temperature gradient between the circulating blood (37.5 degrees C) and the skin surface (32 to 33 degrees C on the forearm). Any addition or removal of heat disturbs this gradient. But the actual stimulation might be due to (1) the disturbance of the gradient as such or (2) a change in temperature at the receptors, with the gradient shift purely incidental. At present there is no basis for choosing between these alternatives. We do not even know quantitatively how the temperatures in the skin are altered by brief contact or by radiant stimulation sufficient to arouse warmth or cold. Measurement with buried thermocouples indicates that the temperature at a depth of 1 millimeter is altered only a few degrees by prolonged contact stimulation of the skin at high or low temperatures (Bazett, McGlone, and Brocklehurst, 1930). Estimates of temperature changes at the skin surface following threshold radiant stimulation indicate alterations of a fraction of a degree (Oppel and Hardy, 1937). Neither type of measurement is entirely satisfactory in a quantitative sense, but the evidence is strong that the temperature changes responsible for stimulation may be minute indeed.

Nonadequate stimulation. Strong evidence for the specificity of the temperature

receptors is the fact that warm and cold can be produced by several types of stimulation: mechanical, electrical, chemical, and thermal. Jones (1940) showed that a stirring motion of a neutral-temperature rod over a cold spot will frequently produce cold, and over a warm spot, warm. Even the jab of a fine needle is sometimes effective. Electric shock can also arouse warm and cold. (It is interesting to remember that Blix in 1883 first discovered the existence of warm, cold, and touch spots through the use of electrical stimulation.) Chemical arousal of cold by menthol is used commercially in sunburn lotions and in cigarettes. Chloroform and carbon dioxide, when evaporation is prevented, can be used to arouse warmth.

Paradoxical cold—from stimulating a cold spot with an object at about 45 degrees C—has been experienced by many people. Paradoxical warmth—from stimulating a warm spot by a low temperature—is probably also a genuine phenomenon. Its authenticity has been questioned, however, because of the tendency of naïve subjects to call anything “warm” that is not definitely cold.

Radiant versus contact stimulation. The statement that there may possibly be two warmths and two colds is based solely on the puzzling differences between the effects of radiant and of contact stimulation. There is no evidence of multiple types of receptors as there is for cutaneous touch. Nor is there any indication of multiple nerve fiber groups as there is for cutaneous pain. But radiant and contact stimulation show some differences so striking that speculation is inevitable.

The effects of radiant stimulation have been exhaustively studied by Hardy and his collaborators, who used a special radiometer to measure the radiant energy with a high degree of accuracy (Hardy and Oppel, 1937). Analogous effects in contact stimulation have been investigated by the method of *seriatim mapping*, designed to check the reliability of subjective reports of intensity (Jenkins,

1940). In seriatim mapping, the squares of a checkerboard pattern are stimulated in random order. The subject reports 0, 1, 2, or 3 to designate increasing degrees of cold (or warm). The mapping is repeated six times to accumulate a score for each square.

Two major differences are found between radiant and contact stimulation:

1. Warmth cannot be sensed at all with small areas of radiant stimulation. In areas less than about 700 square millimeters only pain is experienced when the radiation becomes strong enough to elicit any sensation at all (Hardy and Oppel, 1937, p. 537). In contrast, warm spots may be mapped with a contact stimulator of 1 square millimeter or even less.

2. Positive summation from the combined stimulation of two areas is quite marked with radiant stimulation (Hardy and Oppel, 1937). At threshold the radiant energy per unit area is considerably less when two regions of the forehead are stimulated simultaneously than when either is stimulated alone. There is even a summation effect when radiant stimulation is applied to the backs of the two hands, though none when a hand and the forehead are stimulated together. In contact stimulation, on the other hand, summation appears at best to be only slightly positive and may actually be negative (Jenkins, 1940). When two adjacent areas give equal seriatim scores (say 12 and 12), stimulating them simultaneously gives a slightly higher score (about 13). But, if the two areas have markedly different scores (say 12 and 6), stimulating them simultaneously gives a lower score than the maximum and only slightly higher than the average of the two (in this case about 10).

Such great differences in the effects of radiant and of contact stimulation indicate that the two forms of stimulation must act differently on the same receptor system — or just possibly that they affect two different systems. The latter hypothesis is at present pure speculation.

CUTANEOUS ADAPTATION

The term "adaptation" has been employed in a confusing variety of ways.

1. Most commonly, adaptation refers to the diminution or complete disappearance of sensation under continued stimulation. For example, a light weight resting on the skin is soon not felt at all.

2. Also called adaptation is another negative effect that may be closely related to the first. This is the blunting of response as the result of previous stimulation. For example, dipping a hand into cold water reduces the intensity of sensation produced by a cold stimulator.

3. Positive enhancement is sometimes also called adaptation, particularly in the case of the temperature senses. Dipping an arm into cold water, for instance, makes a stimulator at 30 degrees C feel warm, although this is below the normal skin temperature of the arm.

4. Most confusing of all, it is said that touch shows "rapid adaptation" because successive contacts up to 20 per second can be felt as discrete. However, this does not mean that the sensation has been either diminished or enhanced as in the three preceding cases, but merely that the touch receptors are sufficiently dead-beat in their operation to permit the sensing of a rapid tactual flicker.

Possibly some of the confusion can be alleviated by eliminating this fourth use of the term completely and by using positive adaptation for the third, and negative adaptation to cover both the first and the second. At any rate, that will be done in this chapter.

However, this semantic housecleaning does not clarify the situation completely. Negative and positive adaptation still refer to gross phenomena without regard to the basic causes. Barring central processes, the diminution or enhancement may be due to a change in the *receptors*, or to a change in the effective *stimulus*, or to some combination of the two. Rather than introduce new terms, or new uses for old ones, we may

employ the terms negative adaptation and positive adaptation to designate the gross phenomena, and continue to search beyond them for the basic causes.

Touch adaptation. Nafe and Wagoner (1942) have done a real service by demonstrating that the negative adaptation of touch, when a light weight is rested on the skin, is due largely to the cessation of the stimulus. They measured kymographically the movement of a weight into the skin while the subject reported on the disappearance of sensation. Consistently the instant of disappearance was related to a rate of movement very close to zero. In short, sensation from the dead-beat receptors stopped as soon as the weight stopped moving. The receptors themselves were still fully sensitive as shown by their immediate response to restimulation.

However, the conclusion of these authors that *all* touch adaptation is due merely to cessation of the stimulus is unsound. Numerous investigators have reported what is called 'threshold lability' (Tschlenoff, 1931). That is to say, a touch spot sometimes fails to respond at all after repeated brief stimulations. In this case it is clearly the *receptors* that have failed. Although studied principally as a symptom of neural disorders, threshold lability has been demonstrated in normal people under conditions of fatigue (Beringer and Ruffin, 1932). Probably related is the slow increase in threshold values when vibratory stimulation is continued for a long time (Geldard, 1940). No clear-cut evidence of positive adaptation (i.e. enhancement) of touch seems to exist.

Pain adaptation. It is common experience that many cutaneous pains do not show negative adaptation but appear to get worse as time goes on. Under carefully controlled conditions, however, complete negative adaptation to needle pricks and to radiant heat has been demonstrated (Burns and Dallenbach, 1933; Stone and Dallenbach, 1934). Since we do not know the nature of painful stimulation, it is difficult to determine

whether a cessation of the effective stimulus is involved in these cases. But the fact that pains wax and wane during adaptation without visible external causes suggests that the receptors are responsible at least in part.

The term "positive adaptation" might logically be applied to the condition of *hyper-*

FIG. 3. Spread of hyperalgesia following skin injury. The cross marks the spot at which the skin was injured by pinching, and the heavy line shows the area in which the mildest stimulation caused pain. To account for such an extensive spread of hyperalgesia, Lewis postulates a system of nocifensor nerves that release a pain-producing chemical.

algia following injury, since there is a definite enhancement of pain. The complexities of this condition have been carefully investigated by Lewis (1942). Ordinarily the hyperalgesic area shows a marked lowering of the threshold for pain. Mild temperatures, friction, and tension readily arouse pain. Sometimes, as is shown in Fig. 3, the hyperalgesia spreads both distally and proximally from the point of injury until it occupies practically the entire area supplied by a main nerve. Significantly the distal spread can be blocked by anesthetizing the

nerve at a point distal to the injury. It is known that the sympathetic system is not essential, because such effects can be produced after sympathetic ganglionectomy. On the basis of his findings, Lewis postulated a special system of nocifensor (effector) nerves which release some pain-producing chemical. Antidromic action over the sensory pain nerves has also been used to explain the effects. Concerning the chemical responsible for hyperalgesia, there is no direct evidence. Histamine is released by painful stimulation (Rosenthal and Minard, 1939) and causes pain when injected or painted on raw wound surfaces, but so do many other substances. Lewis believes that histamine is responsible only for the reddening of the skin, and that the hyperalgesia-producing substance remains to be discovered.

Thermal adaptation. Warm and cold show both negative and positive adaptation. Mild thermal experiences tend to fade out completely, and more severe intensities generally are blunted with the passage of time. On the positive side, a precooled hand feels warm and a prewarmed hand cool when both are dipped into water of neutral temperature. Consideration of such effects led to Hering's still widely accepted theory that thermal adaptation is merely a shift of the "physiological zero."

With large areas, a shift of the physiological zero appears to explain adaptation effects fairly well, if certain limits are assumed. The lower limit seems to be about 25 degrees C. Complete negative adaptation, according to Gertz (1921), does not occur to temperatures lower than this. Likewise 25 degrees C seems to be the lowest temperature that can be sensed as warm, no matter how much the skin is precooled (Hahn, 1930). At the upper limit there is some discrepancy. Complete negative adaptation can occur to temperatures as high as 45 degrees C, but it is doubtful whether any temperature higher than 40 degrees C can be made to feel cool by prewarming the skin (Gertz, 1921).

With very small areas, however, the simple shift-of-physiological-zero theory becomes totally inadequate. Small stimulators produce intricate adaptation effects, as the following examples show:

1. Brief intermittent stimulation frequently knocks out a warm or cold spot completely (Levine and Dallenbach, 1936). This is analogous to threshold lability in touch, except that it occurs much more commonly.

2. Spontaneous recovery occurs slowly after a matter of some minutes, but the recovered spot is unstable when subjected to further stimulation. Short contact with a stimulator at 45 degrees C hastens restoration (Jenkins, 1937).

3. When a spot is surrounded with a controllable field, gradual reduction of the field temperature progressively lowers the liminal temperature of the spot for cold. However, when the field temperature reaches about 25 degrees C, the spot is likely to fade out completely and remain unresponsive even to 10 degrees C. Reversing the field temperature sometimes brings the spot almost back to normal (Jenkins, 1937).

4. When the field temperature is gradually raised, the liminal temperature for cold usually goes up, but never above blood temperature. On the contrary, some spots lose sensitivity as the field temperature is raised and are restored by returning the field temperature to normal (Jenkins, 1937).

5. Under continuous stimulation with the smallest stimulators, the time to reach complete negative adaptation to 10 degrees C is a matter of a few seconds. With slightly larger stimulators, the negative adaptation time is lengthened, but in proportion to the perimeter rather than to the area of the stimulator. Thus adaptation time is longer for rectangular and annular stimulators than for circular stimulators of the same area (Jenkins, 1938a).

It is evident from these examples that thermal adaptation is a complex affair, sug-

gestive of some chemical basis for the receptor action.

THEORIES OF CUTANEOUS WARM AND COLD

The complex phenomena of thermal adaptation provide an excellent background for considering theories of cutaneous thermal sensitivity, because enthusiastic proponents have sometimes failed to take account of all the available experimental evidence.

Nafe's vascular theory. Although Nafe has recently attempted a general theory of sensitivity based on movement as the sole form of stimulation (Nafe, 1942), his best-known contribution is the hypothesis that cutaneous warm and cold are merely kinesthetic sensations from dilating and constricting blood vessels. In support of this, Nafe has marshaled a number of facts showing the coincidence of vascular activity and temperature sensations, including the familiar "chills" from screeching sounds (Nafe and Wagoner, 1936). He has also answered point for point certain objections that have been raised (Nafe, 1938). A new twist has been added by Gilmer (1942a, b) who tentatively suggests that the glomus bodies (see Fig. 1) may mediate both cold and touch, because they have been found in close relation to some cold spots and touch spots.

The preponderance of evidence, however, does not fit a vascular theory (Jenkins, 1939). The facts of dissociation and the phenomena of nonadequate stimulation seem to point rather to *specific* receptors. If only blood vessels are involved, they mimic the behavior of specific receptors to the last detail. There is no independent evidence that blood vessels are capable of such versatility.

The spot theory. Since von Frey's original statement in 1895, it has been widely assumed that the mapped sensory spots, particularly warm and cold spots, correspond point for point with individual receptors. Many gross phenomena can be readily ex-

plained on this basis. Thus the weaker responses of regions between spots are said to be due to conduction through the skin. The increased sensation experienced from more extreme temperatures is thought to be simply the stronger response from the receptors concerned.

Evidence from seriatim mapping, however, has cast doubt on the validity of the spot theory. Consider, for example, two adjacent squares on a seriatim map, one of high and the other of low score. Suppose that the high score is due to the presence of a receptor, and the adjacent low score to conduction to the same receptor. Then a stimulator covering both areas should yield a score at least as high as the stronger one. But actually the two squares together give a score that is consistently *less* than the stronger and approximately equal to the average of the two scores (Jenkins, 1940). Furthermore the squares of a seriatim map do not respond with a uniform increase in their scores when the stimulating temperature is increased, as they should do if only a relatively few receptors were involved (Jenkins, 1941a). In a typical case, half the squares show no increase in score when the stimulus temperature is raised 3 degrees C, whereas the other half exhibit increases of varying magnitude. An increase of 6 degrees C leaves one-fifth of the scores unaltered, although certain individual squares go from zero to maximum with the same change in temperature. Any system of a few warm receptors per square centimeter is much too inflexible to account for such findings as these.

The concentration theory. To explain these and similar results, a concentration theory has been proposed (Jenkins, 1941a). Figure 4 shows the essence of the theory schematically. Instead of a few warm and cold receptors per square centimeter, it is postulated that there are hundreds of receptors with varying limens. The intensity experienced from a given stimulation depends on the *concentration of active receptors*. Thus simultaneous stimulation of a strong

and a weak area yields approximately an average score that corresponds to the overall concentration in the total area. Similarly, different squares of a map may respond quite independently to the same increase in stimulus temperature. In one square, virtually all the receptors are brought into action by mild stimulation, and further increase in temperature can have little or no effect. In another square, most of the receptors may

not be adequately handled in terms of either the vascular theory or the spot theory.

SUBCUTANEOUS OR DEEP SENSITIVITIES

Even after the skin itself has been completely anesthetized, subcutaneous pressure sensitivity and pain sensitivity remain. Under normal circumstances, heavy weights

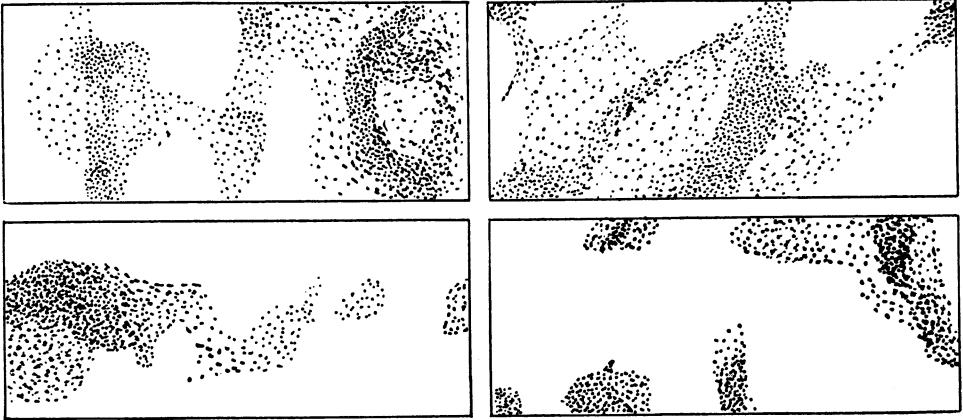

FIG. 4. The concentration theory. The maps show hypothetical distributions of receptors corresponding to scores obtained in seriatim mapping. Warm and cold "spots," according to this theory, do not mark the locus of individual receptors but are points where the concentration of receptors is dense.

be unresponsive except to rather extreme temperatures. An infinite variety of intermediate grades is possible.

It may be objected that the concentration theory offers no possible receptors for warm and cold except free nerve endings, which are thought to mediate pain and probably touch as well. But it is entirely possible that what we loosely call free nerve endings may be differentiated in ways — chemically, for example — that are not revealed by our present histological methods. It appears that they would have to be so differentiated to account for both touch and pain; and the inclusion of warm and cold would be merely another step in the same direction. In any event, the chief merit of the concentration theory as a working hypothesis is that it explains experimental facts that can-

and strong pressures stimulate both cutaneous touch and subcutaneous pressure. Since much longer negative adaptation times are reported for heavy than for light weights, it appears that the subcutaneous pressure receptors are not dead-beat like the cutaneous touch receptors. They continue to respond long after movement of the stimulator into the skin has ceased, although the intensity of the experience diminishes with time.

It is uncertain whether the subcutaneous pressure receptors can sense smooth vibration like that sensed by cutaneous touch. Vibration can be felt when a vibrator is applied to anesthetized skin (Cummings, 1938). But Weitz (1939) has shown that the anesthetized skin tends to move up and down as a unit, and to spread the vibration to unanesthetized areas. Logically it might

be expected that the nondead-beat subcutaneous pressure receptors could not respond to vibratory stimulation as do the dead-beat cutaneous touch receptors.

The large Pacinian corpuscles (see Fig. 5) are generally believed to mediate subcutaneous pressure. They are large enough in size to permit the experimental stimulation of an individual corpuscle while nerve action potentials are being simultaneously recorded. Such experiments show that Pacinian corpuscles do respond to pressure stimulation.

In kinesthesia at least three different kinds of receptors are involved — endings associated with the muscles, the tendons, and the joints (see Fig. 5). The muscle endings are arranged in the form of spirals and flower sprays within the muscle spindles. They appear to be normally stimulated only by the *stretching* of a muscle, and not directly by its contraction. The muscle relaxes and lengthens when its antagonist contracts, and it is then that the muscle endings are activated.

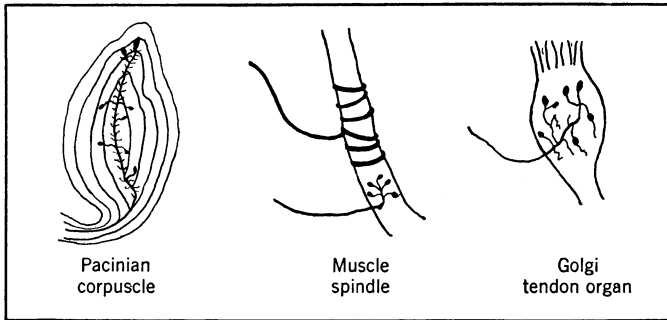

FIG. 5. Subcutaneous and kinesthetic endings.

Subcutaneous pain can be aroused by extreme pressure and probably also by extreme temperatures (Rein, 1924). Puncture of arteries is generally painful, but veins and subcutaneous fat are relatively insensitive (Bazett and McGlone, 1928). Free nerve endings are believed to be the receptors for subcutaneous pain, but the actual nature of their stimulation is no better understood than is the mechanism of cutaneous pain.

KINESTHESIS

Kinesthesia — the sense of position and movement — is probably the most important sensitivity man possesses. Without kinesthesia a person could not maintain erect posture, let alone walk, talk, and engage in other skilled activities. Yet the existence of kinesthesia is not popularly appreciated, and the word has no counterpart in common language.

The Golgi tendon endings (see Fig. 5) are in the form of spirals around the ends of tendons where they attach to muscles. Their primary stimulation occurs when the muscle *contracts*. Thus muscle spindles and tendon endings complement each other in recording muscular changes.

Sensitivity at joints is still a puzzle. No endings have been demonstrated within the joint surfaces, but Pacinian corpuscles are found in abundance in the immediately surrounding tissues. If these are actually the receptors, then the so-called "joint sense" is reduced to subcutaneous pressure in a particular locus.

The most remarkable feature of kinesthesia is that it gives knowledge of *position* as well as of movement. Movement might be handled by receptors operating in the dead-beat fashion of cutaneous touch. Position demands nondead-beat receptors that can maintain characteristic patterns of nerve impulses.

It has already been mentioned that Pacinian corpuscles are nondead-beat in operation. Electrophysiological studies of nerve impulse patterns from muscles indicate that muscle spindles and tendon endings display the same characteristic.

INTERNAL OR ORGANIC SENSITIVITIES

Because of the difficulties of precise experimentation, relatively little is known about the sensitivity of the internal parts of the body, except for the mouth cavity which reacts in much the same way as the external skin. The esophagus and stomach have specific warm and cold sensitivity but no touch sense in response to light contact (Boring, 1915*a, b*). Since the esophagus responds to mild distension, it appears to have something analogous to subcutaneous pressure sensitivity. Strong distension arouses a quality similar to subcutaneous pain. In other internal parts there is no clear evidence of specific touch, warm, cold, or pressure senses.

Even the distribution of internal pain does not rest on too secure a foundation. Much of the evidence is derived from not-too-well-controlled clinical studies of human beings or by inference from animal studies where subjective reports are necessarily lacking. It is reasonably certain that such solid organs as the liver, the spleen, and the kidney can be squeezed, cut, and burned without causing pain. Traction upon the hollow viscera is painful, but possibly only because the tension is transmitted to the mesenteries or abdominal walls (Lewis, 1942, p. 9). A similar explanation can be applied to pain from strong contraction of hollow viscera (Lewis, 1942, p. 170). The peritoneum is generally found to be very sensitive to pain from stretching, but not from direct contact. However cloudy the details, one essential fact stands forth; some internal pains must arise from receptors that are more specific than those of the skin. Not only are they

specific in yielding only pain, but they can be stimulated only in certain specific ways.

An interesting feature of internal pains is their tendency to be referred to other parts of the body, usually following the segmental distribution of spinal nerves. So standardized are some of these references that they are used in clinical diagnosis. There is also a referred hyperalgesia. For example, attacks of angina pectoris often leave a tenderness in the skin over the left side of the chest (Lewis, 1942, p. 152). Superficially this appears similar to the hyperalgesia from direct skin injury, but of lesser intensity. Morely (1937) and others claim to have abolished shoulder-tip pain from pressure on the diaphragm by local anesthesia of the cutaneous region. However, this finding has not been confirmed by some other investigators and definitely does not hold for many types of visceral referred pains. It is possible for local skin anesthesia to abolish temporarily the referred skin hyperalgesia without interfering with the referred pain.

SOMESTHETIC DISCRIMINATION

Many research studies have been concerned with the systematic measurement of such phases of somesthetic perception as the error of localization, the two-point limen, the discrimination of intensity differences, and the discrimination of form. Here space permits only a brief summary of the broad perspectives, with a complete omission of quantitative data such as may be found in the handbook of von Skramlik (1937).

Localization. If a point on the skin is lightly touched, its location can be designated with a degree of accuracy that varies according to a great number of factors, chiefly the part of the body and the method used to designate the spot. Localization by means of subcutaneous pressure is good but less precise than that for cutaneous touch. Pain from a pinprick can be localized about as accurately as touch, even when the sub-

ject reports no simultaneous touch sensation. Warm and cold, whether derived from contact or radiant stimulation, are poorly localized when simultaneous touch cues are excluded.

Two-point limen. The ability to discriminate two simultaneously stimulated points as separate roughly parallels the ability to localize on various parts of the body. The two-point limen is usually found to be two or three times as large as the error of localization. Conflicting results in this connection are sometimes referable to differences in instructions to the subjects. Perceptually the transition from one to two points is not clean-cut but passes through a series of intermediate stages: point, line, circle, oval, dumbbell, etc., before it becomes two clearly separate points. If a subject reports "two" as soon as he gets a hint of departure from singleness, he will show a much smaller limen than if he waits until there is clear duality. By common agreement the latter is considered the true two-point limen.

Discrimination of intensity differences. Kinesthetic-tactual discrimination of weights by lifting is better than the static discrimination of weights rested on the skin. (In static discrimination, it is probable that both cutaneous touch and subcutaneous pressure are involved unless the weights are extremely light.) Appreciation of differences in thermal stimulation is best in the neighborhood of normal skin temperature, and it becomes progressively poorer as the stimulus temperature departs from this level, even when the skin has been exposed to an adapting temperature for some time.

Discrimination of pain intensity is, in general, a difficult topic for psychophysical study because we have so little knowledge of what physical measurements are really significant in relation to most forms of painful stimulation (i.e. needle pricks, pressures, chemicals, etc.). A striking exception is the pain produced by radiant heat. Hardy, Wolff, and Goodell (1948) tested subjects with a series of nine radiant heat intensities

varying from the pain threshold to just below a strength that would blister the skin. The stimuli were spaced at intervals of 1 dol, where a *dol* is defined as a unit of painfulness equal in size to two just noticeable differences in pain intensity. The subjects—73 of them—were exposed to a standard stimulus, corresponding to 8 dols (or 16 jnd's above threshold), and then were asked to judge the intensities of the other stimuli in terms of fractions of the standard. The judgments of apparent fractional intensity were found to agree reasonably well with the dol values of the stimuli. The authors feel, therefore, that the dol scale of pain, originally based on jnd's, can serve as a subjective scale of pain intensity, linearly related to perceived painfulness.

Discrimination of form. Perception of points, lines, and shapes pressed against the skin—usually involving both cutaneous touch and subcutaneous pressure—follows rules that are quite analogous to those for vision, including many of the familiar illusions (Revesz, 1934). Much the same is true when kinaesthesia is added by allowing the objects to be handled. On the other hand, thermal discrimination of forms is very poor, and only the grossest differences can be detected (Stone, 1937).

COMPLEX SOMESTHETIC PERCEPTIONS

So far our discussion has dealt with only a few simple somesthetic qualities: touch, pain, warm, cold, subcutaneous pressure, muscular stretch and contraction. In contrast, consider the wealth of phenomenological terms applied to somesthetic experience. Tickle, itch, wet, dry, soft, hard, smooth, rough, oily, greasy, blunt, sharp, and the like refer to the effects of external stimulation. Nausea, suffocation, dizziness, hunger, thirst, and the awarenesses derived from excretory and sexual processes have internal reference.

What can we say about these complex experiences? Are they unique and unanalyz-

able, requiring the assumption of special sense organs of their own? Or have we succeeded in reducing most of them to patterns of the known simple somesthetic qualities of touch, pain, warm, cold, subcutaneous pressure, and muscular stretch and contraction? Or, in spite of our efforts are we still densely ignorant of their nature?

In our eagerness to avoid postulating special receptors for these complex perceptions there is real danger of our accepting too readily some purely superficial answers. In order to show that a particular pattern of simple qualities provides the basis for a complex experience we must demonstrate that the pattern is both *sufficient and necessary* for the perception. Introspective description cannot do this. Introspection is useful in suggesting the possible composition, but it can never prove that a particular pattern is either sufficient or necessary.

Synthesis can establish sufficiency. Certain complex somesthetic perceptions, or reasonable facsimiles thereof, can be synthesized artificially from simple qualities. For example, artificial wetness from cold plus pressure can be readily demonstrated, even to a naïve subject. Heat, or some unique and interesting experience, can be synthesized from mild warm and mild cold (Burnett and Dallenbach, 1927), although many naïve subjects do not spontaneously call the warm-cold fusion "hot" (Jenkins, 1938b). However, all that such synthetic experiments prove is that a certain pattern of simple qualities is sufficient — provided the artificial product is indistinguishable from the natural perception. They do not show that such a combination, or any part of it, is necessary. To demonstrate necessity requires a subtractive procedure.

Subtraction tests necessity. To prove that a simple quality is necessary, its removal must destroy the complex experience. For example, if mechanically preventing rhythmic contractions of the stomach stops hunger pangs, the contractions are necessary for the experience. Yet this does not mean

that they are sufficient in themselves. They may be only a necessary part of a larger pattern.

In reverse, if removal of a component does not destroy the complex perception, that component is *not necessary*. For example, cold is not necessary for the perception of wetness, because water at neutral temperature feels wet (Lauterbach and Crouser, 1933). Cold is not necessary for the perception of what naïve individuals call "hot," because the latter is consistently reported from small skin areas that are consistently negative to low-temperature stimulation (Jenkins, 1938b).

In summary, then, it seems that we actually know little or nothing about what simple qualities are *both sufficient and necessary* for the various complex somesthetic perceptions. This does not imply that the complex phenomena are unique and unanalyzable, or that there are additional sense organs remaining to be discovered. It does mean that the complex somesthetic perceptions are a rich and almost untouched field calling for further research.

Vestibular Functions

G. R. WENDT

University of Rochester

The vestibule is the part of the ear that responds to motion and position. Flourens published the first exact experimental observations on the semicircular canals of pigeons in 1824, setting off an accelerating interest. Since Griffith reviewed the field in 1922, listing 1701 experimental studies, there has been an increasing volume of papers. The German, English, and Italian literatures now contain the best of the studies; interest has been decreasing among the French, but increasing among the Portuguese. A number of useful reviews have appeared (Dusser de Barenne; Griffith, 1922; Fischer, 1928; Camis and Creed; McNally and Stuart; Spiegel and Sommer; Tenaglia; and others), but a reasonably complete and unbiased review has still to be written. The review in this chapter is necessarily sketchy and selective.

ANATOMY OF THE VESTIBULAR APPARATUS

The entire internal ear is called the *labyrinth*. It consists of the cochlear apparatus and the *vestibular apparatus*. The latter consists of the three *semicircular canals* and the *otolith organs* (*utricle* and *sacculle*). The membranous labyrinth lies within a bony labyrinth in the temporal bone, the space between being filled with perilymph.

The preparation of this chapter was aided by funds from a contract between the University of Rochester and the Office of Naval Research.

Since the canals lie in three planes that are roughly at right angles to one another, as shown by the model in Fig. 1, we are able to analyze the turning of the head in any plane. The right and left horizontal canals are in the same plane, tipped back somewhat (Fig. 2). If one tips the head forward so that a line from the corner of the eye to the ear canal is horizontal, the horizontal canals are then brought near the true horizontal. The vertical canals are paired otherwise. The superior canal on one side is in a plane parallel to that of the posterior canal of the other side. These planes form angles of about 45 degrees with the mesial plane of the head. There are, therefore, three pairs of canals: a horizontal pair, a right upper and left rear pair, and a right rear and left upper pair. The canal receptors are in the ampullar swellings of the canals where they join the vestibule (see Fig. 1). The otolith organs in man are found in two sacs: the utricle (or vestibule), from which the canals arise, and the sacculle. These chambers lie close together, joined by a short duct. Figure 3 is a diagram of these relations. The endolymph that fills the sacs and canals has a viscosity and specific gravity like that of cerebrospinal fluid.

The anatomy of the receptors has been studied both histologically and by direct observation. Each canal has within its *ampulla* a transverse ridge called the *crista*, which is supplied by a branch of the vestibular nerve. The surface of the *crista* con-

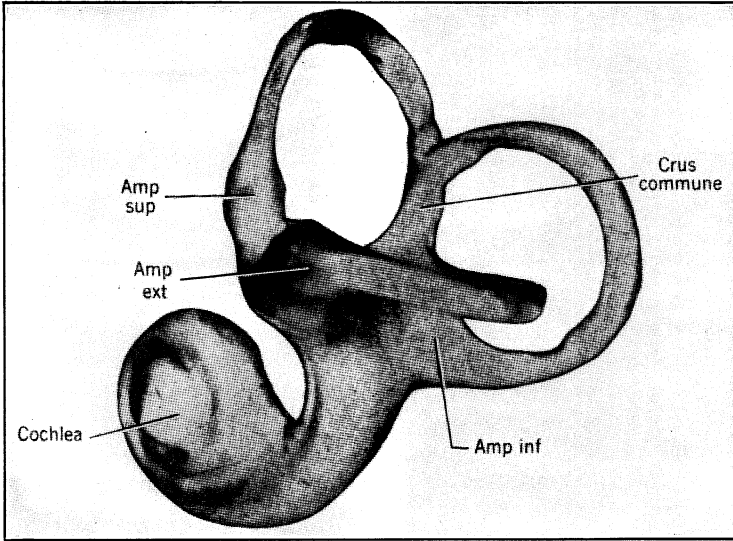

FIG. 1. Model of left human labyrinth. The inner ear is shown in the position it would have in the upright head. This model shows the canals as being more regular in shape than they actually are; normally they follow a somewhat sinuous course, and the geometrical relations of their planes differ slightly among individuals. The three ampullae are labeled: Amp ext = ampulla of horizontal canal; Amp sup = ampulla of superior canal; Amp inf = ampulla of posterior canal. (From Spiegel and Sommer.)

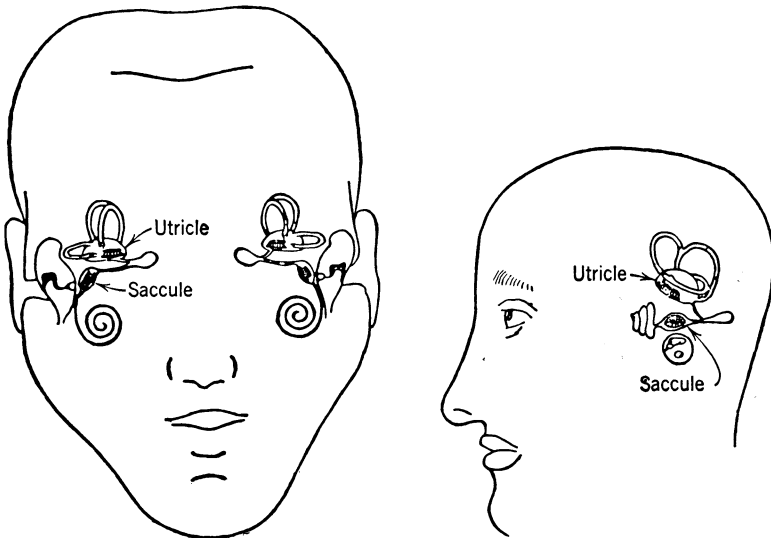

FIG. 2. Diagrams showing the orientations of the labyrinths in the head. (From Camis.)

sists of supporting cells and ciliated receptor cells (*hair cells*). The nerve fibers form a plexus about the base of the hair cells. The cilia project into a flattened gelatinous mass, called the *cupula*, which extends from the ridge of the crista to the roof of the ampulla. One can see in live fish that

The utricular receptor is the *macula*, an oval flat thickening of the vestibular wall with supporting cells and ciliated receptor cells on its surface, and nerve fibers forming plexuses about the bases of the hair cells. The hair cells protrude into a thin gelatinous pad. This contains calcareous crystals, the

FIG. 3. Nerve supply of vestibular apparatus and cochlea. The seven branches of the vestibular nerve and the cochleosaccular nerve are shown, as described in the text. Lat = horizontal canal. (From Hardy.)

the crista and cupula fill the whole cross section of the ampulla. The cupula acts like a swinging door, hinged on the cilia, and moving because of endolymph pressures. The fit of the cupula in the ampulla is close, so that endolymph does not flow past it. Dye put into the endolymph on one side of this barrier does not seep past it, even during induced motions of the cupula. Although direct observations have not been possible in warm-blooded forms, it is assumed that they have the same cupular structure.

otoliths (oto = ear, lith = stone), up to 14 microns in diameter in mammals. The pad has definite shape and some stiffness, so that it presumably tends to act as a whole. The plane of the utricular macula in man is like that of the horizontal canal (see Fig. 2). The saccule also contains a macula like that in the utricle. Its axis is at right angles to that of the utricular macula. Unlike the canals, which are similar from fish to man, the otolith organs show wide anatomical and perhaps functional variations among animal groups. In fish the saccular organs are be-

lieved to be in part vibration (or sound) receptors.

The neurons of the vestibular nerve in man (see Fig. 3) form two main divisions which split into seven branches, one to each of the three ampullae, one to the utricle, two to the saccule, and one (Oort's nerve) to the cochlea. Their cell bodies lie close to the vestibule in Scarpa's ganglion; their fibers travel in the vestibular division of the VIIIth nerve. The vestibular fibers usually make up more than half of the VIIIth nerve and are about 19,000 in number. Most of the fibers are large (10 to 15 microns), but there are fibers as small as 2 microns (Rasmussen). On entering the medulla, fibers end in the vestibular nuclei and possibly in the cerebellum. The place of ending of the fibers from the saccular maculae is unknown. The saccule, in addition to being supplied by *both* divisions of the vestibular nerve, receives a small nerve (cochleo saccular nerve) which appears to come from the cochlear ganglion and presumably enters the medulla by way of the cochlear division of the VIIIth nerve (Hardy).

Neural connections. The bipolar first-order neurons whose dendritic endings are in the cristae and maculae and whose cell bodies are in the vestibular (Scarpa's) ganglion are believed to have their synaptic endings mainly in the vestibular nuclei in the medulla. There are four major nuclei on each side: Deiter's nucleus, Bechterew's nucleus, the medial vestibular nucleus, and the nucleus of the descending vestibular root. Some investigators believe, also, that some first-order neurons go directly to the cerebellar vermis. The details of distribution of fiber endings from the individual cristae and maculae to the various nuclei are not known, nor is the functional organization of these centers. Lorente de N6 believes that each group of receptors has endings in each of the nuclei. Others conceive of a nucleus for each peripheral functional unit (Spiegel and Sommer; Gray).

A complete description of the neural connections of the vestibular apparatus would be extensive since most of the effectors of the body are influenced by it.* Connections go to the spinal motor centers for movements of head, trunk, and limbs, to the motor centers for movement of eyes, to the flocculonodular lobe of the cerebellum, an organ that is phylogenetically and also embryologically an outgrowth of the vestibular nuclei, to the autonomic centers in medulla, midbrain, and thalamus, and to the cerebral cortex. The connections to the autonomic centers and to the cerebral cortex are probably in part direct, but also indirect, by way of the cerebellum. The evidence for cortical representation is physiological rather than anatomical. Spiegel showed that vestibular stimulation changes the electrical activity of a region of the temporal lobe, near the parietal area, and of a region of the frontal lobe, and that strychninization of the temporal area leads to epileptiform seizures on vestibular stimulation.

ACTION OF THE SEMICIRCULAR CANALS

The canals are the chief receptors for rotational movements, being affected by angular accelerations. There is evidence that they are stimulated also to some degree by position and linear acceleration, and by sound. They may also be stimulated calorically (by irrigating the ear canal with warm or cold water, thereby causing convection currents in the endolymph), electrically, chemically, or by direct mechanical means (pneumatic hammer).

The most striking advance in knowledge of the canals came from direct observation of the ampulla in fish. Steinhausen (1933) and Dohlman (1944), using living pike and cod, observed that the cupula moves with

* For detailed descriptions of the anatomy of these systems see Barré (1937); Van Gehuchten; Leidler; Magnus; Rademaker; and Riley.

movement of the endolymph. By direct manometric measurement Dohلمان (1941) found cupular movement from pressure changes equal to 0.05 millimeter of water (0.00004 gram). Deviations of the cupula were slowly restored (in about 20 seconds) by its own elasticity. By use of models he tried to show (1938b) that motions of the cupula slacken the hair cells on the side toward the bending and stretch those on the other side.

Apparently no one has yet studied end-organ potentials in the ampullae.* On the other hand, action potentials from the vestibular nerve have been recorded. Lowenstein and Sand, using primitive fish (rays), and leading off either from an ampullar nerve by gross electrodes or from teased-out single fibers, found a spontaneous discharge of impulses during the resting state. This discharge increased on rotation in one direction and decreased on opposite rotation. After a constant state of motion was reached, it took 20 to 40 seconds for the nerve activity to return to normal. These facts correlate well with the direct observations of Steinhausen and Dohلمان and show that in fish and frogs the nerve responds to the degree of displacement of the cupula, rather than to the momentary force acting on it. On the other hand, earlier studies on turtles, fish and frogs have given somewhat different results (Mowrer, 1935a; Zotterman; Ross).

There are no directly comparable data on higher animals. However, Adrian took records from the vestibular nuclei of the cat

* The evolutionary development of the cochlea from the vestibular apparatus suggests the desirability of studying the vestibule by the techniques used for the cochlea (thresholds, effects of various frequencies and amplitudes, end-organ potentials, prolonged stimulation, etc.). To some extent this has been done, but not systematically. Guinea pigs have been subjected to prolonged periods (250 hours) of rotation (Jonason, Kyhlstedt, and Nylén), being accelerated for 16 seconds and then decelerated for 16 seconds. Histological examination of the vestibular apparatus, vestibular ganglia, and vestibular nuclei showed degeneration, but the results were inconclusive.

(presumably not from first-order neurons). Acceleration followed by constant movement set up activity lasting up to 25 seconds. With the head at rest there was, in most locations, persistent spontaneous activity. This could be increased by rotation in one direction or suppressed for as long as 30 seconds by opposite rotation. Gernandt, recording from what he believed to be second-order neuron cell bodies in the nerve, got like results. He found units excited by rotation in either direction, others inhibited by rotation in either direction and others affected oppositely by opposite rotations.

How the canals work has been studied in many ways: theoretically, by models, experimentally, and clinically. The chief theories agree that forces act on the canal contents only during *acceleration* of motion (positive or negative). This has been dogma since Mach, Breuer, and Brown simultaneously, but independently, proposed it in 1878 (see Griffith, 1922; Dusser de Barenne). According to the *flow* hypothesis the inertia of the endolymph, acted on by rotary accelerations of the head, causes an endolymph flow that is maximum when the rotation is in the plane of a canal. This hypothesis holds that the cupula is deflected by the force of the stream of endolymph. The *displacement* hypothesis appears to be better supported in view of Steinhausen's and Dohلمان's reports that in the fish the cupula fills the entire lumen of the ampulla so that no streaming can take place. Inertia acting on the endolymph and cupular mass is regarded as causing a shift of fluid and thereby displacement of the cupula. Werner suggested that the canals, being of small diameter — 1.4 millimeter in man (Gray) — offer frictional resistance to endolymph movement and thus damp the response of the system.

Rotation mainly affects that canal whose plane is nearest the plane of rotation. But it also affects more than one canal (possibly all to some extent), even when in unfavorable planes. This is shown by theoretical analysis (Summers, Morgan, and Reimann)

and by electrical recording from single ampullar nerves (Lowenstein and Sand). Furthermore, rotation in planes other than the primary canal planes may be the most effective stimulus. This is shown by experiments in which the plane of rotation is varied about one of the major canal planes. Travis (1938) found that rotation about the vertical axis is best sensed when the head is upright rather than tipped forward to bring the horizontal canals into the plane of rotation (see also Werner).

It is likely that progressive movements (linear accelerations) stimulate the canals. De Kleyn, Magnus, and Versteegh found that reflexes to linear accelerations were present after the otolith membranes had been thrown off by centrifugation, although Hasegawa doubts their data. Such effects might be produced by a greater specific gravity of the cupula than of the endolymph. Ter Braak has calculated that the difference in specific gravity of cupula and endolymph need be only one part in 10,000 to allow movement of the cupula at linear accelerations of $1g$. One may also argue for such stimulation from the fact that proper reflexes are present when the canals are artificially stimulated as if by progressive movements. Bilateral equal caloric stimulation producing opposite stimulation of two canals like that to be expected from forward movements results in a pulsion reflex like that produced by actual forward movement (Fischer, 1928).

Under certain conditions the canals are stimulated by sound, as shown by more than a dozen research papers (Tullio and Canova; Zanzucchi, 1939; Rejtö; Tenaglia). If a hole is drilled in a bony canal, reflexes of the head and eyes proper to the ampulla of the opened canal are produced by sound. The effect occurs over a wide frequency range, but the maximum lies between 400 and 1000 cps. The reflexes are present only for the duration of the stimulus. Such effects have been reported clinically in cases of

fistula. Dohlman (1925) recorded eye movements in man from sound stimulation of a fistula. In the intact human ear very loud sounds (10 to 500 dynes per square centimeter) cause head movement by stimulation of the otoliths (Békésy).

The stimulus thresholds of the canals have been measured in a number of ways and found to be very small. Dohlman measured the pressure necessary to move the cupula of fish, finding a value of 0.00004 gram. The threshold can also be thought of as the smallest rate of change (acceleration) that will cause response, or as the lowest speed of movement that causes response at any given rate of acceleration. Ter Braak showed that ocular compensation was produced in rabbits by angular accelerations of as little as 0.09 degree per second per second. The reaction took place in 100 per cent of trials at 0.23 degree per second per second with an average latency of 2.9 seconds. At an acceleration of 0.5 degree per second per second the latency was 1.1 seconds. Mowrer (1935*b*) found the average acceleration necessary to produce reflex head deviation in the homing pigeon to be 0.8 degree per second per second. The average latency of head movement at this value was 10 seconds. Accelerations of 7.5 degrees per second per second were necessary to reach minimum latency. He found no differences in threshold of a single canal on rotation to right or left (the canal on the other side had been plugged). The thresholds of human subjects for onset of rotation vary with the indicator used and with the method of computation. The threshold as measured by appearance of compensatory eye movements is in all probability lower than that measured by perception of rotation (blindfolded subjects). The lowest values reported for the human threshold are 0.2 degree per second per second (Tumarkin) and 0.5 degree per second per second (Dohlman, 1925; Groen and Jongkees). Allard found an increase of threshold with age in adults.

ACTION OF THE OTOLITH ORGANS

The utricular otolith organs respond to gravity and to linear accelerations. They control static reflexes to position of the head, and dynamic reflexes in response to movements. For experimental purposes they are stimulated by tilting boards, linear accelerators, swings, human centrifuges, and other means.

The evidence for a resting discharge from the utricle is somewhat surer than it is for the ampullae. Electrical records from the nerve of the utricular macula have been made by Lowenstein (1948) with fish, and by Ross with frogs. Adrian recorded from the medulla of cats activity that was presumably set up by utricular stimulation, being gravity controlled. Adrian found a resting activity, the level of which was increased as the head was tilted out of the normal position. The units reacted also to linear accelerations. They maintained these activity levels with only slow adaptation. Lowenstein got the same results from the peripheral units in fish. In addition he found response during rotation at constant speed (presumably due to centrifugal force). Ross' results were concordant with these, but he further believed that there might be two receptors, type I responding when the head was tilted, type II signaling return of the head to the normal position. Magnus showed that the extensor tone of decerebrate rigidity depends on the orientation of the head to gravity; Spiegel found a reduction in postural tone after prolonged exposure of the labyrinth to cold, suggesting the removal of a source of tonic influences.

The way in which the utricle is stimulated is not known. It is of course assumed that the mass of the otolith-laden macula, acted on by gravity or linear acceleration, stimulates the hair cells, but the manner of action is obscure. An interesting lead comes from laboratory studies of motion sickness, which show that wave forces are most effective in

producing nausea when they act along the vertical axis of the head, as when a subject is sitting normally (*Aero med. Ass. Proc.*). Other studies of motion sickness have shown that waves are most effective when their frequencies and accelerations are in the mid-range (Alexander et al., 1947).

The functions of the saccular macula are in doubt. Its anatomical similarity to the utricular macula and its arrangement with respect to the head axes suggest that it shares function with the utricle, just as the canals supplement one another. While there is some evidence for this, the weight of present evidence suggests that the saccular macula is a vibratory receptor or low-tone auditory receptor. In lower vertebrates the functions of this as well as of other structures in the labyrinth (lagena, pars neglecta) and the extent to which they are involved in equilibratory, water pressure, vibration, or sound reception are matters of controversy.

Thresholds of the otolith organs are not satisfactorily known either for tilt or for linear acceleration (Travis and Dodge; Gurnee; Travis, 1944, 1945; Tenaglia). The mode of stimulation in the studies of thresholds was such that muscle or skin stimuli gave cues that probably acted before the threshold of the vestibule was reached. Well-controlled studies are needed.

VESTIBULAR CONTROL OF THE EYES

The reflexes that move our eyes do a marvelous job. When the head rotates from side to side or from front to back, the eyes compensate well enough to keep the appearance of perfect fixation. This eye movement is the result of joint control of the eye muscles by four separate sources: vestibular, visual, neck muscle-receptor, and cortical.

During these active head movements there are two main kinds of eye movements. The one, called by Dodge the coordinate compensatory movement, occurs when the head

is turned while the visual fixation remains the same. It is interesting that the onset of the head rotation and of the compensatory eye movement are simultaneous, showing that the initial phase of the response, at least, is not vestibular in its control, since it starts without latency with respect to head movement (Dodge, 1921). The other type of eye movement occurs when one starts a shift of fixation (and of head position) to a new object. In such an act a saccadic fixa-

wooden block pressed against the lid over the center of the corneal bulge, and so pivoted that it tips from side to side as it remains tangential to the underlying corneal surface.

In a short arc of passive rotation, say 15 or 65 degrees, the eyes show a nystagmoid movement (slow compensatory drift interrupted by fast return movements) during the period of rotation (see Fig. 4). The plane of the eye movements is the same as the plane of rotation. The reflex latency

FIG. 4. Reproduction of a strip of photographic paper, 4 in. wide, showing nystagmoid eye movements during a 2-second horizontal rotation through 65 degrees. Recording by Dodge's method described in text. OR = onset of rotation; CR = approximate cessation of rotation; RI = rotation indicator; HM = record of head movement; LE = record of movement of left eye; RE = right eye; EML = eye-movement latency. Note the alternation of slow and fast phases. The recorder reverses the direction of movement; actually the slow phase is opposite to the rotation. (After Wendt, 1936b.)

tion movement and a head movement in the same direction usually begin simultaneously. The eyes, being quicker, reach their "location" before the head; during completion of the head movement the eyes remain on the object, by means of a coordinate compensatory movement (Mowrer, 1932). Both types of eye movement occur when the lids are closed (Wendt, unpublished).

Eye movements during short arcs of rotation. The canals may be stimulated by placing the subject on a rotating chair (with head fixed so as to avoid tonic neck reflexes). In order to study vestibular response without visual reinforcement or inhibition, vision is excluded. Dodge invented a good method for recording horizontal eye movements through closed lids (see Wendt, 1938; and Wendt and Dodge). A band of light is reflected from a mirror mounted on a small

of the slow phase is 50 to 80 milliseconds (Dodge, 1921). The form of the slow phase, except in minor but significant details, faithfully reflects the form of the rotation (Wendt, 1936b). Figure 5 shows this relation by a plot of the amount of slow phase per unit of time (0.1-second units) along with a plot of the amount of rotation. Quantitatively, the compensation is short of complete adequacy, the total angular degrees of slow drift of the eyes being about 60 per cent of the actual rotation of the chair. The eye movement accelerates a little longer than the acceleration of the chair, the deceleration of eye movement takes place more quickly than that of the chair, and the eyes reverse their direction of drift shortly before the actual end of the movement, showing a slow (3 degrees of arc per second) drift after rotation. All this is

with eyes closed, so only the vestibule is acting.

The saccadic movements (fast phases) in this nystagmus are variable in both timing and size. The first saccadic commonly occurs about one-third second after onset of the slow phase; subsequent ones are separated by $\frac{1}{10}$ to $\frac{1}{2}$ second. Their usual extent is about 5 degrees, but it varies from as little as a few minutes of arc to perhaps 20 degrees. From one to thirteen fast phases

onset to stop) and observing the post-rotation nystagmus. Or we may accelerate the chair at a subthreshold rate (0.5 degree per second per second is slow enough) to a desired rate, and then stop it. Buys (1924) has shown that the sequence of response after a single acceleratory stimulus is in all ways the same as after a single deceleratory stimulus.

Most of the textbooks in psychology and physiology give incorrect descriptions of such

FIG. 5. Slow phase of nystagmus during 65-degree rotation. This graph shows the slow phase of eye movements (EM) plotted on the same time-amount coordinates as the rotation (Rot); HM = head movement. The graph was constructed by averaging, from a number of photographic records like that in Fig. 4, the amount of slow phase in each $\frac{1}{10}$ -second interval and then summing these averages. (After Wendt, 1936b.)

occur in each record for a 65-degree rotation lasting 2 seconds.

When visual reinforcement is added to the vestibular effect (one eye seeing objects about the rotating chair), the adequacy of the slow phase is increased from 60 per cent (with eyes closed) to 80 per cent (with eyes open). With visual inhibition (one eye seeing a fixation field that rotates with the chair), the ocular compensation is reduced to 5 per cent.

Single acceleratory stimuli. The sequence of eye movements after a single acceleratory stimulus looks very different from that during short movements where the chair accelerates and then decelerates. Such a stimulus is produced by bringing the chair to a desired speed (usually 180 degrees per second) and then holding it at that speed until the response has run its course. It can also be obtained by stopping a rotation (after waiting for all action started by its

rotation nystagmus. The true sequence of events (after acceleration to 180 degrees per second) is a series of movements lasting several minutes. These consist of a primary nystagmus followed by a long-lasting secondary nystagmus in the opposite direction. The onset of rotation initiates a nystagmus whose slow phase increases in speed for slightly longer than the duration of acceleration and then shows a gradual decrement lasting for 25 to 50 seconds in different subjects (usually about 35 seconds). This is the primary rotation nystagmus (or post-rotation nystagmus) of the textbook descriptions. But this is only part of the story. As the drift of the eyes slows to zero velocity, they immediately (with no detectable pause) begin to drift in the opposite direction and produce an *inverse nystagmus* (or *secondary nystagmus*). The speed of the inverse grows over a period of roughly 80 seconds until its slow phase is at the rate of about 5 degrees

per second. It then shows a gradual decrement over a period of about 3 to 10 minutes, until the eyes return to their pre-stimulus state (which is usually a slow drift). The time of cessation of the original nystagmus, the time of maximum speed of the inverse, and the duration of the inverse show large variations among individuals. The same individual, on the other hand, shows a remarkable constancy in the dura-

The finer details of this sequence of events are in need of careful metrical study in relation to the amounts of power expended on the ear. Of the numerous studies of the primary nystagmus, only that of Buys (1924) shows an approach to technical adequacy. He reported that the duration of this nystagmus showed "little change" over the range of power levels involved in acceleration to velocities of 18 to 360 degrees per

FIG. 6. Primary and secondary nystagmus. The record reads from left to right. A vigorous primary nystagmus begins with the acceleratory stimulus. After 26 seconds this reverses and a secondary nystagmus occurs. The wavy white line is breathing; the bottom line shows amplitude of pulse in the finger.

tion of the primary nystagmus (i.e. time to reversal of nystagmus) so long as stimuli are properly spaced and the subject is kept alert. Figure 6 shows a sample record of this sequence of events for the 2-minute period following a single acceleratory stimulus to a rotation speed of 180 degrees per second.*

* The general nature of this response has been known since the studies by Buys (1924). The failure of our texts to mention it is because the literature is confusing to the nonspecialist who writes texts. There are six complicating circumstances. First, in much research visual reinforcement or inhibition of nystagmus was not prevented and its importance was not understood. Second, many investigations have been conducted by the standard method of Bárány, ten rotations performed in 20 seconds, thus having an acceleratory and deceleratory stimulus close together, a method that complicates the response to each stimulus by the presence of the other. Third, direct visual observation of eye movements has often been used, which is totally inadequate to show fine detail. Fourth, interference due to habituation has not been controlled. Fifth, some-

times investigators, confronted by peculiarities of response that did not fit the textbook statements, have apparently been blind to their existence or unwilling to comment on them. And, sixth, unjustified inferences have been made from the subjects' reports of sensations of rotation to the (inferred) presence or absence of eye movements. Although a strong nystagmus is usually accompanied by a corresponding sensation of rotation, slow nystagmus may be accompanied by no sensation or by sensations that do not correspond.

Since the time of Buys' paper a number of other investigators have studied the characteristics of the secondary nystagmus (Pilossian; Woletz; and others), but none with methods as good as those of the original study. Fischer and Wodak (Fischer, 1928) reported that changes of head position during the early part of the pri-

mary nystagmus may be accompanied by no sensation or by sensations that do not correspond.

times duration of acceleration; i.e. the "output" in terms of velocity of the eyes is a function of the "input" in terms of power expended on the ear.

M. H. Fischer (1928), who has been most active in the study and discussion of the secondary phases, believes that the sequence of events following a single stimulus is quite protracted, consisting of a continued rhythmical alternation of opposite phases lasting up to 1 hour, each succeeding phase growing progressively briefer and weaker. This belief is based on finding such alternations in subjective reports of the sensation of rotation. Other investigators have not confirmed this finding (Dodge, 1923*a*; Buys, 1924; Pilossian). My own eye-movement records show satisfactory evidence for only a single inverse phase. In those subjects showing a spontaneous drift of the eyes there may be a pseudo third phase when the spontaneous drift is reestablished at the end of the secondary nystagmus.

The fast phase of nystagmus is in general inversely related to the speed of the slow phase in both frequency and extent. However, the saccadics show great irregularity in both magnitude and temporal separation. In a weak nystagmus there are typically

many post-rotational phase changed the plane of the response, but there was no change when the head was moved during the secondary or late in the primary phase. One wonders whether the effect of the movement depends merely on intensity of response.

The discovery of an inverse phase of nystagmus was apparently made independently by Dodge in America, by Fischer and Wodak in Germany, and by Bárány in Sweden. The reports of the first two were based on an inverse phase in the sensations following acceleration. The inverse is apparently also found following the original nystagmus induced by caloric stimulation (Fischer and Oldberg). Dohlman (1925), who studied calorically induced nystagmus with a recording mirror attached directly to the eye, published records showing reversals but made no mention of them in the text. Studies of the so-called "oculogyral illusion," the apparent movement of a very faint light in a darkened room, have verified the fact that secondary phases occur as a result of rotation about planes other than the horizontal (Andreas, Brown, and Wendt, unpublished).

also some forward fixation movements, i.e. saccadics in the same direction as the slow phase. In these respects the primary and secondary nystagmus do not differ.

Visual reinforcement or inhibition greatly changes the sequence of response to single stimuli. In a subject rotated with eyes open and in the presence of good fixation objects, a visually induced nystagmus lasts throughout the rotation, whatever its duration, the visual response being dominant over the weak opposing secondary nystagmus of vestibular origin. The post-rotation nystagmus, since it is opposed by still fixation objects, is less vigorous than with eyes closed. It is shortened and has no noticeable secondary phase. When a subject is producing a vestibular nystagmus in the dark, and visual inhibition is suddenly introduced by lighting up a fixation field, the inhibition takes about 1½ seconds to develop fully when the nystagmus is weak. On removal of the fixation by ending the illumination, the vestibular nystagmus is reestablished within ¾ second. The inhibition acts the same on the primary and on the secondary nystagmus (Andreas, Brown, and Wendt, unpublished).

Dodge (1923*a*) studied conflicting visual and vestibular control of the eyes by rotating vertical stripes about the subject to induce a visuo-ocular reflex nystagmus in one direction while actual bodily rotation at low velocities induced a vestibulo-ocular nystagmus in the opposite direction. When both stimuli started together, the vestibular deviation was the first to appear after its usual brief latency, to be overcome about ¼ second later by a visually induced slow phase in the opposite direction. When vision of the stripes was then cut off, the vestibular response came back immediately. With increased velocities of body rotation, a value was reached where the two stimuli were approximately balanced. Control then shifted alternately from one to the other, each response being weak.

Deceleration preceded by an acceleration. In the common clinical rotation tests (Bárány method), the patient is rotated ten times at a rate of 180 degrees per second, i.e. ten turns in 20 seconds, and then suddenly stopped. Only the post-rotation nystagmus is observed. Here the nystagmus sequence resulting from the start has not run its course by the time the stop occurs. The observed post-rotation nystagmus is therefore the algebraic sum of the response to the start and the response to the stopping. When the time between starting and stopping is systematically varied, this interaction is clearly seen (Buys, 1924; Fischer, 1928). The limiting case is the normal head movement of everyday life, where the deceleratory stimulus follows immediately after the acceleratory. The second stimulus then almost completely cancels the effects of the first.

Rotation about other axes. The plane of the vestibular compensatory eye movement is the same as the plane of the head turning, whether horizontal, vertical, or oblique. If the subject is lying down, so that the axis of rotation passes from the front to the back of the head, a rotary nystagmus develops (Majewsky). Limited observations suggest that secondary nystagmus occurs in each case (Fischer, 1928; Andreas, Brown, and Wendt, unpublished).

Tilt, position, and rectilinear movement. When the head and body are tilted very slowly so as to avoid canal stimulation and stimulation of neck muscle receptors, tonic compensatory eye deviations occur. These are present in man in response to a variety of positions of the head. Fischer (1930) showed that lateral tilt produced a positional "counter-rolling" of the eyes such that 60 degrees of tilt produced 5 to 12 degrees of rotation about the line of regard. But such tonic reflexes are far more readily observed in lower mammals and especially in reptiles and fish, where the positional reflex is large and maintained (Hasegawa, 1940; Dusser de Barenne). Fischer and Veits made limited

observations on an elevator, using a visual after-image to indicate ocular deviation during linear acceleration. Only small deviations (estimated at $1\frac{1}{2}$ degrees) were found.

Eye Movements Due to Other than "Adequate" Stimuli

The adequate stimuli for the vestibule are head movements. One may stimulate these receptors experimentally by caloric, mechanical, electrical, or chemical means. No account will be made here of experiments on chemical stimuli.

Caloric stimulation. The caloric method confines stimulation largely to the cupula of a single canal. Irrigation of the external auditory canal with water either warmer or colder than the canal wall (cold water is usually used) produces a heat exchange that is readily transmitted to the vestibule. The heating or cooling of the endolymph causes an upward or downward movement of the fluid which deflects the cupula.

Dohlman's excellent investigation (1925) showed that the temperature change first reaches the horizontal canal. If this canal is oriented vertically, the caloric stimulus produces a horizontal nystagmus. The maximum speed of the slow phase is linearly related to temperature difference and this maximum occurs at about 1 minute after onset of irrigation. The duration is variable among individuals, but of the order of 3 minutes. There is a secondary nystagmus after caloric stimulation (Fischer and Oldberg).

The temperature change also reaches the other canals (at a greater latency) and, if they are vertically oriented, produces a corresponding nystagmus.

Mechanical stimulation. If the bony wall of the vestibule is eroded by infection, it may become perforated with a permanent fistula. Such an ear was used by Dohlman (1925) to show that rapidly alternating pneumatic pressures compressing the canal wall were reflected exactly in corresponding

oscillatory deviations of the eyes. Rates of alternation up to 100 per second were reflected in eye movement.

The "pneumatic hammer" method was also used by Ewald in experiments with pigeons to find the effects of fluid displacement in the canals.

Electrical stimulation. There is a large but confusing literature on the effects of "galvanic" stimulation (see review in Spiegel and Sommer). Little of an analytical nature with sharply localized stimulation has been reported. Usually electrodes are placed over the mastoids or in the saline-filled ear canals, and current is passed through the head. It appears to be demonstrated that the main locus of stimulation is the first-order neurons.

On passage of a direct current through the head there is a vigorous nystagmus of brief latency (10 milliseconds, according to Dohlman, 1925) with the slow phase toward the anode. This subsides to a moderate nystagmus within about 2 seconds to continue for the remaining time of current passage. If the current is passed for 2 to 3 minutes, a post-galvanic nystagmus is found, lasting about a minute (Caussé, 1928). Fischer and Wodak (Fischer, 1928) found a sequence of alternating phases in the subjective phenomena. Alternating current passed through the head yields no response, yet alternating current applied directly to the canal receptors produces strong ocular deviation limited to the period of stimulation (Rossi, 1936).

Vestibular "imbalance." Usually some slow conjugate drift of the eyes is present when highly magnified records of horizontal eye movements are obtained from the stationary subject with vision excluded. No systematic study of this has been made, but observations incident to other experiments (Wendt, 1936*b*) show that its rate and direction differ among individuals and even in the same individual on different days. Related data may be found in a large literature concerning clinical phenomena variously

called spontaneous nystagmus, readiness for nystagmus, vestibular disharmony, and directional preponderance of nystagmus (Alfandary, 1938; Arslan, 1938; Barbey and Morsier; Barré, 1942; Fitzgerald and Hallpike).

Effects of bodily conditions. Only a few of the many studies of the effects of disease and of drugs have value for our present purpose, since such studies are usually made to understand the disease or the drug rather than the vestibular apparatus. Bartels (1910) said that narcosis affects the fast phase of ocular nystagmus before the slow phase. This needs to be checked by experiments with oscillation through small arcs where one can get the slow phase continuously. Angyal and Blackman (1941) found that alcohol increased caloric nystagmus in normal man. Since their subjects had some vision of the surrounds, this effect might be due to a lessened visual interference. (I have found that alcohol slows visual nystagmus.) In the study of Angyal and Blackman, excess CO₂ depressed nystagmus, and low CO₂ increased it. In each case the effects were opposite in schizophrenic patients—the patients without drug show lessened response to stimulation (Claude, Baruk, and Aubry; Angyal and Sherman). Intravenous injection of certain morphine derivatives produces in man a spontaneous vertical nystagmus, with slow phase up (Zum Gottesberge and Sellerbeck). Bulbocapnine, given to the dog (Delmas-Marsalet, 1937), leaves ocular nystagmus unaffected but completely blocks other vestibular reflexes. (For the effects of other drugs, see Camis and Creed.)

VESTIBULAR CONTROL OF NECK MUSCLES

The head shows nystagmus and compensation, much as do the eyes. In many animals, especially among the long-necked reptiles and birds, the head (rather than the eyes) does most of the compensating. Pigeons,

for example, show a compensatory head nystagmus during rotation, with slow and fast components. This nystagmus, after single acceleratory stimuli, has a secondary inverse phase (Buys, 1924). In the laboratory, human subjects show little head movement during rotation. Figure 4 demonstrates, however, that at the onset of a strong stimulus there is a small amount of active head compensation with latency like that of the eyes.

Tonic labyrinthine reflexes on the muscles of the neck from changes in orientation to gravity are easily demonstrated in lower mammals, birds, and reptiles. The head turns so as to keep its normal relation to gravity (see reviews by Dusser de Barenne and by Camis and Creed). Magnus and his collaborators have studied the righting reflexes by which an animal, placed in an abnormal posture, reflexly returns to the normal position. These responses are not easy to get in the normal human adult in the laboratory, but they are present in the infant (Landau) and may be assumed to operate in the adult as one of the controls of his normal motor activity.

VESTIBULAR CONTROL OF TRUNK AND LIMBS

The vestibular apparatus is the second most important source of stimuli for postural tonus and body posture. Only the muscle receptors take precedence. Normally the vestibule acts in conjunction with other sources of stimulation, and it is not always easy to separate vestibular effects from other factors.

Effects of rotation. Dusser de Barenne hung a frog by a thread through the praemaxilla and let it rotate, meanwhile watching limb movements. The pattern is complicated, but it involves extension of the trailing limb during the acceleration, and flexion of the leading limb.* Similar re-

sponses have been studied in rabbits and in monkeys (Dusser de Barenne).

Fischer and Wodak and others (Fischer, 1928; see review by Lange) have shown the general nature of the body response in human subjects. Suppose we rotate a subject to the right for a while and stop him (the terminal stimulus is then an acceleration acting from right to left). The subject is asked to stand with arms outstretched and to offer no voluntary resistance. The head then turns to the right (compensatory deviation), as do the trunk and arms, the left arm rises while the right is lowered, and there is a tendency for the left leg to extend, the right to flex. The resulting position has been described as that of a discus thrower.

Effects of rectilinear movement. Progressive movements cause responses of the limbs and the trunk muscles. Magnus and de Kleyn (see Magnus) and Bard (1937) have investigated the "vestibular placing reactions." If an animal (e.g. cat) is suddenly lowered, the legs extend and the toes spread. If raised, the legs flex slightly. Fischer (1928) has studied the same thing in human beings stimulated by an elevator. This response is presumably a resultant of stimuli from vestibule and musculature.

Studies of animal righting during a drop from the inverted position show a complex series of responses involving the trunk and limbs — and also the neck and eyes (Rademacher and Ter Braak; Warkentin and Carmichael). These are illustrated (Fig. 7) in the tracings from successive frames of a motion picture of the fall of a young rabbit.

Phenomena probably related to response to progressive movements are found in the pulsion reflexes affecting the limbs (the standing subject makes forward or backward compensatory movements) as a result

by an ingenious preparation in which the head can be rotated while the body is fixed for recording. They remove a section of the frog between head and lower body but retain the connection by the spinal cord.

* Brazilian investigators (Ozorio de Almeida, Moussatché, and Vianna Dias) have verified this

of bilateral calorization of the ear canals (Fischer, 1928). These are best elicited when the head is about 60 degrees back (or 180 degrees from this position); they are

merous studies of geotropic responses in animals are also relevant.

The position of the head affects the extensor tone of the limbs. In the normal standing position of the cat, for example, tone is balanced. Raising the head increases extensor tone of the forelimbs and decreases that of the hind limbs; lowering the head

FIG. 7. Tracings of successive frames of a motion picture (64 frames per second) of a 20-day-old rabbit dropped while upside-down. (From Warkentin and Carmichael.)

absent in the midpositions. Therefore they may be assumed to come from simultaneous stimulation of the two horizontal canals.

Effects of head position. The most important students of the labyrinthine positional reflexes are de Kleyn and Magnus (see Magnus), who systematically studied the contribution of these responses to the righting reflexes of mammals. The nu-

FIG. 8. Influence of head position on extensor tone of forelimbs. Lowering the muzzle reflexly decreases the tone of the forelimbs; raising it extends the forelimbs. In this case reflexes from the neck muscle cooperate with reflexes from the vestibule, causing this change. (From Camis after Magnus.)

decreases the tone in the forelegs. Figure 8 shows this for a normal cat. The positions of maximal effect are 90 degrees away from the normal head position. The nature of the

response varies with species. When an animal lies on its side, the down-limbs are extended, the up-limbs flexed (Bieber and Fulton). Similar labyrinthine positional reflexes are seen in human infants and adults lacking cortical motor function (Fischer, 1928; Fulton). They presumably contribute to normal posture, but their demonstration in the normal adult in the laboratory is far from satisfactory.

Tonus. The tonic effects of the labyrinths may also be inferred from experiments showing a slight loss of extensor tone after removal of both inner ears (see McNally and Tait for review). Damage to the vestibular nuclei causes a further severe loss of tone, showing that the continuous activity of these centers is involved. The peripheral source of the tonic impulses may be from spontaneous "canal tonus," otoliths, or both (Cawthorne, Fitzgerald, and Hallpike). A decrease in oxygen consumption after labyrinthectomy may be due to loss of tonus (Ciurlo).

VESTIBULAR CONTROL OF OTHER SYSTEMS

Autonomic effectors. The data in this field* are exceptionally difficult to interpret, as compared to the simpler striped muscle effects. There are various reasons: (1) The recording methods used do not ordinarily permit adequate temporal analysis of the response. (2) The reflexes of the autonomic system are interdependent in complicated ways, having many "feedback" mechanisms. (3) Sequential or simultaneous reaction at a number of neural levels produces effects that may facilitate or inhibit one another. Arguments rage, especially over the role of "psychic" factors. In short, there is no single correct description of these behavior systems; they vary greatly with the conditions of the experiment.

* For general reviews of the autonomic effects of vestibular stimulation see Camis and Creed; Fischer, 1928; Arslan, 1939; Tenaglia; and Spiegel, 1946.

Emotional consequences of vestibular stimulation. There is an extensive literature about the emotional effects of vestibular stimulation, especially of "loss of support" (Carmichael; Armstrong; Buys, 1937; Chavany; Griffith, 1920b, c; Majer; Wendt, 1948; Schilder, 1939). The interests of investigators have included the emotional repertory of infants, the role of the body-image in ego development, and the role of anxiety in motion sickness. Stability of orientation is generally regarded as necessary to feelings of security, and vestibular disturbances or vestibular stimulation lead to feelings of insecurity, anxiety, fear, or panic.

Motion Sickness

World War II stimulated a large volume of research on motion sickness.† Motion sickness occurs, not as an immediate effect of motion, but only after stimulation has lasted for a time. Some have concluded therefore that motion sickness is not a reflex response to motion but rather a secondary result of anxiety produced by motion, or of other psychic factors (Armstrong; Green). That it is solely such a secondary phenomenon seems disproved, however, by Bard's observations that cortical lesions or even decerebration do not affect susceptibility in the dog, and that cerebellar removal prevents vomiting (Bard, personal communication).

Nature of the response. In cats and dogs the onset of sickness is shown by profuse watery salivation, urination, or anxiety behavior. As sickness progresses, the saliva becomes viscous and defecation occurs. Finally there is chop licking, retching, and vomiting. Spiegel (1944) concludes that the gastrointestinal events begin with relaxation of the fundus of the stomach, cessation of contractions, closure of the pylorus, and reverse peristalsis of the duodenum. In vomiting, the pyloric region also contracts, the cardia and esophagus relax, the glottis is

† A review of this work by Bard and Tyler is to be published in *Physiol. Rev.* See also McEachern and Lehman.

closed, with inhibition of breathing. Strong contraction of the striped musculature of the diaphragm and abdominal muscles expels the stomach contents, and other appropriate postures are part of the pattern.

In man the pattern is the same, except that urination and defecation are rare. There is local "cold sweating," distributed differently from thermal sweating (Hemingway). These events in man are usually (but not always) accompanied by unpleasant feelings of depression, by subjective muscular weakness, and by sensations of malaise referable to mouth, abdomen, and head. When the sickness is due to rotation, there may be dizziness. In exceptional cases the discomfort may last for 3 days after the motion has ceased. It is believed that in some people this whole pattern does not occur but that there is only headache.

Pregnant cats that aborted their fetuses after motion showed no signs of motion sickness, yet were harmfully affected by motion. Perhaps we can conclude that the nausea pattern is not the only "sickness" possible from motion (Cramer and Wendt, unpublished).

Factors producing sickness. The vestibule is primarily involved in the production of motion sickness, as is shown by the fact that those deaf people who show no vestibular sensitivity do not get sick (McNally and Stuart). Rotation causes sickness when the acceleration and deceleration are separated in time (Alexander et al., 1945a), as in automobiles on mountain roads or in acrobatic flying, but not when movement phases are short, as in normal head movements. On the rotating chair, nausea is rare so long as the head is fixed (Fischer, 1928; and personal observation), but rotation in several planes favors sickness. Repeated rectilinear accelerations acting along the vertical axis of the head, as for the seated passenger in an airplane in rough air or on a heaving ship, are the most common cause of sickness. Experiments with other motions and other head positions indicate that there can

be little effect of the lateral motion due to the roll of ships (*Aero med. Ass. Proc.*). Waves of moderate frequency and acceleration cause sickness quicker than either very gentle or very rough waves (Alexander et al., 1947). A 7-foot wave of 22 cycles per minute produced sickness in 53 per cent of a group of naval officers within 20 minutes. Yet the head rotations of everyday life and the rough movements of walking and running do not make one sick. The mechanism by which certain waves produce sickness is not yet known.

Common experience shows that other stimuli facilitate or inhibit motion sickness. Moving visual objects or visual disorientation (Witkin), unpleasant odors, and uncomfortable warmth probably facilitate sickness, whereas an interesting task, pleasant odors and comfortable temperature inhibit it. Pilots and drivers, for reasons unknown, rarely become sick; passengers often do.

Psychic factors play a variable role, depending on the person and the situation. The identifiable factors are expectation of sickness, influence of suggestion from others, conditioning by past sickness to the stimuli associated with motion, the protective effects of habituation, effects of concurrent activity, emotional state (anxiety, etc.), conscious or unrecognized desire to become sick, and neurotic patterns of adjustment (Wendt, 1948). These factors probably operate maximally for airsickness, owing to the novelty of air travel, and least for sickness due to the more accepted modes of transportation.

Susceptibility is greatest in childhood, decreasing during adolescence and adulthood, and it is greater in women than in men. At the present time susceptibility is most frequent to airplanes, then to boats, automobiles, streetcars, and trains, in that order. About 20 per cent of college students have never been motion sick, and about 5 per cent suffer often enough to consider it a handicap. It is possible that motion sickness is associated with extreme neuroticism and with migraine, but for the general popula-

tion it appears to be unrelated to neurotic tendency. Personality correlates of susceptibility other than neuroticism are not, however, excluded. Previous history of motion sickness and frequency of vomiting in other situations are prognostic (Alexander et al., 1945*b*; Wendt, 1946*a, b*; Birren, Fisher, and Stormont).

Prevention. About three-fourths of motion sickness is preventable. When sickness is psychologically influenced, as in a first airplane trip, psychological procedures may help greatly. Habituation helps, but its effects may be temporary if the person has a history of motion sickness. Its effects are probably lasting when the person habituates without allowing sickness ever to occur (Van de Water and Wendt). The laboratory experiments on direction of forces suggest that placing the head so that forces act at right angles to the vertical axis, e.g. by reclining, would prevent sickness. Certain drugs are effective. Hyoscine hydrobromide, a belladonna derivative, 0.6 milligram by mouth, reduces average sickness rates by 60 per cent when given to all passengers 2 hours before motion (Tyler, 1946). An anti-histaminic drug, trade-named Dramamine, seems to have not only a fairly good preventive action but also a curative action (Gay and Carliner). How these drugs prevent sickness is not known. By finding how they do it, we may find how motion sickness is brought about.

PERCEPTION OF MOVEMENT AND POSITION VIA THE VESTIBULE

Is there a vestibular sense? Unlike the other senses discussed in this volume, few of the data on the vestibule come from the study of sensations. There is, in fact, no agreement that there are *unique* sensory qualities from rotation, rectilinear motion, or position. There are several reasons for this: (1) We are not sure whether there is

a cortical vestibular projection area. (2) It is introspectively hard to distinguish possible vestibular from kinesthetic sensations, especially when reflexes of the trunk and limbs and autonomic systems complicate the experience, or to separate them from vision, when the eyes are open. (3) We lack words in our language to distinguish phenomenal motion from the physical event. (4) This, plus the sheer intellectual difficulty involved in thinking about a set of data where the sensations often have little relation to what is being done to the subject, makes for confusion. These difficulties prevent our knowing whether there is a vestibular sense modality. Griffith (1922), who denied its existence, stated:

We have found the experience of dizziness or vertigo to be made up of a large number of processes the most prominent of which are (1) kinesthesia from the eyes, neck and in the arms, (2) pressure from the region of the abdominal viscera, the chest and head, and (3) certain vascular processes which supply an obscure background and which give to the whole experience a characteristic shading.

Despite this alternative possibility, it is my tentative opinion that there are unique vestibular sensations from rotation, movement, and position. Spiegel's data on a possible cortical projection area suggest it. And the experience of rotation near threshold, the experience of sinking slowly while under water, and the awareness of the direction of gravity while under water do not appear in my own introspection as kinesthetic. Although, to be sure, there is no proof that the rotational experience is not of extra-ocular muscle origin (since there is nystagmus), such an explanation fits less well the experiences of straight-line movement or position.

A point against the notion of a special vestibular sense is that the experiences of rotation, movement, and position are introspectively similar when the visual field is rotated or moved (as when the train on the

next track moves) or given a tilt (as in the tilted-room experiment), or when a sound is rotated about the head (the sound is heard as stationary, cf. Dodge). Since these sensations of body movement or position do not require the vestibule, it is concluded that there need be no vestibular sense. But seen motion is a similar experience whether the moving object is fixated (and thus "seen" to move via the kinesthetic sense) or allowed to move across the visual field (and thus seen to move via changing visual pattern). Arguing from these facts alone we might as well claim that, since the experience of motion requires no kinesthesia (or vision), kinesthesia (or vision) does not exist. Experiments could perhaps be devised to shed light on this question. What, for instance, are the introspections of a subject with complete anesthetization of all extraocular muscles, or of a subject after loss of both eyes?

At any rate, if there are unique vestibular qualities, we may speculate that their major attributes are sensations of rotation, rectilinear movement, and position. Presumably the first two vary also in direction, intensity, and complexity. Holt (1910) found that the common element in rotational experiences at threshold was only a "feeling" of rotation, also described as a "swimming sensation." As speed of movement rises, the experience becomes more complex (Griffith, 1920c). The subject may then call it "dizziness," a term he may also use when visual objects appear to rotate about him. "Vertigo," a complex of sensations with autonomic components and an unpleasant feeling tone, is another term used. This experience is not confined to the results of vestibular stimulation (Witkin). The several sensory qualities aroused by bodily rotation and by the responses to it are introspectively difficult or impossible to tell apart. These difficulties have also been recognized in the problems of space perception and of

the body-image* (Göthlin; Marburg; Schilder, 1942).

Sensations of rotation when vision is allowed. For a subject on a rotating chair with eyes open, the course of events is quite different from that for a subject with closed eyes. When the subject turns at 180 degrees per second and then stops, the sensations are as follows: First he feels that he is turning, the room being fixed. Or he may feel as though he and the room are both rotating within some outer fixed space. After a time this may be replaced by the feeling that he is still while the room whirls around him. On stopping, the subject seems to spin and the room with him. This may be replaced by movement of the room alone. Finally everything seems to come to rest, but he still feels vague sensations, as though he were not back to normal.

When the rotation is done in a dark room with a faint fixation light mounted on the chair, the sensations are the same after acceleration as after deceleration. First, both self and light rotate, then light alone rotates as for full vision. The movement of such a faint light is called "oculogyral movement" (Graybiel et al.). In this case, however, there may be a brief pause at the end of the primary phase of movement of the light, followed by a secondary inverse phase. It seems, then, that a faint light does not inhibit the secondary nystagmus as does full vision.

Instead of a fixation light, one can use an after-image of a strong light as the object whose movement is reported. Its movement is in the same direction as that of the slow phase of nystagmus, being opposite to that produced when the image of an actual light

*The literature of "vestibular sensations" is chiefly old, written before adequate recording techniques for analysis of the response systems were devised. Darwin (1801), Purkinje (1820), Crum Brown (1878), Mach (1878), Holt (1910), and Griffith (1920b, c) may be consulted (see Griffith, 1922). More recent work has been done by Travis, and by Fischer and his collaborators (Fischer, 1928). For reviews, see Griffith (1922); Leiri; Fischer (1928).

moves across the retina. In oculo-ocular movement, the light, although moving constantly, does not seem to change its position, whereas with an after-image the light does change position and returns during the saccadic phase.

DAMAGE TO THE VESTIBULE

The effects of damage to parts of the vestibule, of unilateral or bilateral removal in various animals, and of peripheral disease and removal in man have been studied by many experimental and clinical investigators. The phenomena following such damage are very complex but in some ways most instructive. For reviews, see Dusser de Barenne; Camis and Creed; McNally and Stuart; and others noted below.

Otolith organs. Separate surgical damage to the otolith organs can be done in frogs and some fish, but it is hard or impossible in warm-blooded forms. The heavy otolith membrane may be torn loose (in both low and high forms) by "centrifuging" the animal (Maxwell; Dusser de Barenne; Camis and Creed; McNally and Stuart; Hasegawa, 1935). Extirpation of the sacculus is apparently without effect on the labyrinthine compensatory reflexes, but this has not settled the problem of whether it has vestibular functions. Utricular function may be studied by destroying all the canals. In frogs, posture is then nearly normal, righting reflexes are present but slow, and the animal jumps, but somewhat clumsily. If the utricles are taken out, leaving the canals, the righting reflexes are also present and the animals are able to jump, but must be prodded to do so. After the centrifuging off of the otolith membranes of guinea pigs or frogs, tonic labyrinthine reflexes remain (Dusser de Barenne). It seems, then, that reflexes to position and linear acceleration come from both otoliths and canals.

Canals. The experiments using a pneumatic hammer, those on rotation after plugging single canals, and those on electrical

recording from the nerve show the contribution to function of each canal. These studies are supplemented by those in which all canals except one are destroyed, or one ear is destroyed and the animal is rotated in different planes. Results are ambiguous, for both lower and higher forms, as to whether each canal is unidirectional, bidirectional, or multidirectional in response to rotation in various planes (Maxwell; Lowenstein, 1937; Camis and Creed; Cawthorne, Fitzgerald, and Hallpike; Sand). It is probable that the horizontal canal is bidirectional but that it causes stronger reflexes on rotation toward its own side. The responses of this canal to rotation in opposed directions need not be of the same nature. The mechanism of the effect of rotation away from the side of the canal may be by suppression of a tonic discharge, whereas opposite rotation may truly stimulate. The vertical canals are less understood but may tentatively be assumed to work like the horizontal canal.

The experiments on injury to single parts of the labyrinth show that the remaining parts, although somewhat impaired or changed, usually support all the reflex responses. This forces us to give up the view that each part alone has a special function and to recognize the functional duplication of parts.

Labyrinthectomy. Animal experiments on the removal of a whole labyrinth (or the cutting of an VIIIth nerve) are more revealing than studies of man. Human cases of loss of the receptor are available as a result of inherited defect, labyrinthine infection (labyrinthitis), Ménière's disease, or surgery.*

* A brief statement on the reasons for surgical interference with the human labyrinth is in order, since a large literature exists in this field. This is done for relief of Ménière's syndrome, which may be treated by intracranial cutting of the nerve, by cutting only its vestibular division, by surgical labyrinthectomy, or by alcohol injection into the labyrinth. Ménière's "disease" has been ascribed to many causes. The best present evidence is that it is due to distention of the labyrinth from an

The immediate effects of bilateral labyrinthectomy or VIIIth nerve section vary with phylogenetic status (Maxwell; Camis and Creed). They are quite striking in the pigeon, which shows violent movements and is unable to hold itself upright. After several days some recovery occurs, probably through use of kinesthetic and visual senses to control the movements. The pigeon stands and walks unsteadily and holds up its head except while asleep. It does not fly or feed itself again. The immediate and late effects in mammals are much less striking, decreasing in the higher forms (Dow, 1938; Ferraro and Barrera). There is unsteadiness in standing, tremor of the head, and impaired running, jumping, etc., especially when the eyes are covered.

Deaf people often lack vestibular response. About 20 per cent lack all response, and about another 65 per cent have varying degrees of vestibular deficit (Tenaglia and Scevola; Vastine). They have poor equilibrium, but not poor enough to handicap them noticeably. There is a correlation between extent of hearing loss and of vestibular deficit.

The immediate effects of the loss of one ear also become less as we ascend the phylogenetic scale (Magnus; Dandy and Kunkel; Dow, 1938; Camis and Creed; Ferraro and

Barrera). In the monkey, in the earliest postoperative period, there may be much disturbance when movements are tried. The animal then lies on its side with the remaining labyrinth up, with the head bent away from the good labyrinth and turned toward it. The eyes show a continuous nystagmus (mainly horizontal) with the slow phase away from the good ear. In man the postural effects are usually inhibited (perhaps because the patient is relaxed in bed), but there is nystagmus.

These immediate effects decrease with time in all forms, owing to the development of a central compensation and to increasing dominance of other senses. In animals below mammals postural defects are permanent. Dow (1938) found that in the rhesus monkey nystagmus lasted for a day, then became occasional, and was not seen on the third day. Recovery, at least from the postural defects, was faster in baboons and chimpanzees (see also Northington and Barrera; Ferraro and Barrera). Observations of man conform to this picture (Cawthorne, Fitzgerald, and Hallpike). There is at first a strong spontaneous nystagmus. At this time the nystagmus is strengthened by rotation toward the remaining ear; it is slowed by weak opposite rotation or reversed in direction by stronger stimuli. This spontaneous nystagmus soon comes under the control of vision, but when the eyes are closed it persists in decreasing amount for at least several weeks (Wendt, unpublished). Shaking the head from side to side reestablishes the nystagmus for a time. Even after many years, rotation toward the good ear produces excessive response (Fischer, 1928; Cawthorne, Fitzgerald, and Hallpike). It has been noted that the loss of function in a diseased ear may be so slow that compensation keeps pace with the loss, with the result that no symptoms are noticed by the patient (Fernando and de Ocampo).

Effects of a second labyrinthectomy after compensation for the first. Phenomena of

overproduction of endolymph. This has been ascribed to allergy, histamine sensitivity, disorders of adrenals, thyroids, or gonads, autonomic imbalance, dietary deficiencies, lack of vitamin B complex, etc. The afflicted patient has occasional sudden violent vestibular "storms" of unilateral peripheral origin (although the disease process is bilateral; cf. Cawthorne, Fitzgerald, and Hallpike), in which usually he falls, has extreme vertigo, and is severely nauseated (Cawthorne; Cawthorne, Fitzgerald, and Hallpike; Crowe). "The overwhelming vertigo, the awful sickness and the turbulent eye movements—all enhanced by the slightest movement of the head—combine to form a picture of helpless misery that has few parallels in the whole field of injury and disease" (Cawthorne, p. 271). In response to the pleas of wretched patients, surgeons have removed the offending source, even though the opposite ear may later become affected. For review of the literature see Altman and Fowler; Brunner, 1959; Grove; McLaurin; Simonton.

the greatest theoretical importance occur when, after one ear is removed and partial or complete compensation is allowed to occur, the second ear is then removed. In this behavior system there is a good chance to study the neural mechanisms underlying the recovery of function. Bechterew in 1883 cut out one labyrinth from the dog. This operation caused a nystagmus that decreased and in time disappeared. Removal of the second ear (producing an animal with no afferent input from the vestibules) was then followed again by a prolonged nystagmus, opposite in direction to the original. This, too, disappeared within a few days. Bechterew's nystagmus, as it has since been called, has been studied in a number of animal forms (Carréga, Appaix, and Paillas; Dow, 1938; Gatteschi; MacKenzie; Pike). The only reasonable explanation for these eye movements is that the original compensation was due to some change in activity of the nerve centers that counterbalanced the effects of the input from the remaining vestibule. On removal of the second ear this central compensation is left unbalanced, producing a nystagmus.

The central compensation that causes Bechterew's nystagmus is seen in animals after removal of the cortex or the cerebellum (Cawthorne, Fitzgerald, and Hallpike; Ross and Olsen). This, plus the fact that one-sided injury to the vestibular nuclei can cause a nystagmus for which compensation never develops, leads to the hypothesis that the nuclei are the site of the compensation. There are, however, two aspects of this recovery process. One is central compensation for the unbalanced activity of the remaining vestibule. The other is the learning process by means of which visual, kinesthetic, and other stimuli gain dominance over the vestibular reflexes and come to substitute for them. The latter process has apparently not been studied, but it is certainly different from the compensatory process accounting for Bechterew's nystagmus.

Damage to the Central Parts of the Vestibular System *

The vestibular responses are mostly low-level reflexes. One gets nystagmus with both slow and fast phases in the absence of all brain except the vestibular nuclei and ocular motor centers. In an anencephalic child lacking cerebrum, cerebellum, and all except the posterior brain stem, containing the abducens nucleus, and having only abducens muscles, de Kleyn and Schenk recorded a nystagmus contraction pattern. Conversely, damage to the midbrain and medulla produces defects in the righting reflexes and leads to permanent abnormalities of posture and to nystagmus (Buchanan; Falkenberg; Ferraro and Barrera; Lurie and Dempsey; Magnus; Nylén; Rademaker; Seiferth; and reviews). Decortication, decerebration, and decerebellation, or decerebration plus decerebellation leave nystagmus normal and do not change the essential pattern of postural reflexes from the vestibule (Buchanan, 1939; Dow, 1942; Dusser de Barenne; Halstead, Yacorzynski, and Fearing; Yacorzynski, Halstead, and Fearing). The effects of visual stimuli upon the vestibular systems are lessened or lost after decortication or decerebration, and all these procedures reduce habituation to rotation. More limited lesions in the frontal lobes cause changes in the postural effects of the vestibule and lengthen after-nystagmus (Austregesilo and Borges Fortes; Delmas-Marsalet, 1936; Jayle; Kennard and Ectors). Temporal lobe lesions that include the supposed labyrinthine projection area cause a spontaneous nystagmus

* This review will be brief. The reader should consult reviews for details concerning this field. See especially Barré, 1937a, 1938; Dusser de Barenne; Van Gehuchten; Leidler; Magnus; Rademaker; Riley. For reviews and data on the vestibular effects of tumors, concussions, gunshot wounds, and such diseases as Parkinsonism, encephalitis, syringomyelia, and multiple sclerosis, see Barré, 1938; Leidler; Alexander and Scholl; Falkenberg, 1942; Nylén; Brunner, 1936a, b; Delmas-Marsalet, 1936; Fitzgerald and Hallpike; Frazier and Rowe; Gibbs; Jayle; Kolodny; Moruzzi; Müller; Seiferth.

and increase the after-nystagmus (Barré, 1937*b*; Fitzgerald and Hallpike; Kolodny). Such increased after-nystagmus may be due to a reduction in the inhibitory action of vision. Cortical lesions do not prevent formation of conditioned responses to angular acceleration (Oppenheimer and Spiegel).

Search for the mechanism of the fast phase of vestibular nystagmus has been actively pursued, but without complete success. The alternations of direction of eye movement in nystagmus have been attributed to rhythmically alternating peripheral vestibular discharge, but this is most unlikely. The response is not caused by proprioceptive stimulation from the antagonistic eye muscles, as is shown by the following facts (de Kleyn and Schenk; McIntyre; Kollner and Hoffman; de Maré; McCouch and Adler; Dohlman, 1925). (1) A single muscle, the others cut away, shows alternating slow and fast phases. (2) Stretching a muscle produces no stretch reflex and is without any effect on nystagmus. (3) Local anesthetic applied to the efferent and afferent fibers of a muscle, presumed to affect sensory fibers first, has no effect on nystagmus until the motor fibers are affected. The notion that the fast phase is from the cortex was based on the alleged observation that only the slow phase is present under general anesthesia and in coma (Alfandary, 1937; Dohlman, 1938*b*). This observation may be questioned on the ground that the eye deviation is probably not the slow phase. It must first be shown that the slow deviation observed is actually conjugate and is quantitatively related to the stimulus. The present tendency is to localize the centers responsible for the fast phase in Deiter's nucleus and in the reticulate substance (Dohlman, 1938*b*; Spiegel and Price). Lorente de Nó (1939) has proposed a mechanism by which these centers could produce such an alternating response. It seems more reasonable, however, to expect to find this mechanism associated with the ocular muscle nuclei. It is difficult to believe that the slow phases of

both visual and vestibular nystagmus come from the vestibular nuclei, because of the way they interact under conflict. And, if the visual slow phase does not use these nuclei, then the fast phase would be unlikely to come from them. On the other hand, the many functional likenesses between the fast phase of visual and vestibular nystagmus suggest that they have a common source. It seems reasonable to place this at the natural point of convergence of the systems.

Theory of balanced centers. Högyes in 1881 (Sugár, p. 134) suggested that the vestibular centers operate as though in a balance. One may think of the nuclei on each side as being in continuous, partly self-maintained activity. (Tonic impulses from the vestibule may contribute to it.) So long as this activity is equal (i.e. "balanced"), tonus distribution is normal and the eyes do not move. Stimulation raises or depresses the activity of one side of the system (thereby producing reflex change), and the balance is only gradually restored. The evidence for such a theory rests on the presence of circular circuits, on the studies of Bechterew's nystagmus and of compensation after unilateral labyrinthectomy, and on the nystagmus produced by unilateral lesions of the nuclei (Lorente de Nó, 1933; Cawthorne, Fitzgerald, and Hallpike).

MODIFIABILITY OF THE VESTIBULAR SYSTEMS

The vestibular systems are in some ways highly modifiable; in others not at all.

That the postural reflexes are greatly affected by learning is shown by their absence in adults, except as a substrate for coordination, and by the fact that effects due to the loss of one ear are soon overcome. Nystagmus comes under learned control by the use of vision, especially in dancers and acrobats. Voluntary control is possible to some extent by near-fixation or by looking in the direction of the slow phase (Griffith, 1920).

The compensation after loss of an ear may rest on the same mechanism as the "disembarkation syndrome" after a sea trip or other prolonged motion. Others have given anecdotal accounts of this syndrome (Larroudé) and I shall add my own to these. One summer, after 9 days in the most forward cabin of a light cruiser, I felt decreasing effects for 6 days after landing. My bed felt as though I were still at sea, and I was quite unsteady in walking. After the first 2 days I experienced these effects only on waking and for a short time after rising.

Learning experiments in the laboratory have been directed at two phases of the effects of repetition of stimuli, conditioning and habituation. These effects may proceed collaterally, but they are different in nature.

Conditioned responses. Vestibular stimuli have been used both as conditioned stimuli and as unconditioned stimuli. Spiegel and Oppenheimer, using dogs, found that responses based on electric shock to the leg could be conditioned to a rotation stimulus, linear movement, or to a particular position in space. Differentiation and other phenomena were shown. Wendt (1936*b*) used rotation through short arcs as the unconditioned stimulus (human subjects) with sound as the conditioned stimulus. Apparently the slow phase of the response cannot be conditioned. The fast phase, on the other hand, is conditioned, in the sense that anticipatory responses to sound appear before the rotation. There is a "regularization" of timing of saccadics during the rotation, and there is a learned inhibition of saccadics coinciding with the end of rotation. Löwenbach and Gantt used sound as the conditioned stimulus and a galvanic vestibular stimulus as the unconditioned stimulus with dogs, recording the postural adjustments. The characteristic body movements were conditioned.

Habituation. For a time following World War I few subjects could so arouse American psychologists as the question whether there was habituation to rotation (Dunlap, 1919). Disagreements had arisen with Medical Corps

otologists, who denied that the Bárány tests of nystagmus used in airplane pilot selection showed reduction on repetition. We can now see that both groups could have been right. Under certain circumstances there is a reduction in the duration of nystagmus (and of all other consequences of stimulation, including sensory and autonomic). In fact, the typical course of events on repetition of stimulation is habituation of all parts to the response (see reviews by Harris; Mowrer, 1934*b*; McNally and Stuart). Under other circumstances the character of ocular nystagmus, at least, may remain wholly unchanged. My own rotation nystagmus, for example, is still normal after 20 years of using myself as subject. Careful investigators such as Dohlman and Buys have obviously obtained repeated records of nystagmus that did not suffer from habituation.

The resolution of this contradiction has not previously been successful. I believe, however, that the reasons for it are clear in the evidence. There are two factors in habituation, two kinds, in fact, which may be present separately or together. The one shows up especially in the usual method of observing after-nystagmus with the subject's eyes open. In this case visual stimuli tend to inhibit the vestibular nystagmus, and with repetition these stimuli become increasingly dominant. Such habituation is probably not preventable. The other shows up even with the eyes closed. In this case loss of nystagmus occurs when the subject fails to remain alert to his external surroundings. This habituation is preventable by keeping the subject attentive to the external surroundings and avoiding inward-directed reverie states.

I shall describe the character of this second kind of habituation from my own experiments on human subjects and on monkeys (1936*a*). Highly magnified records of eye movements to rotation, taken simultaneously from both eyes (through closed lids), show that "habituation" occurs as a competition between the vestibular reflex and an-

other system of control of the eyes. This system consists of an autogenous wandering of the eyes in a nonconjugate manner such as has been described in states of sleep, unconsciousness or coma. The reflex and this system compete for control in an almost either-or fashion. There are usually sharp, bilaterally simultaneous transitions from reflex to wandering movement and from wandering movement to reflex. Figure 9 shows such periods of interruption of nystagmus, bracketed for ease of identification. The first appearance of these periods of nonconjugate movement, during a series of rotations, is usually in that portion of a response when nystagmus is weak, as at the end of the primary phase of nystagmus. With continued stimulation it encroaches further, or it may appear several times during the course of a prolonged nystagmus. The records resemble, in abruptness of the rivalry, those taken when strong visual rivalry is introduced and withdrawn, except that the onset of the wandering movement is sharper. These autogenous movements are apparently like those under general anesthesia, in coma, and in normal sleep (Alfandary) and are identical with those present in animals when immobilized, i.e. so-called "animal hypnosis" (Wendt, 1936a).

Not all subjects can avoid such habituation. Usually, however, it can be done. When monkeys are used as subjects, any strange sound (clicking the fingernails, watch tick), blowing lightly against the face, or bringing a piece of banana to the nose will restore nystagmus immediately. Closing the monkey's nostrils with the fingers is a sure way to do it. With human subjects, properly instructed and stimulated, alertness can be maintained for continuous 10-minute periods of recording. The trick is to maintain an environment-directed orientation.

Conversely, factors that favor an inward orientation of attention — such as firm body support, darkness, quiet, regularity, and monotony — favor autogenous movement (Griffith, 1920a, b; Mowrer, 1934a, b;

Dorcus; Wendt, 1936a). Sleeping infants are said to show no nystagmus (see McNally and Stuart). It is also suggestive that catatonic schizophrenics have reduced nystagmus times. The correlation of vestibular response with personality traits relevant to internali-

FIG. 9. "Habituation" to 65-degree rotation. Four photographic records of human nystagmus showing periods of interruption (bracketted) by an intruding eye-movement system (habituation). In the lowest record there is a brief return of nystagmus (at the point where a fast phase occurs). Note in this record also that the eyes drift in a nonconjugate way both before and after the rotation.

zation of reference has been made by Buck (1936) and is currently under investigation by Syz and by Witkin and Wapner.

The neural origin of this competing control of eye movements is probably different from that of the slow phase of nystagmus. Were they the same, there could presumably be no sharp alternations between wandering movement and reflex within a single nystagmus sequence. On the other hand, habituation occurs after decerebration and decerebellation. A number of facts suggest like-

nesses between the wandering movement and the saccadic movement. Perhaps their nerve mechanisms are related.

Dodge (1923*a*) introduced a disturbing confusion when he stated that habituation is due to loss of the saccadic phase, so that only ocular deviation occurs. This has been repeatedly quoted as fact. This conception confuses two processes, the one a resystematization of the vestibular response, which is an active conditioning process, the other the intrusion of the autogenous wandering due to habituation. The former effect is on the spacing of the fast phases in the vestibular reflex. They become regularized and may either drop out (during oscillating rotation with an alert subject) or become more frequent (with longer turns with a subject in revery). The other effect is due to the dominance of the other system of control, the autogenous wandering. This frequently produces a deviated eye position that looks as though a slow phase had produced it. But the movement toward this position is not the slow phase of the reflex, as Dodge supposed; it is a nonconjugate movement bearing little direct relation to the stimulus. Both processes, resystematization of the nystagmus and competition for dominance by the autogenous movement, may proceed concurrently.

With vision allowed, there is little loss of nystagmus during rotation, but great reduction of the after-nystagmus with repetition. Dodge (1923*a*) ascribed the latter to the increased dominance of the visual stimulus; nystagmus is replaced by visual still-fixation (cf. Mowrer, 1934*b*). However, I have seen (especially in monkeys) the eventual appearance of autogenous wandering of the eyes even when they were open. Most human subjects presumably find the visual surrounds of sufficient interest to hold an environmentally focused body localization. Hence, habituation in human subjects with open eyes is usually due to increased visual dominance, whereas in monkeys both types of habituation may occur.

Much effort has gone into the study of habituation as a learning process. In "well-controlled" experiments, where no instructions about attention are given to the subject and extraneous stimuli that might keep the subject alert are intentionally avoided, habituation, as indicated by lessened duration of after-nystagmus, is at first rapid and then proceeds more slowly. It is favored by spaced repetition and shows some transfer from one type of stimulus to another (Dodge, 1923*a*; Dorcus; Dunlap, 1925; Fearing; Griffith, 1920*a, b, c*; King; Maxwell and Pilz; Mowrer, 1934*b*).

If one adopts the views here presented on the nature of habituation to rotation, most of the quarrels between the psychologists and other groups can probably be resolved. I suspect that many of the latter have used attention-directing devices, thereby avoiding the autogenous eye wandering. When such wandering has occurred, the fact has probably been overlooked. One of Dohlman's published records, for example, appears to show the wandering (Dohlman, 1925, plate I, record 466 at 140 seconds).

REFERENCES

Time Perception

HERBERT WOODROW

University of Illinois

The data that have been accumulated in the illusive field of time perception show two outstanding characteristics. One is the conflicting nature of the findings of different experimenters; the other is the mentalistic nature of the data. There have been, however, a few studies of physiological influences on judgments of time and of the behavior of animals with respect to temporal stimuli.

The Comparison and Reproduction of Times

Temporal stimuli are ordinarily one of two sorts: (1) what are called empty intervals, for example, two flashes of light or two short sounds, separated by a period of time; and (2) sounds or lights lasting continuously over a period of time. Behavior with respect to these stimuli has been extensively studied by methods that have usually required judgments of the relative length of two empty intervals or of two continuous stimuli presented for comparison, or the reproduction of an interval by taps upon a reaction key. From data on the comparison of the relative lengths of intervals may be calculated such things as differential thresholds and time-order errors; from the data obtained by the method of reproduction may be calculated the mean error, often termed the constant error, and some measure of the variability of the reproductions about their mean.

The accuracy of discrimination of intervals and durations. Among the few questions concerning temporal perception to which fairly definite answers can be given are those

concerning the accuracy of discrimination as measured by the differential threshold. Dependable data have been obtained for three types of temporal stimuli: (1) empty intervals, bounded by sound clicks, (2) continuous tones, and (3) continuous lights. In general, the just noticeable difference is smallest at some relatively short magnitude or range of magnitudes and increases both above and below this middle region.

A thorough investigation of the comparison of empty intervals was made by Blakely (1933). His intervals were bounded by the clicks produced by the impacts of an electromagnetic hammer, with a pause of 1.5 seconds between the first and second interval of each compared pair. From data obtained by the method of constant stimuli, with the standard given second as often as first (so as to eliminate the effect of the time-order errors), he calculated relative just noticeable differences (jnd's). He found discrimination to be most accurate at intervals of 0.6 and 0.8 second. At these lengths the relative jnd (taken as the difference giving 75-per cent correct judgments) was slightly less than 8 per cent of the standard. With shorter standards and also with longer ones the relative jnd was slightly greater, but throughout the range extending from 0.2 to 1.5 seconds, inclusive, it was less than 10 per cent. With longer intervals, 2.0 seconds and 4.0 seconds, the relative differential threshold rose to approximately 16 per cent. With still longer intervals ranging from 6 to

30 seconds, the indications were that the variable would need to differ from the standard by from 20 to 30 per cent to yield 75-per-cent correct judgments. It is obvious from these data that Weber's law does not hold for the range extending from 0.2 to 30.0 seconds. Naturally there are marked individual differences in accuracy of discrimination. Values for the relative differential threshold of a particular subject have been found, with intervals less than 2 seconds, to vary from 1 per cent (Fröbes, 1923, p. 384) to over 20 per cent (Blakely, 1933).

For continuous tones or lights the accuracy of discrimination is almost the same as for empty intervals bounded by clicks. In the case of continuous tones, Stott (1933), using fifteen college students as subjects, obtained the following values for the average relative jnd: approximately 10 to 12.5 per cent, with standards varying from 0.4 to 2.0 seconds; a somewhat larger value for a standard of only 0.2 second; and a considerably larger one for durations varying from 4 to 30 seconds. Accuracy of discrimination of the durations of continuous lights seems to be approximately the same as for continuous tones, with more or less representative values of the relative jnd lying in the range from 7 to 14 per cent for durations varying from 2.0 to 8.0 seconds (Quasebarth, 1924).

Related to the accuracy of discrimination is the accuracy of reproduction. As in the case of discrimination, accuracy is greater for very short intervals than for those of 4.0 seconds or longer. The greatest accuracy for both discrimination and reproduction lies within the range extending from 0.2 to 2.0 seconds. When the same empty interval is presented repeatedly and reproduced at each presentation, the standard deviation of the reproductions is typically, for the most favorable intervals, about 8 per cent of the standard, but it increases to twice this magnitude for intervals of 4 to 30 seconds (Woodrow, 1930).

The indifference interval. No phenomenon connected with short times has been the object of so many investigations as has the indifference interval. Vierordt (1868) first stated as a law that short intervals are overestimated and long ones are underestimated. This statement carries the implication that some intermediate length is neither overestimated nor underestimated. This intermediate length is the indifference interval.

Overestimation, underestimation, and indifference interval are terms that need careful definition. They all refer to values calculated from the results of procedures that require either a comparison of two time intervals presented in succession or the reproduction of an interval presented once. Accordingly we may speak of a comparison indifference interval, and of a reproduction indifference interval. The comparison indifference interval may best be defined as that length of the variable at which the percentage of judgments *meaning* that the variable seems longer than the standard remains the same irrespective of the order in which the variable and the standard are presented. If the frequency of judgments meaning variable longer is plotted separately for the two orders, variable first and variable second, the indifference interval is the length of the variable at which the two curves intersect (see Fig. 1).

By time-order error is meant the effect due to the temporal order of presentation of the standard and the variable. If the frequency of judgments meaning that the variable seems longer is greater when the variable comes first, the time-order error is called positive; if greater when the variable comes second, the time-order error is labeled negative. What is meant by the terms overestimation and underestimation, when applied to the comparison of intervals, is peculiar and misleading and is based on the false assumption that the sole error is in the estimation of the standard. Thus, when the time-order error is positive, the error is called one of overestimation (of the stand-

ard); and when the time-order error is negative, the error is called one of underestimation (of the standard). As a matter of fact the errors are in the outcome of the comparison: there is no separate estimate of either the standard or the variable.

Time-order errors in the method of reproduction do not have quite the same meaning as in the method of comparison. When the

FIG. 1. Graph showing time-order errors. Both curves show the percentage of judgments meaning variable longer. The curve showing this percentage when the variable is first is marked V_1 , and the one showing this percentage when the variable is second is marked V_2 . When the V_1 curve is higher than the V_2 curve, the time-order error is positive. The interval at which the curves intersect is the indifference interval. (Data from Blakely, 1933.)

average length of the reproduction is equal to the stimulus interval, that interval is called the indifference interval; when the reproductions average longer than the stimulus interval, the time-order error is labeled positive, and the standard is said to be overestimated; and, when the reproductions are shorter than the standard, the time-order error is called negative and the standard is regarded as underestimated. As in the method of comparison, the terms overestimation and underestimation are misleading. In neither method does the subject estimate the length of the standard: in one he compares two lengths, and in the other he reproduces a given length.

Over a score of investigators have sought to determine the indifference interval, but

seldom have two investigators found the same value. Perhaps indifference intervals of 0.5 to 0.7 second have been reported more frequently than others, but the range extends from under 0.36 to 5.0 seconds (Woodrow, 1934). Sometimes no indifference interval has been found; sometimes several. Early investigators claimed to find periodic indifference lengths but disagreed on the length of the period. Rather exceptionally, a few investigators, contrary to Vierordt's law, have reported negative time-order errors (underestimation) for intervals shorter than the indifference interval and positive time-order errors (overestimation) for longer intervals. One study, made with relatively large groups of subjects, found a considerable percentage of subjects making positive time-order errors (by the method of reproduction) for all lengths of stimulus intervals from 0.3 to 4.0 seconds (Woodrow, 1934). It follows that, even under fixed experimental conditions, there is no single indifference interval valid for all subjects. A few investigations have been extensive enough to afford an estimate of the average indifference interval for a group of subjects. One study (method of reproduction of empty intervals bounded by short sounds) indicated a mean indifference interval of approximately 0.6 second (Woodrow, 1934); another (method of constant stimuli with empty intervals) indicated a mean indifference interval of approximately 0.7 second (Blakely, 1933); and a third (method of constant stimuli with continuous tonal durations) showed an indifference interval of approximately 0.9 second (Stott, 1935).

Early theorists attempted to identify the indifference interval with the duration of some physiological event, such as the duration of the swing of the leg in walking or the time between two pulse beats. The time per word in talking could also have been suggested. Others have attempted to connect the indifference interval with the duration of an alleged wave of attention, or, quite different, the time required to adjust the

attention for the most effective apprehension of a stimulus. On the whole, the full explanation of any indifference interval is still uncertain. Something is known, however, concerning factors that affect the indifference interval; and these factors are of considerable significance for the light they throw upon the processes involved in the temporal comparative judgment. The most important of these influences may be classified under two headings: (1) aspects of the temporal stimuli presented the subject, and (2) the ways in which subjects make comparisons.

The effect of characteristics of the stimuli. The first class of factors affecting judgments and reproductions of temporal intervals and durations may be termed objective or environmental as distinguished from the attitudinal or subjective conditions. Temporal perceptions are reactions to stimuli. Whether the stimuli are continuous or are those bounding empty intervals, they may vary in intensity or quality and, in the case of cutaneous and light stimuli, in area. When two temporal stimuli are presented for comparison, the pause between them, though ordinarily about 1.5 seconds, may be of any desired length, as may also the preparatory interval between the ready signal and the beginning of the first temporal stimulus. Very decided effects upon the comparison of empty intervals are produced by variation in the length of the bounding stimuli and by inequality in their length. For example, two empty intervals, one of which is 0.5 second and the other 0.66 second, may be judged equal, if the 0.5-second interval is bounded by a long initial sound and a short terminal one and the 0.66-second interval is bounded by the same sounds but with the position of the initial and terminal sounds reversed (Woodrow, 1928).

In addition to the objective characteristics attaching to individual comparison pairs, one must consider the whole series of such pairs presented at a single sitting, and even during the entire course of an experiment, extending perhaps over a good many days.

The total range of times used is extremely important because of a tendency to become adapted to an interval repeatedly presented. As a consequence of adaptation to times of one length, judgments at other lengths may be altered. Practice alone may cause a pronounced change in the magnitude of the time-order errors or a reversal in their direction. In the course of a long experiment the indifference interval tends to move towards the average length of the intervals constituting the total series. In one study, for example, 110 subjects were given 120 comparisons of empty intervals with a standard of 1.0 second and variables of 0.8, 0.9, 1.0, 1.1, and 1.2 seconds. The pooled data (see Fig. 2) show that if the indifference interval were calculated from the first 60 trials it would fall below 0.8 second (estimated by extrapolation). During the last 60 trials, however, the responses were what might be expected if the variables were being compared with a standard of about 0.94 second. With practice the indifference interval moved towards the average length of all the intervals presented during the entire sitting, namely 1.0 second.

The effect of attitude. By attitude is here meant not a fixed state but rather the manner in which a subject goes about his task. Information on this matter is available only through introspective reports. It is amazing what variety these reports indicate in the internal activities of a subject when he has been asked simply to tell which of two short temporal stimuli is the longer.

Sometimes the reports suggest a division of subjects into two classes. One class consists of those for whom the two compared intervals form a single pattern, perceived as a whole and described as a whole. Within the total pattern, different subjects may introduce differences in accent, producing differences in rhythm or phrasing. Benussi (1913) has emphasized the effect of this subjective phrasing on the outcome of the judgment in the comparison of empty intervals, particularly when the two intervals are

marked off by three short stimuli, the second of which both ends the first interval and begins the second one. A second class of subjects seems to pay attention to the first temporal interval as a separate phenomenon and then in some manner to start reproducing the first as the second begins. The first may be reproduced by the subject through his initiation of a kinesthetic experience of strain or some other process, either sensory or imaginal. The final comparative

ently originate in almost any part of the body. Frequently mentioned are sensations of strain from the arms or hands, from the muscles involved in breathing, and from the vocal organs, the latter being sometimes accompanied by auditory imagery.

Little confidence can be placed in the relation between these impressionistically described attitudes and the errors of comparison supposed to depend upon them, unless the relation is established by the method of

FIG. 2. Graph showing change in the indifference interval with practice. (Data from Woodrow, 1935.)

judgment, then, refers to two simultaneous experiences, one instigated by the subject's own effort to reproduce the first, and the other by the second of the temporal stimuli (see Kastenholz, 1922).

Another classification distinguishes between objective and subjective attitudes (Hülser, 1924, p. 367). In the objective attitude attention is centered upon characteristics of the stimulus, e.g. in the case of two continuous light stimuli, upon area, color, and brightness; in the subjective attitude the subject intentionally abstracts from, or ignores, the objective stimulus and concentrates upon the experience of duration. This subjective attitude may be reported either as a passive waiting or as one of attention to strain. The strain may be described as a feeling, as strain of attention, as strain of expectation, or as a group of kinesthetic sensations. The sensations of strain may appar-

differential instruction. This method consists in instructing or training the subjects in different attitudes, and then having them carry out series of comparisons under those attitudes. Quasebarth (1924, p. 407), by this method, was able to change the direction of the errors made by her subjects. They were first instructed to distinguish between an attitude of passive listening and one of maximal, active attention. Subjects who gave maximal attention to the second of two tones overestimated its duration, whereas subjects who listened passively to the second tone underestimated its duration. Another investigator (Woodrow, 1933) has reported marked effects on the direction of the time-order errors and therefore upon the indifference interval as a result of changing instructions given subjects who, by taps on a key, reproduced empty intervals bounded by instantaneous sounds. The

subjects were, in one case, asked to pay attention only to the sounds, to listen to the interval as a pair of sounds, and then, in another set of instructions, to attend to the interval between the sounds as a duration. In the first case the reproductions were much shorter than in the second. For example, in reproducing the interval 4.0 seconds, with attention directed primarily to the bounding sounds, the average error was one of underestimation of the stimulus interval by 0.46 second, whereas, with attention to strain, it changed to one of overestimation by 0.26 second.

Introspective Reports Concerning Single Temporal Experiences

The studies considered in the preceding section have dealt with behavior with respect to two time intervals, one of which is compared with the other or constitutes a reproduction of the other. A second class of data consists of introspective descriptions of experiences of single temporal stimuli. These descriptions, particularly in the case of longer times, may take the form of estimates of duration in terms of seconds or other physical units. They refer ordinarily not to duration as such, which seems scarcely to be describable, but to such things as the following: the absolute impression, as regards length, pleasantness, or other attributes; the characteristics of the stimuli used to present times to the subjects; fading images of these stimuli; feelings of strain, expectation, and surprise; and awareness of breathing, counting to one's self, and a variety of kinesthetic and organic sensations.

The absolute impression. It has generally been supposed that different lengths of time give rise to qualitatively different experiences: adequate, pleasant, long, short, etc. The terms long and short, in spite of their obvious connotation of relativity, are here intended in an absolute, qualitative sense. To what lengths of time they apply has been a subject of particular study. The length at which the judgments change from

short to long is termed the absolute judgment indifference interval. It is not necessarily identical with either a comparison or a reproduction indifference interval.

Almost any time, apparently, may be judged either short or long, depending upon the length of preceding temporal stimuli. Benussi (1907), for example, found that, when subjects were presented a series of intervals ranging from 0.09 to 2.7 seconds, the change from judgments of short to judgments of long occurred at three widely different lengths, depending upon whether the series was presented in an ascending order, in a descending order, or in a mixed order. The ascending order gave an indifference interval of about 0.23 second; the descending order, one of 1.17 seconds; and the mixed order, one between 0.58 and 0.72 second. Other ranges of intervals would undoubtedly have produced still other indifference intervals. Thus Abe (1935), using a range of intervals extending from 0.3 to 10.0 seconds, found indifference intervals scattered over a range of 0.75 to 3.4 seconds. These results indicate that the terms short and long probably always carry the implication of a comparison with a standard, though the subject may be unaware of the fact. This standard is largely a function of recent temporal experiences, or of a composite trace left by them. It is worthy of note, however, that the absolute indifference interval is seldom reported as equal to the mean length of the series of times presented the subject for his judgments. It tends to be much closer to 0.6 second. There is no conclusive evidence, then, to rule out the possibility that the "standard" for the absolute judgment of long and short may be a relatively stable one, corresponding to an absolute judgment indifference interval.

The thresholds of unitary duration. If one listens to the ticks of a clock, he may notice that he is aware of several clicks at once. It may be asked, therefore, how many ticks before the last one, or how many successive ticks, can be heard simultaneously.

More generally the problem may be stated as that of the physical time over which stimuli may be spread and yet all be perceived as present. This time has sometimes been termed the temporal span of attention. The question may be better phrased, perhaps, as that of the maximal physical time over which may extend a temporal stimulus pattern, the successive parts of which are perceived as a whole, possessing a unitary property of duration. There is also a minimal time which constitutes the lower duration threshold.

There can be little doubt that the answer to the question here envisaged depends upon the nature of the stimuli that fill the physical time. In any case, however, there are marked individual differences, due in part, perhaps, to ambiguity in the meaning of unity. Unity is by no means an unequivocal term, since unity may be more or less perfect, more or less disjointed, or more or less vague as regards boundaries. Moreover, the answer to this question, like that to any other question of thresholds, should be conceived in statistical terms. There are variations in the probability that a subject will perceive an interval in its entirety, even under fixed external conditions.

Using continuous lights, Quasebarth (1924) concluded that the upper limit of the psychological present, the limit permitting a unitary awareness of duration, is reached when the stimulus has a duration of about 6 seconds. For continuous tones, the duration was about 5 seconds. The introspections indicated that above these limits the light or sound loses its character of being all present at once. On account of the discordant results of several other investigators, however, it is impossible to state definitely the upper limit of the psychological present. The limit probably lies between 2.3 (Kastenholz, 1922, p. 217) and 12.0 seconds (Dietze, 1885), but it is possible that it may under some conditions be considerably higher (Titchener, 1923).

An indirect way of determining the upper limit of the psychological present may be afforded by the study of rhythm. It is possible to determine at how slow a rate certain factors producing rhythmical grouping lose their force. One such factor is a difference in the relative loudness of sounds composing a rhythmical series. For example, if every second sound in a series of equally spaced sounds is louder than the others, and if the rate of sequence of the sounds is moderately slow, the sounds tend to be perceived in trochaic rhythm, that is, in groups of two with the louder sound the first member of the group. However, when the sounds succeed each other at a very slow rate, this segregating effect of loudness may vanish: the subject no longer reports any grouping at all. The rate at which this grouping vanishes has been found to vary from one sound every 3.5 seconds to one sound every 13 seconds (Woodrow, 1909, p. 37). The grouping becomes very feeble and is obtained only with considerable effort at rates slower than one sound every 3.5 seconds. If, now, it is assumed that a rhythmical measure represents a perceptual unity, then these results appear to be in substantial agreement with those obtained by direct introspections on temporal unity.

The preceding discussion pertains to the maximum length of time that may be perceived as a unitary duration. If we ask whether there is also a lower limen, we meet with some complexities. A very short stimulus no doubt gives rise to a unitary experience; but, if it is perceived as momentary or instantaneous, it is usually said to lack the quality of duration. It follows that there exists a lower limen for duration. The values reported for this lower limen have varied with the investigator and with the conditions under which they were determined. For continuous light, Durup and Fessard (1930) obtained duration thresholds varying around 0.12 second, and for continuous sound much lower thresholds, varying from 0.01 to 0.05 second.

Much lower are the limens separating doubleness from singleness. By such a lumen is meant the interval at which successive impressions fuse into a single experience. For essentially instantaneous stimuli, Wundt (1903) gives the following mean values, based on the findings of four investigators: sound, 0.002 to 0.016 second; touch, 0.027 second; and light, 0.043 second. If the stimuli follow each other at longer intervals, they are perceived as separate; if at shorter intervals, they fuse into one. In the case of light this interval is called the critical flicker interval. This critical interval decreases with the intensity of the light. When light alternates with darkness, the critical interval between successive light stimuli may vary from more than 0.200 second to less than 0.025 second (Zoethout, 1947).

The estimation of long times. It is a familiar fact that the seeming length of long periods of time depends largely upon the nature of the experiences by which these periods are occupied. In general, a time filled by pleasant, interesting, well-motivated activities seems shorter than one spent simply in waiting. In retrospect, however, the relations may be reversed. A period of idleness and monotony, as in sickness, may seem short when remembered after recovery. This influence upon temporal estimates exerted by the way time is occupied has been the subject of several experiments. Gulliksen (1927), for instance, found that subjects who were required to estimate the time elapsing between two signals gave much longer estimates when they passed the time doing nothing or performing a task of monotonous nature than when they were engaged in work or forced to endure pain. For example, an interval of 200 seconds was estimated at 242 seconds, on the average, when filled with mere waiting, but as only 169 seconds when devoted to work on problems in long division.

It is probable that in many situations the sense of time is more or less completely absent. It is, indeed, possible that this is

always the case, with both long and short times, unless there exists an intention to make some temporal judgment. Situations especially favorable to an experience that is subjectively timeless are those characterized by intensely absorbing occupations, such as reading an interesting novel, contemplating the beautiful hallucinations produced by some drugs, or battling for one's life. Ferrari (1909) reports such a timeless experience on the part of three brothers who were entombed for 18 days by the earthquake of Messina in a very narrow space, in which the body of their little sister was putrefying. They remembered only certain facts: how they had been buried, how they ate, how they escaped; but they could not say how much time they had spent underground. When asked to do so, they estimated the time as from 4 to 5 days. It seems likely that the basis of such an enormous error lies in conditions, including those prevailing at the time of the estimate, that have not been clearly set forth. The same may be said when a patient, after hashish intoxication, estimates a period of a quarter of an hour as a century (Pick, 1919). Again, further analysis is needed to understand why a given drug, for example, mescaline, sometimes produces enormous overestimation (Fröbes, 1923) and sometimes enormous underestimation (Favilli, 1937).

A number of physiological influences other than intoxicating drugs have been investigated. In one case an influenza patient with fever was asked to estimate a period of 1 minute by counting to herself at the rate of one per second (Hoagland, 1935). The subject completed the count in considerably less than a minute, particularly when the fever was relatively high. This result indicates that what was actually a minute by physical time seemed longer than a minute to the subject—an interpretation in agreement with the subject's report that time seemed to pass very slowly. That the overestimation of physical time in this case may be attributed to the increased bodily temperature,

and perhaps to an increased rate of brain metabolism, is indicated by the fact that a similar result is produced by heightened temperature due to a high-frequency alternating current passed through the body. On the other hand, Gardner (1935) found no significant difference in the temporal reactions of hyper- and hypothyroid subjects. For example, there was no significant difference between two groups, one of which showed a basal metabolism of +25 per cent or more and an average pulse rate of 114 and the other a basal metabolism of -11 per cent or less and an average pulse rate of 80. Schaefer and Gilliland (1938) likewise could find no significant relation between physiological processes and the accuracy of estimation, in terms of seconds, of empty intervals varying in length from 4 to 27 seconds. The physiological processes studied included pulse rate, breathing rate, heart work, lung work, and blood-pressure changes.

The effect of sleep on estimation of time was studied by Boring and Boring (1917), who attempted to ascertain the cues used by subjects in giving the time of night at which they were awakened. Since the subjects knew that the time would not be earlier than 12:15 A.M. nor later than 4:45 A.M., they did not designate times outside these limits. Immediately after estimating the time of night, the subjects wrote down the conscious cues on which their judgment was based. Most frequently mentioned were feelings dependent upon the general bodily state, such as degree of restedness or fatigue and degree of sleepiness. The state of the excretory and digestive functions was less emphasized and appeared to furnish less accurate cues. A secondary cue for some of the subjects was the ease with which they could pick up or remember the topic in mind at retiring. These cues were regarded by the authors as sufficiently definite to obviate the need of assuming an unconscious mechanism of timekeeping, a conclusion that seems very reasonable in view of the large mean error of 50 minutes in the estimated

times. The alleged remarkable accuracy with which some persons can awaken themselves at a time decided upon before going to sleep (Omwake and Lorz, 1933) needs further study, as does the temporal accuracy with which subjects carry out post-hypnotic suggestions. Stalnaker and Richardson (1930) required each of nine subjects, both when in a hypnotic trance and when awake, to indicate the lapse, after a signal, of times varying from 1 to 3 minutes. The subjects showed no greater accuracy when hypnotized than when in the normal state.

Rhythm

By rhythm, in the psychological sense, is meant the perception of a series of stimuli as a series of groups of stimuli. The successive groups are ordinarily of similar pattern and experienced as repetitive. Each group is perceived as a whole and therefore has a length lying within the psychological present.

The nature of the perceived grouping is largely, but not entirely, determined by characteristics of the stimulus series. The most important of these characteristics are the relative intensities of the members of the series, their durations, both absolute and relative, and their temporal spacing. It is possible to measure the degree to which any of these factors promotes rhythmical grouping. For example, with equal temporal spacing, and not too fast a rate, and every second sound louder than the others, the series of sounds tends to be heard in groups of two, with the louder sound beginning the group. If, however, the interval following the softer sound is decreased while that before it is correspondingly increased, a point is reached where grouping occurs with the softer sound first and the louder sound second. In other words, the rhythm changes from trochaic to iambic. At some point in this progressive change in the intervals the probability of a report of trochaic just equals that of a report of iambic. The difference

between the intervals before and after the louder sound at this neutral point may be used as an index of the tendency towards grouping produced by making alternate sounds louder.

In the same way, the group-producing tendencies of quite different stimulus characteristics, such as duration and pitch, may be determined. The effect of a given factor may therefore be expressed in terms of an index consisting of the difference in duration of the intervals between the members of the stimulus series that must exist in order to neutralize the grouping effect exerted by the factor when the temporal spacing of the members of the series is uniform. With such an index it has been determined that the group-beginning tendency of relatively greater intensity on the part of alternate sounds (with equal temporal intervals between the sounds) increases in a negatively accelerated fashion with increase in the difference in intensity between the more intense and the less intense sounds (Woodrow, 1909).

As regards the effect of the relative duration of the stimulus, when intensity and temporal spacing are uniform, if every second sound is longer, the probabilities are in favor of an iambic grouping, i.e. the longer sound is the second member of the group. Ordinarily this longer sound also seems to be more intense (though physically of the same intensity as the shorter one). When every third sound is longer, the series is most likely to be heard as anapestic rhythm, that is to say, in groups of three members with the longer one ending the group. In general, we may say that, with equal temporal spacing, a regularly recurring, relatively greater intensity exerts a group-beginning effect, and a regularly recurring, relatively greater duration a group-ending effect.

Objective characteristics of the stimulus series by no means completely determine the grouping. The stimulus series may induce in the subject a rhythmical series of actions

on his part. The experience of these movements blends or fuses with the experience of the external stimulus series, and largely determines the nature of the perceived grouping. Even imagery of these movements, either auditory or visual, may affect the apparent rhythm. Ordinarily these subjective accompaniments of the external series are involuntary; but they may be set up intentionally. In the absence of strongly rhythmical objective characteristics, the apparent rhythm of a series of stimuli may be arbitrarily changed merely by imagining first one rhythm and then another. It is probable, however, that even where marked objective rhythmical influences are present — for example, when alternate sounds are much louder than the others — subjective factors act in cooperation with the objective to determine the nature of the perceived rhythm.

When the stimulus series is composed of stimuli that are physically identical and uniformly spaced in time, any grouping perceived must, except for the influence of the rate of sequence, be due to subjective factors. Provided the rate at which the series is run off is neither too slow nor too fast, the subject will ordinarily perceive a series of groups, with some member of each group carrying an accent. Rhythm perceived under such conditions is called subjective rhythm, and the accent is termed subjective accent. The number of members grouped together in one rhythmical measure is increased from two to six, or more, with increase in rate. In a subjective grouping by four, with the first member accented, the third member is apt to be given a lesser, secondary accent. A series heard in pronounced waltz rhythm may have a very slight accent on the third member of the group in addition to the principal accent on the first member. In general, however, subjective rhythms show considerable variation in the position of the accented members.

Subjects presented with a uniformly spaced series of clicks, all of equal loudness, may be asked to form groups containing a

specified number of clicks; and for a grouping of each specified number the rate of sequence preferred by the subject may be determined. It is then found that the preferred rate increases with the number of elements grouped into one measure. The preferred rate increases less rapidly, however, than the number of elements grouped. Thus the preferred rate, indicated by the time in seconds between successive clicks, was found by Harrell (1937) to be as follows: twos, 0.63; threes, 0.79; fours, 0.97; fives, 1.14; sixes, 1.29. The grouping by fives is the most difficult.

Various theories have been proposed to account for rhythmical grouping, but they are all seriously lacking in factual support and in the precision with which the explanatory concepts are formulated. Without attempting to explain all the known facts, they endeavor to give some notion of the reason for perceived grouping. These theories usually regard grouping as determined by pulses or waves of attention or by pulses or waves of muscular contraction.

Theories of Time Perception

The duration of which one is aware is sometimes termed protensity, in order to distinguish it from physical duration. According to one view, the amount of protensity depends merely on the physical duration of the experience to which this attribute is attached, somewhat as the apparent extensity of a horizontal line varies with the physical length of the line. Protensity has often been considered an attribute of sensation. Whether this attribute could remain unitary and yet apply to a succession of sensations—for example, two short tones bounding an interval filled with strain sensations—is not altogether clear. Whatever may be the answer to this question, it is clear that protensity is a characteristic immediately given in experience.

A modification of this view holds that all sensations, perhaps all conscious processes, have an attribute of progression, and that

protensity or subjective duration is something that afterwards may or may not be added on, and does not belong to sensation as such (Curtis, 1916). The difficulty with this view is that its proponents have never clearly indicated what is added on, nor the process by which progression is integrated into protensity. The doctrine of protensity, either as an attribute of mental processes or as an integration of progression, has not led to any special theory to explain the comparison of durations. Its advocates appear to assume that the comparison of durations, like the comparison of any other attributes, is simply a matter for the general theory of successive comparison.

In the minds of a number of theorists there exists a special difficulty concerning duration. The difficulty is due to the plausible assumption that the perception of duration can arise only with change. The idea is that, if all change stops, then time stops. It would follow that a fully stable content, one that over a time remained perfectly constant, could not have any apparent duration, except by reference to other, simultaneous, changing events. This logic has been held to be incompatible with the doctrine that the duration of a uniform sensory experience can be perceived directly or immediately. It suggests that time is always judged indirectly by means of some process that serves as a cue. By a temporal cue is meant any process that changes progressively with the lapse of time.

A number of cues have been suggested. One of the earliest theories saw a temporal cue in the stage at which the image had arrived in the process of fading out. Lipps (1883), who first developed this theory, designated the various stages in the fading of the immediate memory image as temporal local signs. According to this theory, when a second momentary sensory impression follows an earlier one, the duration between the two moments is given by the degree to which the first has faded when the second occurs. James (1908) adopted the view of

Lipps, except that he restated it in terms of brain traces. The fainter the trace, he held, the longer would seem the time elapsed since the impression that originated the trace.

A second group of proposed temporal cues consists of processes connected with the activity of attention. As a result of the act of attention various feelings or sensations may be supposed to occur, and to vary with the physical time consumed by whatever is attended to. Some sort of strain, attributed to the process of attention, is the cue most commonly advanced as the basis for judgments of duration. It is held that to appreciate the duration of any interval an act of attention is required, and that this act produces strain, either directly as a central process, or, more plausibly, through the muscular tensions that accompany the direction of attention to an event. It is further supposed that the sense of strain increases with the duration of the attention. Schumann (1893) stressed not only the role of expectant attention but also that of the feeling of surprise when the terminus comes sooner than expected, and that of the feeling of intensified expectation when the terminus is delayed.

Klien (1919) attempted to summarize the whole matter of time perception by classifying the processes of judging times into two types. One of these, which he termed the S-type, refers to the use of the degree of fading of the immediate memory image as the cue for duration. The other, the P-type, refers to the use of a cue consisting of an activity feeling, which he thought of as dependent for its intensity upon an act of attention or will, conceived as a psychoenergetic process of which the subject has direct awareness. The P-mechanism may be used in perceiving any time that is long enough for the development of an activity feeling but not too long to be grasped by a unitary act of attention.

In addition to sensations or feelings of strain, various other cues are undoubtedly used, particularly for times that exceed the

upper threshold of unitary duration. Münsterberg (1889) emphasized the importance of sensations from breathing. Counting to one's self is one of the commonest and most accurate ways of estimating times running into minutes. Still longer times may be estimated in terms of general bodily condition, or in terms of the known time required by the events remembered as having occurred within the period in question.

Time is not a thing that, like an apple, may be perceived. Stimuli and patterns of stimuli occupy physical time; and we react to such stimuli by perceptions, judgments, comparisons, estimates, etc. Whether some mental variable such as duration or propensity is an immediate property of our perception of temporal stimuli, or of mental processes in general, is a matter of some disagreement. If there is no such immediately given property, it follows that time is a concept, somewhat like the value of pieces of money, that attaches to perceptions only through a judgmental process. The ease and apparent immediacy of the temporal judgment in certain cases might be explained as the result of practice, much of it occurring in the first few years of life, in the interpretation in terms of physical time of the numerous alleged temporal cues.

Selection

HAROLD P. BECHTOLDT
The State University of Iowa

The development of techniques and procedures to be used in selecting individuals for various jobs, training opportunities, or forms of therapy has become a major activity for many psychologists, and has resulted in an extensive body of knowledge, a multitude of techniques, and a few generalizations of theoretical value.

The objective of this discussion is to summarize the current work in this field and to present some of the general problems and theoretical considerations. No attempt will be made to list the various devices used in selection, to review the literature, or to treat the standardization of tests, the preparation of norms, or the office procedures required for the proper protection and utilization of classification materials. Statistical procedures will be discussed, but the formulas and computing procedures have been omitted.

Definition of Selection

Selection is defined by Warren (1934) as "the picking out or emergence of a character, an object, or a phenomenon from a group of alternatives in accordance with some standard or principle," and vocational selection is presented as "the process of choosing from a group of applicants for a vocation those most likely to succeed in that vocation."

Four characteristics of selection may be distinguished.

The writer gratefully acknowledges the extensive assistance and constructive criticisms given by Dewey B. Stuit, State University of Iowa.

First, selection of a few individuals from among many is a *process*. This process may be applied only once, as in the selection of a given number of punch-press operators for an individual plant, or it may be a recurring process, as in the periodic grading and elimination of graduate students. The process either may be formalized, with definitely stated critical levels of performance, or it may appear only as an attitude indicative of continuous scrutiny of an individual's behavior.

Second, the selection process always involves selection for some purpose: for speed of response, for capacity to lead men, or for any of the nearly limitless activities of human beings.

Third, selection requires procedures for assigning individuals into classes appropriate to the objective of the selection process. The development of these procedures constitutes the *classification problem*. The classifications may be made in terms of any *relevant* attribute of the individual. The procedures utilized may require (1) the obtaining of responses, verbal or nonverbal, from an individual, (2) reports from observers or "judges," (3) records of past performances, or (4) direct observation by the experimenter.

Fourth, selection implies prediction. The goal of a selection process is the prediction of an individual's "success" or his behavior at some future time. Success, of course, must be defined in terms of attributes other

than those used in the "sorting" operations of the selection process. The forecasting of future behavior constitutes the *prediction problem*.

Selection typically involves two independent assessments separated by a temporal interval. On the basis of the first assessment we set up "predictor categories." The second assessment leads to "criterion categories." The problem, then, is to predict the criterion categories. The predictions represent *estimates* of the *expected values*, and the estimates are determined from empirical investigations of the relations between the two sets of categories. From these investigations we determine the *most probable* criterion categories corresponding to the various predictor categories.

Because the behavior of the individual is continuously modified by external events, predictions of future behavior are usually made conditional upon the occurrence of a specific state of affairs. When predictions are hedged in this manner, they are said to be conditional predictions (Horst, 1941). For example, predictions of parole success may be conditional upon whether or not the parolees return to their previous environment. The isolation of the conditional factors that are relevant to the criterion classifications is a crucial problem in prediction. The relations between such factors and the "success" categories are analogous to the stimulus-response "laws" sought in experimental studies.

The criterion category is a classification based on a performance characteristic. In contrast, the predictor category may represent *any* attribute of the individual, defined by how he appears to others, what he can do, or what he has done. Either of the two classifications (predictor or criterion) may be expressed in terms of a single characteristic or in terms of a set of measures, as in a multiple regression problem. However, the criterion attributes are usually combined to provide a single composite "measure of success" in terms of which the

prediction statements are tested. When the selection process is a recurrent one, the criterion classification at an intermediate stage may be considered a predictor category for a later stage, and the final measure of success is then designated the "ultimate" criterion.

SELECTION AS AN ASPECT OF PERSONNEL PSYCHOLOGY

Unfortunately, there are few occasions in personnel selection when ready-made techniques can be applied. The personnel psychologist must meet most situations armed only with a method of approach. He must first study the problem in terms of the purpose of the selection, then formulate working hypotheses, devise the necessary procedures, try them out experimentally, check on the validity of his hypotheses, and finally revise his procedures in accordance with his findings. Each of these steps is a separate problem to be solved before the actual selection of individuals is undertaken.

The psychological analysis of behavior has not progressed to the point where direct application of general laws to the "engineering problems" of selection can be made. Each new problem has a few elements in common with old ones, plus a number of novel aspects, the effects of which can rarely be accurately predicted. Hence there is a demand for continued patient research in the applied field—a demand that usually runs counter to the demands for immediate results. This conflict is probably responsible for a concentration of effort on formalized tests of aptitude and achievement, and for the use of linear prediction equations.

Individual differences, which are often assumed to be a mere source of error in other problems, are the meat of the selection business. If individuals are homogeneous with respect to the predictor attributes, no *differential* classification in terms of these attributes can be made. If individuals are

homogeneous with respect to the criterion categories, there is no selection problem.

Individual prediction, it should be pointed out, is to some extent a misnomer. Predictions are properly applied to classes of individuals homogeneous (within limits) with respect to a set of characteristics (Sarbin, 1944). The personnel psychologist is concerned with assigning individuals to classes and with making statements about the expected performances of members of the classes.

Similarity of selection research to other psychological research. Between selection and other areas of psychological endeavor there is a similar objective and a similar point of view. The objective is the formulation of empirical rules based upon observed consistencies in the attributes of individuals, and in the effects upon behavior of various stimulus conditions. The point of view is a behavioristic one in the sense that observations of overt behavior, verbal and non-verbal, and discriminable attributes of individuals are the terms related.

In pushing toward this objective of discovering relations among variables, personnel psychologists are tending to consider their problems strictly in empirical terms. This extreme empiricism is largely a reflection of the specific problems formulated in selection studies, and a reaction against the unwarranted generalizations frequently used in the past. The typical selection project has some specific purpose, and its success is evaluated strictly in terms of the accuracy of its predictions. The empirical relations between the criterion and predictor categories are the pertinent observations; no abstract or theoretical constructs need appear in the expression of these relations. If the procedures work, they are accepted. This justification of selection techniques by a pragmatic criterion may explain Guthrie's characterization of the test movement in applied psychology as ". . . highly useful and practical work, but it has not contributed to psychological theory" (1946).

This is not to suggest, however, that the applied psychologist can make no theoretical contributions and achieve no important generalizations. He appeals to psychological principles when he chooses predictor variables and estimates the effects of situational factors. The agreement between the obtained and predicted observations constitutes a partial test of these principles. Furthermore the applied psychologist accumulates observations on the empirical regularities in human behavior. These regularities may form the basis for useful hypotheses and generalizations.

Both trait concepts and descriptions of stimulus conditions are used by the personnel psychologist, but trait concepts are probably given the greater emphasis in selection because of the difficulty of manipulating environmental conditions.

Trait concepts develop from the obvious fact of conspicuous individual differences. "Few jobs exist which can be performed equally well by practically all of the participants" (Flanagan, 1948). Although some differences among individuals are subject to change, other differences are quite stable. Furthermore, a high degree of specificity is found in the traits associated with the performance of various tasks. This specificity in performance is not explicable in terms of some unreliability of evaluation, for a high degree of consistency within each single area of activity can often be demonstrated.

Consistency of performance in a given domain and independence of performances in different areas have given rise to the notion of functional unities, i.e. traits expressed as abilities, motives, interests, and temperamental variables. The provision for more adequate operational definitions of these postulated traits is one of the outcomes of the factorial approach. It has been suggested that the number of traits necessary to account for the various occupational performance measures may be relatively large (Flanagan, 1947a). It should perhaps be noted also that the factorial methods do not

always sustain the initial hypotheses concerning the characteristics of a given trait; as often as not these hypotheses are subject to drastic modification in the light of the intercorrelations obtained among the tasks selected to represent the trait (Thurstone, 1947).

The definition of these traits by a set of test situations involves no assumptions about the origins of the traits; their source may lie in the social or in the physiological structure. The traits may be acquired or inherited, easily modifiable or resistant to change, specific to a given situation or common to many situations. Traits having the greatest stability and generality are of the greatest interest, of course, and the personnel psychologist seeks to isolate and define them and to establish relations among them.

Steps in Selection Research

The preceding discussion has emphasized two operations: the classification of behavior and the prediction of behavior. Before these operations can be carried out it is necessary that certain basic research be completed. The following five steps, modified from those listed by Horst (1941) and Sarbin (1944), represent the tasks involved in selection research:

1. The establishment of the criterion categories of "success," which involves the definition of the behavior to be predicted and the development of procedures for the classification of performance.

2. The selection of the attributes on which prediction is to be based, and the establishment of the several predictor categories for each of the attributes (for a representative sample of the population). These prediction attributes are those that are expected to have significant relations with the criterion attributes.

3. The determination of the relations between the criterion categories and the several predictor categories. These empirical relations are then used to predict the criterion category for each individual.

4. The verification of the relations determined on the basis of the original sample by the application of the classification procedures to a new sample of the population. This verification, or cross-validation, constitutes a crucial step that is too often omitted.

5. The application of the selection procedures in the routine situations for which they were developed, provided the stability of the prediction in the cross-validation step has been sustained.

Simplifying assumptions. In carrying out the selection process, we make certain assumptions for the purpose of simplifying the operational procedures. The first of these is that *human attributes that differ in magnitude can be represented by numbers*. Certainly numerical operations are used in the statistical procedures of selection, but are these statistics justified? Two replies have been given to this question. The first answer is based upon the logical implications of measurement in science: that the representation of empirical magnitudes by numbers requires that certain empirical operations be performed (see Chapter 1). "Additive" (or ratio) scales exist for some of the physical properties of responses but not for the more ubiquitous aspects known as qualitative attributes because the operations for the determination of zero and for the process of addition are not available (Bergmann and Spence, 1944; Richardson, 1941b). Psychological scales that are more than simple rank-order scales (Gulliksen, 1946; Stevens, 1946) can be constructed for some psychological properties, but they are rarely used in selection problems.

The second answer is that the use of numerals to represent the discriminial differences in attributes serves a practical purpose. Qualitative dichotomous attributes are often assigned numbers, as 0 and 1, and various statistics are computed. Multiple-category qualitative variables representing intensive dimensions are "scaled" in various ways, and numerical scores are determined.

Since the results are useful, these practices will continue. And the continued search for operations that will meet the logical requirements of measurement may eventually place these procedures on a sound basis.

The second of the simplifying assumptions is that *attributes differing in magnitude can be considered as continuous variables*. Classification categories are considered to represent intervals along a continuum. Of course, there is no assurance that the phenomena under consideration are continuous and not discrete. For example, only completed responses on a test are scored. Such responses are usually discussed, however, as though any given response might be represented by some value between zero and one.

The third simplifying assumption current in selection work is that *the criterion magnitudes can be expressed as linear functions of the predictor variables*. Horst (1941) has pointed out that increased accuracy of prediction may require the use of nonlinear relations. Such functions are current in the formulations of other psychological problems, for example, in the various mathematically stated learning theories. However, for a variety of monotonic functions within the range of values conventionally used, a linear equation provides a useful first approximation. For selection purposes, nonlinearity of relations is not crucial since linearity can often be secured by a modification of the measuring devices or by a transformation of the scales or scores. Furthermore, empirical evidence indicates that sampling fluctuations of regression parameters are of such magnitude that very large representative samples would be required to provide accurate estimates of nonlinearity (Flanagan, 1948).

Necessary Characteristics of Classification Procedures

An acceptable categorizing procedure is one that provides stable differentiations between individuals with respect to a characteristic of performance. Differentiations

with respect to a single variable are desired, but for many selection purposes complex "multidimensional" sets of attributes are useful. In every case, however, the classification procedures are expected to show *discrimination* and *reliability* (Adkins, 1947; Thorndike, 1949).

Discrimination is the aspect of a classification procedure that is reflected in the number of categories to which significant proportions of individuals are assigned. A procedure that assigns all individuals to a single class fails to discriminate. If each individual is assigned to a separate class, discrimination is maximal. Most classification procedures exhibit a discrimination intermediate between these two extremes.

An index of discrimination has been developed in terms of the obtained number of differentiations between *pairs* of individuals (Ferguson, 1949). The number of possible differentiations is the number of combinations, $n(n-1)/2$. The index δ , derived in terms of s different *possible* score categories, ranges from zero for the test on which everyone has the same score to unity for the test providing a rectangular distribution extending over the entire range of scores. The formulation is

$$\delta = \frac{s}{s-1} \left(1 - \sum_{j=1}^s p_j^2 \right)$$

where s = the number of possible score categories, and p_j = the proportion of individuals in the j th category, j ranging from 1 to s .

The effectiveness of the classification procedure can also be considered in terms of the possible number of differentiations, i.e. when each individual is assigned to a separate class. In this case, an index δ' is provided by

$$\delta' = \frac{n}{n-1} \left(1 - \sum_{j=1}^s p_j^2 \right)$$

where n = number of individuals in the sample, and the other symbols have the same meaning as before. A value of unity for δ' is obtained only when $s = n$ and

$p_j = 1/n$. The index δ' expresses the proportion of the total possible number of discriminations that is provided by the classification procedure.

If the number of discriminations made by a classification procedure is used as a criterion of "goodness of discrimination," the best procedure is one that provides a rectangular distribution of scores (or categorizations) for the group. Since a single item, scored correct or incorrect, can be considered as a "test," the most discriminating item ($\delta = 1.00$) is one that has 50 per cent of the cases in each of the two categories (Adkins, 1947). For sets of two or more items, however, the maximum number of discriminations made by the s total test scores (each item scored 0 or 1) may or may not be obtained with items at the 50-per cent level of difficulty. The intercorrelations of the items and their reliabilities, as well as the difficulty level of each item, must be considered (Brogden, 1946*b*; Carroll, 1945; Flanagan, 1939*b*; Gulliksen, 1945; Richardson, 1941*a*). It has been shown that the variance of the total score (the score defined as the sum of unit-weighted items scored 0 or 1) varies directly with the average intercorrelation of the items and with the average item variance, and varies inversely with the variance of the distribution of item difficulty values. Since a large variance is associated with a flat distribution of test scores, the relations that tend to maximize the test variance will also tend to increase the index of discrimination of the test. A decrease in the average interitem correlation for a given difficulty distribution will lead to a more nearly unimodal distribution of scores and to a smaller test-score variance and fewer discriminations. When the maximum discrimination is desired, a wide range of difficulty values is recommended in order to secure an approximately rectangular distribution of scores (Adkins, 1947; Loevinger, 1947).

If the function of a test is to measure some hypothetical trait or "ability" common to

its several items, the difficulty level of the test providing the maximum discrimination will vary with the ability of the subjects. Easy items ($\bar{p} \geq 0.70$) will give the greater number of discriminations for subjects having low ability, and difficult items ($\bar{p} \leq 0.30$) will be more appropriate for subjects having high ability (Adkins, 1947; Richardson, 1936*a*).

The fineness of discrimination required may, however, vary from time to time, depending primarily upon the purpose to be accomplished. If the problem is simply one of accepting or rejecting each individual on the basis of some requirement, only a dichotomous classification is needed. In this case the test-score distribution would be bimodal or U-shaped. When fine discriminations are desired only among individuals at either extreme of the range of ability, the test-score distributions can be definitely skewed or J-shaped, with the flat section of the distribution occurring in the region where the differentiations are to be made. Rectangular distributions are the goal when the number of classes desired is limited only by the errors of measurement and by the range of the sample.

It should be emphasized that this concept of discrimination does *not* refer to the relation between the assessments of two independent classification procedures. Such relations are used to provide an indication of the "validity" of one of the classifications. A classification procedure may discriminate without being valid (for a given criterion).

Reliability is the consistency or stability of the evaluations obtained from repeated observations. Repetitions of a reliable procedure lead to similar scores. Either the score (or classification) can be shown to be "essentially" the same on repeated trials, or the position of the individual relative to the group remains "relatively" constant. The terms "essentially" and "relatively" indicate that some variation is always expected. The nonsystematic or "chance" variations in repeated observations are termed "errors of measurement." If only a small fraction of

the total variance of the scores is associated with these errors, the test is reliable; if the fraction is large, the test is less reliable.

Two common indices of reliability are used in selection studies, the *standard error of measurement* and the *reliability coefficient*. The square of the standard error of measurement is an estimate of the variance of the repeated measurements (error variance) of the same individual's performance. The reliability coefficient is defined as one minus the ratio of the average error variance (estimated from the entire set of observations) to the total variance of the test. This coefficient, ranging between zero and unity, is an index of the stability of a classification relative to the classifications of a group of individuals. The standard error of measurement, at least for a given score or classification, is independent of the range of performance in the sample of individuals (Adkins, 1947; Cronbach, 1947; Jackson and Ferguson, 1941; Thorndike, 1949).

The basic assumption made in estimating the reliability of a procedure is that the repeated observations can be considered as measures of the "same thing." The behavior observed is assumed to remain constant; variations are attributed to extraneous factors that operate in a nonsystematic fashion. The definition of the sources of error variance, the development of experimental procedures for securing the relevant data, and the formulation of statistical techniques for the evaluation of the error variance are three general problems of test reliability.

Since the variance included as "error" by the psychologist may arise from many sources, there are several different reliability concepts. They concern repeated measurements in situations involving (1) samples of the individual's behavior, (2) samples of the tasks or operations, and (3) samples of the performance of observers or scorers evaluating a given behavior or attribute. Estimates of the stability of classifications (relative to the variability of the group), over a sample of similar tasks, over

a period of time, or over both, are provided by three coefficients: (1) *equivalence*, (2) *stability*, and (3) *stability and equivalence* (Cronbach, 1947).

Three different experimental procedures are used to obtain the data for these three coefficients. The coefficient of *equivalence* is estimated from the data obtained with a single sample of items presented at one time to a group of individuals. The coefficient of *stability* is determined from the results of two or more administrations of the same test at different times. The coefficient of *stability and equivalence* is estimated from two or more samples of items (parallel forms representing samples from the same universe of items) presented at various intervals of time. As the time interval decreases, the coefficient of stability and equivalence for two or more tests approaches the coefficient of equivalence for a single measurement consisting of the combined samples of items.

The statistical operations used to compute these various coefficients stem from the assumption that the error factors are independent of the systematic factors, or that the responses to any item on any trial are independent of the responses to other items on other trials. The mathematical details are presented by various writers (Adkins, 1947; Cronbach, 1947; Guttman, 1945, 1946; Horst, 1949; Hoyt, 1941; Kuder and Richardson, 1937; Jackson and Ferguson, 1941; Loevinger, 1947; Rulon, 1939).

The pertinent sources of variance can be classified in terms of the duration and generality of their influence. These factors may operate in a *persistent* or in a *temporary* fashion (duration) and may be *specific* to one task or *common* to two or more tasks (generality). All reliability formulations consider the systematic nonerror (true) variance to include common persistent factors such as general skills and abilities. Such factors as luck in guessing or the influence of momentary stimulus conditions are assigned to the error variance. The three formulations of reliability, however, assign

different combinations of the remaining factors to the error variance.

The *coefficient of equivalence* assigns all the specific-factor variance, either temporary or persistent, to the error variance. The specific factors include all characteristics of the individual (skills or information) or of the task (form of item or terminology) that may cause the performance on *one* item alone to be more or less satisfactory. Since the data are obtained in a single test administration of the sample of items, the true variance will include any common factors that persist over the time required for the test. The Kuder-Richardson (1937) formulation of the reliability concept (and its variants) provides an exact estimate of the coefficient of equivalence if the specified assumptions are met. If the assumptions are not sustained, the Kuder-Richardson formulas provide conservative estimates of this coefficient. The coefficient of equivalence is often determined by splitting the test into halves (as odd versus even items). The estimate obtained from the Spearman-Brown formula in this case may provide either an overestimate or an underestimate of the coefficient, depending upon the comparability of the halves (Kuder and Richardson, 1937). All these estimates assume that all items of the test have been attempted, and they are not applicable to time-limit testing procedures.

This general equivalence formulation of the problem of the consistency of responses to a given set of items has been termed the *internal consistency hypothesis* and is utilized in the factorial methods, in the principal-axes solutions for combining measures, in the definitions of homogeneous tests, as well as in the estimation of a reliability coefficient (Burt, 1936; Horst, 1941; Loevinger, 1947; Wherry and Gaylord, 1943). The concept of a homogeneous test as developed by Loevinger (1947) provides an alternative formulation of the internal consistency of the responses to a single sample

of items ordered with respect to the proportion of correct responses to the items. An index of homogeneity is then provided by the ratio of the obtained interitem covariances to the maximum interitem covariances for an ordered arrangement of the items. For both the Kuder-Richardson and the Loevinger formulations the concept of the total variance of the scores, as a function of the item variances and the interitem correlations, is important; these functions also provide an indication of the close relation between discrimination and reliability.

The error variance for the *coefficient of stability* includes all temporary sources of variance; these are the common and specific factors that do not persist from one test administration to another. The temporary factors may include the individual's degree of motivation, health, or degree of skill in the mechanics of taking the test. An estimate of this coefficient is provided by the correlation between repeated presentations of the same test. The estimates tend to vary with the time interval between test administrations. Guttman's (1945, 1946) formulations are based on this concept, although he provides estimates of the lower limits of this reliability coefficient from a single trial. Two of his estimates are comparable to those secured from the more precise of the several Kuder-Richardson formulas.

All temporary factors, common and specific, as well as the persistent specific factors, are included as error variance in the *coefficient of stability and equivalence*. This coefficient is estimated from the correlations between two (or preferably three) parallel or comparable tasks separated by a time interval. The coefficient is affected by the length of the time interval as well as by the degree of comparability of the forms of the test. This coefficient has been considered most appropriate for evaluating the reliability of the classification procedures used for selection purposes.

Basic Concepts of Prediction

In their prediction procedures, psychologists have made extensive use of the concepts of *probability* and of *validity*. The *relative-frequency* concept of probability provides the basis for the mathematical procedures used to forecast future behavior and to evaluate these forecasts.

Probability. A degree of probability attaches to any estimate of future behavior. The best estimate is the one yielding the least error, i.e. the most probable values, for the population as a whole (Bridgman, 1932; Guttman, 1941). For qualitative data these estimates are the criterion categories having modal frequencies at each predictor category in the bivariate or multivariate distribution. For quantitative data the most probable criterion values are the arithmetic means of the criterion variables determined for each predictor interval (Guttman, 1941). These mean values are computed from the line of regression of the criterion on the predictor variable. When the linearity assumption is accepted, these means are determined from the usual single or multiple regression equations. When the criterion represents a dichotomized variable (scored 0 or 1), the linear prediction equation (for quantitative variables) is Fisher's discriminant function (Garrett, 1943; Travers, 1939).

Because predictions are always inexact, an estimate of the error of prediction is required. This takes the form of a probability statement expressing a relation between a proposition and a set of data (Jeffreys, 1937; Sarbin, 1944). The data are the criterion classes into which the individuals fall; the proposition is the statement that such and such criterion classes are associated with each of the various predictor measures. The relative frequencies of the *successes* of these *propositions* then provide an index of the accuracy of the prediction.

These probability statements properly refer to predictions made about members of classes. A class may be defined, for ex-

ample, by the consistent behavior of an individual in a given situation over a period of time or by the similar behaviors of the individuals in a group (Sarbin, 1944). The statement that the probability of John Brown's success is 80 per cent is inappropriate; the probability properly refers to the accuracy of our predictions about individuals in the same class as John Brown, say Class X, rather than to John Brown himself. Verification of probability statements is possible only in terms of relative frequencies. If additional *relevant* data are available, a more useful designation of John Brown may be as a member of Class Y rather than X, where the relative frequency of successes may be different for the two classes. A class designation for an individual can be modified by extending or reducing the attributes used to define the class. Augmented class definitions are of value if the additional data are relevant to the criterion measures (Sarbin, 1944).

Validity. The discussions of validity by Mosier (1947), Rulon (1947), and Thorndike (1949), among others, have differentiated among several different concepts of validity encountered in selection.

The first of these has been termed "validity by definition" (Mosier, 1947). It requires a judgment concerning the pertinence and comprehensiveness of the operations used to define the characteristic to be measured (Bechtoldt, 1947; Rulon, 1947). This concept of validity involves the *acceptance* of a set of operations as an adequate definition of whatever is to be measured. The concept appears in two logically similar phases of selection research, namely, in the choice of an ultimate criterion measure and in the development of tests for a specified trait or quality of performance. If the criterion is defined as the ability to use a lathe to machine a steel screw within a given period of time, a work sample involving exactly this task would be an "obviously" *valid* measure of the skill, although it might not necessarily be a reliable one. A valid

test of skill in arithmetic could be defined, likewise, as one requiring the execution of addition, subtraction, multiplication, and division. In selection studies that use criteria such as these, agreement among competent observers constitutes a measure of the validity of the criterion.

The second type of validity concerns the agreement between evaluations of the same individuals by two nonequivalent measures, one of which is termed the criterion (dependent) variable and the other the predictor measure. The basic similarity between the statistical concepts of validity and reliability is evident in this formulation; the difference between them rests with whether the measures are nonequivalent or equivalent.

Obviously the statistical concept of validity, since it refers to a relation between a criterion measure and some other assessment, is dependent upon the particular criterion used. For each different objective or purpose a different criterion is required. The statistical validity of a measure varies then from one activity to the next. In this sense a test has no intrinsic validity; it has as many validities as there are criterion measures to be predicted.

Validity by assumption, involving "common-sense" judgments about the abilities measured by the test, is both common and dangerous in selection (Mosier, 1947). The blithe disregard of empirical evidence of validity in favor of the appearance, the title, or the reported factorial composition of the test and of the criterion is seen too frequently. Tests entitled "mechanical ability," that have proved useful in selecting lathe operators, may, for example, be applied to the selection of engineering students under the *assumption* that they are valid for that purpose also, but this assumption must be verified.

Still another type of validity has been termed "palatability," or "face validity" (when the term does not refer to validity by definition) (Mosier, 1947). Since this con-

cept concerns the way in which the respondents react to the appearance of the test, it is not an important phase of validity, as the concept is used here.

Validity coefficients. When two variables are continuous and linearly related, the product-moment correlation coefficient is the index of validity most frequently used. The multiple correlation coefficient is used for the index of validity of sets of predictor variables under similar conditions. When the relations are to be determined between attributes and between both qualitative and quantitative variables, agreement as to the appropriate statistic is not so widespread.

When there are artificial or true dichotomies in the criterion and predictor variables, the point biserial, the biserial, the *phi*, the *phi* biserial, or the tetrachoric correlation coefficients are used. The point biserial and *phi* coefficients represent the product-moment correlations for true dichotomies (scored zero and one) for the cases of one and of two dichotomous measures, respectively. The biserial and tetrachoric coefficients represent estimates of the product-moment correlations under the assumptions of continuous and normal distributions and linear relations for the cases of one and of two artificial dichotomous variables, respectively. The *phi* biserial coefficient is derived for the case of one artificial and one true dichotomy scored 0 and 1, using the assumptions required for the biserial coefficient (Thorn-dike, 1949).

The point biserial and *phi* coefficients are regarded as the appropriate statistics for the determination of regression coefficients, in place of the biserial and tetrachoric coefficients, even for artificial dichotomies, since these coefficients indicate what the effective relation is for the case of linear prediction (Wherry and Taylor, 1946). The magnitude of the point biserial coefficient, however, is a function of the proportions in each part of the dichotomy (e.g. the difficulty level of a test at the point of division). This characteristic has led some workers to prefer

the biserial, tetrachoric, and *phi* biserial coefficients for those cases involving artificial dichotomies (Burt, 1944; Thorndike, 1949). If the analysis is concerned with the homogeneity or factorial complexity of a set of observations, the dependence of the point biserial and *phi* coefficients upon the difficulty level may lead to the appearance of "difficulty" factors if the measures are not homogeneous with respect to proportion passing (Carroll, 1945; Ferguson, 1941; Wherry and Gaylord, 1944). For purposes of item analysis or of analysis of the interrelations of measures in a single sample, the biserial or tetrachoric coefficients are more appropriate, since the difficulty of the items can be established by the proportion of correct responses.

When the qualitative predictor variable contains three or more categories, the multi-serial *eta* coefficient, with the categories assigned scale values equal to their means on the continuous criterion variable, is recommended for purposes of prediction (Bittner, 1945; Wherry and Taylor, 1946). When these scale values are used, this coefficient is equal to the product-moment correlation between the two variables. One degree of freedom for each category is lost, provided the categories are ordered and weighted in terms of the differences in the criterion means of the category samples.

THE CLASSIFICATION PROBLEM

In the preceding sections selection has been treated as two interrelated activities: classification and prediction. The present section is concerned with the specific aspects of the classification problem as they arise in the development of the criterion and of the predictor "variables."

Detailed discussion of the development of classification procedures for educational, governmental, and military applications have been presented by Adkins (1947), Crawford and Burnham (1946), Davis

(1947a), Flanagan (1948), Guilford and Lacey (1947), Melton (1949), Stead, Shartle, et al. (1940), Stuit (1947a), and Thorndike (1949). Earlier and somewhat more general discussions by Bingham (1937), Horst (1941), Hull (1928), Symonds (1931), and Viteles (1932) provide valuable reference materials. Additional publications of special interest, other than the numerous journal articles, include the critical reviews in the several *Mental Measurement Yearbooks* (Buros, 1949), the *Manual of Examination Methods* (Board of Examinations, 1937), and the *Assessment of Psychological Qualities by Verbal Methods* (Vernon, 1938).

Statement of objectives. A first step in selection is the determination of the characteristics to be used in classifying individuals. For each classification we must determine (1) what traits or performance characteristics are to be evaluated, (2) what standards of success are to be used, (3) what attributes should be present or absent, and (4) what relative importance is to be assigned to the characteristics. When these aims have been defined by the pooled judgments of competent persons, general agreement can be expected on the areas of performance to be included in the success continuum (Flanagan, 1948).

For simple activities the problem of selection is straightforward enough. But when success is defined as a "flying officer competent as a leader and as a pilot or navigator," we face a difficult problem of analysis. Success so defined, although considered as a unitary variate, is actually multi-dimensional (Bechtoldt, 1947; Horst, 1941; Toops, 1944). It is rare, therefore, that assessments on a single trait will provide the required ranking of the individual with respect to the total success variable.

Job analyses. In locating the areas of performance to be assessed, the selection psychologist uses several methods to secure the information he requires. These methods of analyzing an activity are discussed in detail by Horst (1941, Chapter III), Hull

(1928, Chapter IX), Stead, Shartle, et al. (1940, Chapter X), Thorndike (1949, Chapter II), and Viteles (1932, Chapter IX).

The major hazards of job analysis are (1) the possible omission of relevant aspects of the activity, (2) the introduction of extraneous factors through the biases of observers, (3) the inability of the observers to make accurate descriptive observations, (4) the differential effect of experience or training on the performances of successful and unsuccessful individuals, and (5) the relative contributions of previous training to the performances of novices and experienced personnel.

The methods of collecting the data required for job analyses may be grouped, for convenience of exposition, into (1) those based on the judgments of individuals other than the investigator, and (2) those involving direct observations by the investigator.

Sources of information concerning an activity include the published literature on the problem, records of performances of individuals, reports of causes of failure and of common complaints, formal job classification materials, and technical or training manuals. Other sources include interviews with experts, supervisors, and independent observers. Valuable data are often had from interviews with individuals engaging in the activity, including those just entering the field, those still in the learning phase, and those who have been judged relatively successful or unsuccessful. These sources must not be used uncritically.

Of more value are the direct observations by trained persons of individuals engaged in the activity and of situations characteristic of the activity. Systematic, recorded observations directed by a variety of hypotheses are usually necessary to determine those traits or characteristics in which the successful and unsuccessful individuals differ most significantly. Participation in the activity is often helpful to the investigator.

General forms for the summarizing of job duties, essential knowledges, specific infor-

mation, characteristic activities, and typical inadequacies have been described (Adkins, 1947; Stead, Shartle, et al., 1940). Such forms or trait lists may prove to be deceptively exact, because operational definitions of traits such as initiative or emotional stability are by no means precise.

Tests of ability and skill. A test is defined as one or more tasks presented to the individual, together with the method of appraising the response (Thurstone, 1947). For each task some standard is provided by which to appraise the performance and in terms of which the individual is assigned to a specified class. In the testing procedures used in selection, research workers sometimes concentrate so exclusively on the "accuracy" of a response that they ignore other relevant properties. Such matters as variability, speed, frequency of omissions, frequency of wrong responses, and the ratio of correct to total responses may be indicative of behavior tendencies important in prediction (Coombs, 1948; Guilford and Lacey, 1947).

Tests are most frequently presented in printed form. They may utilize photographs, drawings, maps, etc., as well as verbal symbols, and may require that the subject provide definitions, state purposes, indicate causes or effects, recognize errors, evaluate alternatives, point out differences, rearrange materials according to some requirement, or indicate a common principle (Adkins, 1946; Mosier, Myers, and Price, 1945). Examples of the printed aptitude and achievement tests are provided by Brigham (1932), Crawford and Burnham (1946), Davis (1947a), Guilford and Lacey (1947), and by the publications of the several commercial testing organizations.

For large-scale testing programs, items calling for a limited response or a simple recognition are favored over items that require an essay type of answer. The limited response makes scoring objective; it minimizes the possible effects of fluency; and it reduces the ambiguity of the task set for the

subject. The construction of such items is discussed by Adkins (1947) and by the staff of the Board of Examinations (1937). Considerable ingenuity, experience, and technical preparation, bolstered by a thoroughly systematic procedure is necessary for the development of items that require more than trite verbalizations and the parroting of definitions.

Apparatus tests of the work-sample type are utilized whenever the trait to be measured is defined in terms of manipulatory skill. Examples of apparatus tests are those that require the manipulation of peg or form boards, the solution of mazes and assembly tasks, or the judgment of speed and direction of movement. The tasks may require the use of slide or motion-picture projectors, reaction-time equipment, complex "training devices," or actual pieces of military or industrial equipment. Instructions on the development of apparatus tests are presented by Adkins (1947), Melton (1949), and Stuit (1947*a*).

The demands of expediency and convenience in large-scale testing are such that apparatus tests tend to be used only when forms that are easier to administer and to score are unacceptable. The problems of large-scale administration of apparatus tests were solved fairly satisfactorily, however, by the military services (Flanagan, 1948; Thorndike, 1947*a*; Stuit, 1947*a*). The military testers found it necessary to coordinate the testing sessions, to duplicate apparatus, to centralize controls and recording devices, and to standardize instructions.

Attitude and interest questionnaires. Considerable attention has been paid to attitude questionnaires and preference inventories because of the administrative convenience of these devices. The development of such questionnaires is discussed by Maller (1944), Symonds (1931), and Vernon (1938). Pertinent triennial reviews of the general topic of "Psychological Tests and Their Uses" are provided by the *Review of Educational Research*.

Ellis (1946) has pointed out that the validity studies of these questionnaires are equivocal. The authors of the devices usually find their instruments useful, but other investigators often fail to confirm their utility. Some success in military screening, where a psychiatric diagnosis was employed as the criterion, has been reported for several types of items (Ellis and Conrad, 1948; Guilford and Lacey, 1947; Wexler, 1947). However, the usefulness of questionnaires as measures of psychological variables has been questioned by Maller (1944) and by a sample of 79 psychologists polled by Kornhauser (1945), among others. The major objections to these devices appear to be the lack of internal consistency in the set of items, the influence of changes in mental set on the part of the subjects, the instability of the responses over samples of items and periods of time, and the absence of significant relations between such devices and other aspects of behavior.

Improvements designed to reduce the ease with which the "best" responses can be determined by the subject include the use of "forced-choice" items, with elements from two or more different continua presented in pair or triad form, and the application of empirical scoring weights based upon the performances of unlike groups (Fowler, 1947; Horst, 1941; Jurgensen, 1944; Meehl, 1945; Sisson, 1949; Wexler, 1947). Improvements in the stability of the validation data can be expected from the consistent use of cross-validation procedures. Modification of the usual criterion measures, so that they may be made to include evaluations of social and personal "adjustment" and of job satisfaction, may result in increased validity indices for these devices (Maller, 1944).

Biographical or personal history forms. Previous experiences of the subjects are often collected by self-rating or biographical data sheets as well as by the case history and interview methods to be considered later. Although administratively conven-

ient, these self-rating procedures have been characterized by low validity in cross-validation. However, biographical items have proved moderately useful in the prediction of success in selling life insurance, in the selection of army officers and pilots, and in the admission of students to some educational institutions (Bittner, 1945; Guilford and Lacey, 1947; Kurtz, 1941; Richardson, 1947). The importance of the empirical determination of the weights to be assigned to the items and the establishment of their stability on new samples should be stressed, for there is a widespread uncritical use of biographical items scored on the basis of small-sample results or *a priori* judgments.

Personal history data can be criticized on two counts: (1) the ease with which the responses may be biased to the advantage of the respondent; and (2) the inability of the individual, even when favorably disposed, to recall accurately his past experiences. The procedure is most successful when the probability of falsification is low, when the responses are not regarded as accurate sources of personal history data, and when item-scoring weights are empirically determined.

Ratings. In selection, we usually want classifications based on the attributes of the subject and not on those of a rater observing the subject. In the rating processes, however, the data obtained are the responses of an observer to a situation of which the subject and his behavior are only a part. The observer, furthermore, is a complex mechanism subject to both systematic and variable errors. In spite of these weaknesses, ratings of one type or another are widely used in the development of criterion and predictor categories. Even such matters as salary and academic grades are basically ratings (Jenkins, 1946; Patterson, 1946).

Two different functions may be served by raters, namely, recording and evaluation. The recording function is of particular importance in tasks that leave no permanent record as, for example, in interpersonal situ-

ations or complex performance tasks. The function of evaluation is less straightforward. Here the rater serves as a computer presumed to possess the ability to synthesize nonlinear data and to determine what sorts of observations are to be included. These synthetic evaluations, characteristic of summary ratings and clinical judgments, are apt to be affected by the biases of the observers (Thorndike, 1949).

A variety of methods are used to secure an analytical judgment of some aspect of a performance or of a single trait, or to obtain a summary evaluation of the individual. These methods include paired comparisons, rank orders, and designations of position on a scale. Also, check lists on which specific aspects of the performance are marked as present or absent are used in rating a sequence of operations. The voting or nominating technique, as one form of rating device has been called, may be used when a number of judges are available for evaluating complex traits.

The problems involved in rating procedures are mainly those of securing discriminating, valid, and reliable measures. Discussions of the problems of developing such rating measures are contained in Symonds (1931) and Vernon (1938). For additional phases of the problems associated with ratings of limited behavior units and summary ratings used as criterion measures, see Adkins (1947), Cooper (1940), Flanagan (1948), Stuit (1947a) and Thorndike (1949).

The observer's biases pose the most difficult problem in the rating techniques. It is possible to reduce these biases by training the raters, by providing detailed descriptions of the performance to be evaluated, by specifying the standards to be used in the evaluation, and by indicating the ways in which the separate aspects are to be combined. Pooling the independent observations of several raters and securing repetitions of the evaluations are other means of counteracting bias.

Special mention should be made of the synthetic evaluations characteristic of clinical situations and interviews. The interview routinely used in selection is an extremely complex activity in which the interviewer can be considered as (1) a variable part of the social situation, (2) a recorder of the specific types of behavior being evaluated, and (3) an interpreter of the observations (Flanagan, 1948; Rundquist, 1947; Sarbin, 1944). In the interview, the problems of variability between individuals over samples of behavior and over a period of time may be entirely insignificant compared to the variability attributable to the situation and to the interviewer.

Adequate studies have not been made of the contribution of the evaluative type of interview to the efficiency of the selection process. Those that have been made indicate that the interview contributes relatively little to the other available techniques unless it is carefully standardized, uses trained interviewers, and is directed toward traits not otherwise evaluated (Davis, 1947*b*; Flanagan, 1948; Rundquist, 1947; Sarbin, 1944; Stuit, 1947*a*).

For vocational and military selection, there is little evidence of a significant increase in accuracy of prediction because of the addition of clinical judgments. Davis (1947*b*) summarized a number of studies using clinical tests and case history materials by saying that the subjective evaluation of empirical data appears to add little or nothing to the accuracy with which personnel can be classified for selection on the basis of suitable objective tests. The studies he reviewed include those made for the Coast Guard, the Army Air Forces, the Navy, and the Civil Aeronautics Authority. These studies utilized the Rorschach test, various work methods, and clinical evaluations of other types. A number of other investigators, working in situations in which the accuracy of their predictions could be tested, have likewise concluded that clinical judgments are of little

use in classification techniques (Sarbin, 1944; Stuit, 1947*a*; Wallin, 1941).

It should not be inferred, however, that the interview is valueless in the selection process. The interview is a method of collecting biographical and preference data; it also provides an opportunity to evaluate the voice, the manner of expression, and the poise of an individual. Whether the interview is the most economical, efficient, and accurate method of securing such data depends upon the situation and upon the skill of the interviewer. It may also provide an opportunity for the interviewer to explain matters to those being selected, and to establish desirable personnel relations.

CRITERION MEASURES

An acceptable criterion of success is crucial because it constitutes the basis for validation. It provides the standard in terms of which the relevant predictor variables can be isolated, the efficient testing procedures separated from the inefficient, and the relative weights determined for use in predicting future performances and in combining sets of observations. The criterion must provide an adequate definition of the success continuum for the activity in question.

The success measure is usually assumed to lie on a single continuum. However, as Toops (1944) has demonstrated, success is not unitary; an analysis of any but the simplest activity will indicate that success is often the resultant of a large number of separate abilities, traits, skills, and knowledges. We can resolve this difficulty if we express the success continuum as a multi-dimensional variable, with each dimension an independent component. The success measure can then be defined by (1) a single overall evaluation, (2) a weighted composite of the separately measured components, and (3) a pattern or profile of these several variables (Adkins, 1937; Bechtoldt, 1947; Horst,

1941; Toops, 1944). The first two procedures are the ones most used.

The merits of criterion measures are judged in terms of their validity, reliability, and discrimination.

The validity of sets of criterion measures is evaluated in terms of statistical evidence of positive intercorrelations among the measures. The presence of significant correlations cannot safely be assumed; some of the psychologists working on military and industrial selection have found that individual criteria may be quite independent of one another, or, what is more pertinent, even independent of, if not negatively related to, the ultimate criterion (Flanagan, 1948; Jenkins, 1946; Stuit, 1947a).

The reliability and discrimination of criterion measures are evaluated in terms of statistical evidence of consistencies over periods of time and over samples of situations and by the distributions of the assigned values. Although no test can consistently predict a criterion that has zero reliability, high reliability in a criterion is desirable but not necessary. Low reliability introduces chance factors that attenuate the relations but do not introduce systematic irrelevant variables (Thorndike, 1949). Likewise, multiple classification categories of success permit improvements in prediction, but a dichotomous criterion, if relevant and reliable, will be superior, for validation purposes, to a multiple-category criterion that is either less valid or less reliable. An acceptable working procedure seems to be to utilize all the categories that (1) are necessary for the purpose of the selection situation, (2) can be shown to be reliably discriminated, and (3) meet the demands for accuracy of representation of the data.

THE PREDICTION PROBLEM

After the criterion and predictor classifications have been established, the next phase is the determination of the empirical relations between them and the verification on a

new sample of the forecasts based upon these relations. These matters have been discussed by Adkins (1947), Flanagan (1948), Horst (1941), Hull (1928), Stead, Shartle, et al. (1940), Stuit (1947a), and Thorndike (1949). These general references form the basis for the following discussion of three major topics, namely: (1) the evaluation of prediction statements, (2) the factors influencing the accuracy of prediction, and (3) differential prediction.

Evaluation of Prediction Statements

Since predictions are based on probability estimates, errors of prediction are to be expected. For the *qualitative* case, the efficiency of prediction can be expressed in terms of the proportion of individuals correctly assigned (Guttman, 1941). The accuracy of *quantitative* predictions, on the other hand, is usually expressed as a function of the correlation between the criterion and the predictor measures.

The effectiveness of a given value of a correlation coefficient is usually expressed in terms of k , the coefficient of alienation, and E , the index of forecasting efficiency (Hull, 1928; Horst, 1941). Validity coefficients, corrected for attenuation, of less than 0.45 or 0.50 evaluated in terms of these indices are considered by some workers to be of little value in prediction unless a favorable selection ratio is obtained.

This conservative view is appropriate when a criterion value is to be predicted for each individual and the accuracy of the prediction for all cases is to be evaluated. However, for selection purposes, the utility of a prediction may be assessed in terms of the relative number of correct predictions and in terms of attaining or exceeding some critical value of the criterion (Horst, 1941). A higher validity coefficient means an increase in the proportion of cases scoring above some arbitrary criterion value. The magnitude of this increase for the special case of linear relations in a normal bivariate distribution can be estimated from the tables provided

by Peters and Van Voorhis (1940). The correlation coefficient can be regarded as a direct index of the efficiency of prediction, according to Brogden (1946a). He shows that, when the regression is linear and the frequency distributions are similar, the correlation coefficient represents the ratio of the mean criterion score of the group selected from the top portion of the "combined predictor" distribution to the mean value that would be obtained by selecting a group of similar size by means of the *criterion* itself. Still another method of indicating the effectiveness of a selection device is provided by Richardson (1944), who defines predictive efficiency in terms of the increase in efficiency due to the use of a selection device, as compared with selecting the cases at random (Jarrett, 1948).

These measures refer to the accuracy of prediction in the original sample and not necessarily to the accuracy of the procedure when applied to a new sample. The value of a prediction procedure must be demonstrated on the new sample (Horst, 1941). The ratio of the quadratic mean of the errors of prediction in the new sample (based on the regression weights from the initial sample) to the standard error of estimate of the original sample provides an estimate of the accuracy in new samples. The quadratic mean of the errors is used, since both additive and multiplying constants based on the original sample are required. The correlation between predicted and obtained scores in the new sample is a less effective measure of accuracy because variations in the means and standard deviations are automatically corrected by the correlation coefficient (Horst, 1941).

The use of a cross-validation sample for the evaluation of the stability of a prediction equation is desirable because of the often unwarranted assumptions of (1) random sampling, (2) normality of the distribution, (3) independent errors, and (4) constant marginal frequency distributions on the predictor variables that are used to pro-

vide estimates of the sampling fluctuations of various regression statistics (Guttman, 1941). The mathematical solutions for non-normal population distributions are not yet available.

Factors Influencing the Accuracy of Prediction

The accuracy of predictions is affected by a number of factors other than the intrinsic relation (validity) between the predictor variables and the criterion. In addition to the reliability of the classification procedures, such factors include (1) the selection ratio, (2) the difficulty level of the activity, (3) the method of selection, (4) the method of evaluation, (5) the representativeness of the sample, and (6) the number of measures used.

Selection ratio. No selection problem exists unless some individuals are to be chosen and some rejected. The ratio of the number chosen to the number available is the *selection ratio*. The effectiveness of a selection procedure in terms of the performance level of those accepted will be *inversely* related to the magnitude of this ratio. When the selection ratio is low (when only a few individuals are to be accepted), moderate to low validity coefficients may prove useful. On the other hand, if only a few individuals can be *rejected*, a much higher validity would be required for the same effectiveness.

Difficulty level of activity. The possible advantage of selection over nonselection varies *inversely* with the proportion of satisfactory individuals in a random sample. If, for example, 80 per cent of the candidates can be expected to succeed anyhow, there is little value in a selection program unless the proportion of successful individuals among those selected can be significantly increased over the 80-per-cent value (Toops, 1945b). When, however, the proportion of successful candidates in a nonselected group is 50 per cent or less, measures having validity coefficients as low as 0.30 may prove valuable.

The theoretical effectiveness of a selection procedure as determined by difficulty level, selection ratio, and obtained validity has been investigated by Taylor and Russell (1939) both in terms of the expected proportions of successful candidates among those selected and under the assumption of linear relations and normally distributed variables. Their results indicate that acceptable efficiency can be achieved even though the index of forecasting efficiency is below the 10-per-cent point recommended by Hull (1928) as a critical level.

Method of selection. Selection may involve a single hurdle or successive hurdles. In the single-hurdle method, all individuals are evaluated on all the selection devices; with successive hurdles, the number of applicants is reduced successively by separate operations until at the final hurdle only a few individuals need be considered. Successive hurdles are often found in educational programs where there are periodic rejections for unsatisfactory performance. This procedure can be criticized, however, when there is a drastic use of cutting scores on separate tasks. It is sometimes assumed that failure to perform well on each task warrants elimination, and that high performance on one measure cannot compensate for failure on another. As Toops (1932) has pointed out, this disadvantage can be overcome to some extent by a proper arrangement of the tasks and the use of relatively high cutting scores in the first measures. The tasks should be arranged in decreasing order of validity, the most valid first, etc. At the final stage, the selection problem may be of little consequence, since the group may by then be quite homogeneous.

Method of evaluation. The predicted criterion scores may be obtained in terms of formal measures (linear regression equations, cutoff scores, matched profiles) or in terms of a clinical evaluation of the available data.

The more efficient procedures utilize all available data, and the predictions are made by a formal method. The linear regression

equation and the multiple correlation technique are usually applicable (Thorndike, 1949). Since this process is basically one of determining the "best" weights in a linear equation, the special problems of this process will be considered later in the section on the combining of measures.

The methods of successive and multiple cutting scores and of matched profiles have been recommended for use whenever (1) the relations between the criterion and predictor measures are conspicuously nonlinear, (2) competence in one area cannot compensate for weakness in another, or (3) a specified pattern of desirable and undesirable traits has been established (Ruch, 1945; Toops, 1945*b*). A convenient method of utilizing these nonlinear relations or critical values, in case they exist, is to establish a cutting score on each of the crucial attributes. Individuals who fall below the success score are then automatically eliminated, regardless of their standing on other variables. The multiple-cutting-score method selects the most efficient pattern of cutoff values from a series of possible combinations and eliminates individuals falling outside this pattern.

These cutoff methods and the linear regression techniques may not result in the selection of the same individuals (Thorndike, 1949). Individuals barely above the cutting score on each of two predictor variables may be rejected by the linear regression or "summation of traits" method. Those below the cutting score on one of the variables, but who score high on the other measure, may be accepted by some linear composite selection method, but rejected by the successive cutoff procedure.

Additional work needs to be done on the relative accuracy of the predictions made by the methods described above. For large-scale selection problems in which approximately linear relations can be found, the composite score method is probably most appropriate. Critical cutting scores on the composite criterion are of greatest value

when the proportion of individuals to be selected and the proportion above a given point on the composite score distribution can be determined.

Representativeness of samples studied. Perhaps the most insidious factor in selection is the nonrepresentativeness of the validity relations determined on a sample of individuals (Burt, 1944; Marks, 1947; Flanagan, 1948; Thorndike, 1949). Systematic biases may be introduced by the sampling procedure. The ideal sampling procedures may be difficult to formulate, however, because of the uncertainty in the definition of the population from which the selection is to be made. The population to be sampled includes not only those individuals available at the moment but also those who will engage in the activity in the future. When the population cannot be defined accurately, an estimate of the sampling variability may be secured, with some degree of accuracy, from the empirical results of successive large samples.

Since the relations determined on a sample are to be applied to some type of population in a selection process, the heterogeneity of the sample as compared with that of the population is important, especially when successive hurdles are used. As long as the obtained coefficients are to be used with the sample or with similar samples, no correction for heterogeneity is necessary. However, if the selection procedure is to be applied to a more heterogeneous population, an estimate is required of the correlation that would have been obtained had the total population been permitted to reach the final stage of performance. The general formulation of this problem has been presented by Burt (1943), by Kelley (1947), and by Thorndike (1949).

Another sampling question arises from the use of special groups for validation purposes and from the effects of experience on performance. This type of sampling may introduce irrelevant factors into the prediction equation. Since training may modify dif-

ferentially many of the traits used for prediction, it cannot be assumed that performances before and after a given amount of experience are comparable. A similar questionable assumption is frequently made in the validation of personality tests and questionnaires through the use of hospitalized and nonhospitalized groups (Wexler, 1947). These assumptions should not be made unless there exists positive evidence of their validity.

Number of predictor variables. The stability of predictions for new samples tends to decrease with an increase in the number of predictor variables in the original sample when the regression weights are determined by least squares. The addition of variables to the original set of predictors will not, however, reduce the accuracy of prediction in the original sample (Horst, 1941; Reed, 1941). In an effort to increase the stability of their predictions, psychologists try to reduce the number of predictor variables to a minimum. Two different procedures have been used for this purpose. For the prediction of a single complex criterion, batteries of two to five complex predictor variables of the broad "aptitude" type are developed. For the prediction of several criteria, different aptitude batteries would be required. Another solution attempts to develop relatively "pure" measures of the separate criterion "traits" and to combine in various ways the several tests from the single pool of predictor measures. This second procedure is defended on the basis of the increased probability of differential prediction (see the next section) as well as on the basis of general efficiency in test construction.

The importance of comprehensive coverage of all the relevant criterion traits, however, runs counter to the desirability of reducing the number of variables. The effectiveness of a selection procedure will be lessened if any significant aspect of the criterion is omitted from the predictor variables. This has been one of the frequent sources of inaccuracies of prediction (Horst, 1941).

Differential Prediction

Selection can be extended to the situation in which each individual is considered for assignment to one of several activities. This more general selection process has been variously termed *multiple selection*, *classification and differential prediction*, or *placement*. The present discussion will review the major points regarding this problem that have been raised by Brogden (1946c), Burt (1943), Flanagan (1947a, 1948), Horst (1941), and Thorndike (1949); namely, (1) the characteristics of the predictor variables used in differential prediction, and (2) the procedures used in effecting such classifications.

The basic assumption here is that a restricted set of trait measurements, differentially weighted, can be used to predict success in two or more areas of activity. For reasons of parsimony, the number of these fundamental measures should be as small as possible, and each one should be significantly related to only a few criterion measures (Horst, 1941).

From this general point of view, the tests developed for the prediction of single and multiple criteria can be contrasted. For the prediction of single criterion measures, complex tests of the miniature job-sample type resembling the criterion in content, materials, type, and complexity of task have proved efficient. These are designed to measure the hypothetical traits of the criterion in combinations resembling those found in the activity itself (Thorndike, 1949). The tests recommended for use in differential prediction, on the other hand, tend to be more nearly homogeneous measures of a single functional unity and have the advantage that, in combination, the proper weight of each trait for the prediction of each criterion can be determined. Such measures usually represent performances on thoroughly learned materials.

At the present time, two methods are used to determine the functional unities to be represented by these homogeneous tests. One involves the appraisal of the test ma-

terials by sophisticated individuals. The other method utilizes the intercorrelations among the measures and defines the functional unities in terms of high intercorrelations among those measures that may be combined, and low correlations between sets of such combined measures.

After the measures have been assembled and the regression weights for the prediction of each of the several criteria determined, the problem of the most efficient assignment of the individuals arises. The objective is to maximize the selection efficiency for the available group in terms of performance in the several activities (Brogden, 1946c; Thorndike, 1949). The attainment of this objective involves consideration of (1) the reliability of the differentiation between predicted scores as a function of the reliabilities of the measures and their intercorrelations, (2) the selection ratio and critical rejection scores, and (3) the relative importance of the activities.

For an accurate differentiation between activities to which individuals are assigned, the reliabilities of the separate scores should be comparable and as high as possible, and the intercorrelations of the measures should be minimized. If significant differences are to be located, the chance variations in individual scores should be small in relation to the between-score differences for the average individual. If the obtained differences are relatively small, as would be the case with correlated composite scores or with uniformly low multiple correlations, then relatively high reliability is required (Thorndike, 1949). The ratio of the standard deviation of a difference (in standard score form) for a given *individual* to the standard deviation of standard score differences for the *group* has been suggested for the evaluation of pairs of profile differences used in differential prediction (Kelley, 1947; Bennett and Doppelt, 1948).

Although the validity of each composite score for its associated criterion should be as high as possible, only one of the several

validity coefficients (for the different composite scores) for a single activity should be high, and all the other coefficients should be as low as possible (Thorndike, 1949). The highest coefficient should be that between the criterion measure of an activity and the composite score used to select individuals for that activity.

When the selection ratio is favorable and critical rejection scores can be established, a successive-approximation procedure for maximizing the overall effectiveness of selection is applicable. Brogden (1946c) has demonstrated that, in the linear case, efficient differentiation can be effected by establishing, first, a set of critical rejection composite scores for each activity in terms of the number to be accepted, and, second, a set of critical assignment scores equal, in each case, to the differences between the critical rejection scores. For the individuals above the critical values in two or more activities, the assignment is made to the activity for which the difference in predicted standard score units is greatest in terms of the critical difference scores. As the number of activities is increased, the complexity of this successive-approximation solution is increased.

A solution has been proposed for several special cases in which all individuals are to be assigned and no screening can be accomplished (Flanagan, 1948). Whenever individuals are to be assigned in equal numbers to equally important and equally difficult activities involving independent sets of predictor traits, each individual is assigned to the position for which his composite aptitude score is the highest. If cutting scores can be used, say, at the mean of the predicted scores, then for the case of three independent activities, seven-eighths of the individuals could be assigned to one activity with the expectation that their performance would be average or better. If some selection can take place, the individuals above the rejection values on two or more compo-

site scores are assigned to the position for which their predicted scores are highest.

In the practical situation involving differences in the difficulty levels and in the relative importance of the activities, as well as in the number of individuals required, successive selection in terms of the importance of the activity may be sufficiently accurate (Flanagan, 1948). This general problem, however, has not yet been solved.

THE COMBINING OF MEASURES

In the selection process it is often necessary to combine several measures for the purpose either of defining a single composite criterion or of obtaining predictions of future performance. The solutions to this problem can be classified as: (1) the weighting of predictor (independent) variables given some single criterion (dependent) variate, which is the ordinary multiple-correlation procedure; (2) the weighting of measures when there is no dependent variable and the multiple-correlation procedures are inappropriate; (3) the simultaneous weighting of sets of predictor measures and sets of criterion measures to effect the maximum correlation between two composite variables. The first two of these solutions are those most frequently used in selection problems. The third procedure has been criticized as inappropriate for practical selection problems (Horst, 1941; Thorndike, 1949).

Weighting with the use of a dependent variable. Two situations that can be considered as a single problem are: (1) the prediction of a single criterion measure from a set of predictor variables, and (2) the combination of sets of partial criterion measures when an ultimate criterion is available. The general solution is to weight the several measures in such a way that the weighted linear composite will conform as closely as possible to the values of the single criterion observations. If the single criterion is a quantitative one, the theoretically best solu-

tion under the least-squares principle leads to a multiple-regression equation. If the criterion is a qualitative variate, the "best" combination in the same sense is provided by Fisher's discriminant function which, for a dichotomous criterion scored 0 and 1, can be regarded as a regression-equation problem. These techniques take into consideration the intercorrelations of the measures as well as their correlations with the criterion.

The computational difficulties of multiple correlation tend to restrict the applicability of this method. Dwyer (1945), Guttman (1941), and Hoel (1947), however, provide both theoretical and computational simplifications that should extend the usefulness of the technique. Rapid approximations to the exact solutions are provided by a modification of the Kelley-Salisbury iterative solution of the regression weights developed for use in the Army Air Forces research program (Thorndike, 1949). In practice, the exact weights determined by these methods may be modified for computational convenience.

Sets of more or less arbitrary, or intuitive, weights representing the judgments of experts have been used in combining predictor or criterion measures. In spite of the "subjectivity" of such weights, the stability of these solutions, as shown by the effectiveness in new samples, may be comparable to that of the more rigorous techniques (Reed, 1941). In any case the effectiveness in prediction rather than the method of obtaining the weights is the crucial point at issue.

Another important problem associated with the multiple-correlation technique is the "regression" effect in new samples as the ratio of the number of predictor variables to the number of cases in the samples increases (see above). The generality of this fact, together with the absence of a suitable criterion for the number of variables to be used, has led to the "rule of thumb" that multiple-correlation problems should be restricted to fewer than six predictor variables

and that the regression coefficients, in any case, should be based upon large samples of individuals (Horst, 1941; Adkins, 1947; Thorndike, 1949). The actual determination of the stability of regression weights on new samples will provide the evidence for the justification of a larger number of variables.

The multiple-correlation techniques, or approximations thereto, also provide a basis for deciding which are the more "efficient" items of a test (Richardson, 1936*b*; Adkins and Toops, 1937; Flanagan, 1939*b*; Horst, 1941). The dependent variable may be either the total test score or an "external criterion" measure. For computational convenience, an assumption of equal or zero interitem correlations is often introduced, although the adequacy of the solution is thereby reduced. Detailed discussions of these techniques are given by Adkins (1947), Conrad (1944), Davis (1946*a*), Horst (1934*b*), and Toops (1941). The main objectives of item analysis are (1) to increase the internal consistency, as measured by the average interitem correlation, of the set of items, (2) to increase the predictive efficiency of some external criterion by a set of items, and (3) to locate specific faults in the construction of the test items.

Whenever the purpose is to secure an internally consistent set of items, as in the development of a measure of a single trait, the dimensionality of the set of item intercorrelations and the "homogeneity" of the responses should be considered. For the practical purposes of selection, useful approximations to this objective are obtained from the correlation of the item with the total score, since this coefficient is proportional to the average correlation of the item with all the items in the set (Richardson, 1941*a*). Rejection of items with low item-test coefficients will increase the average intercorrelation and, in this sense, the homogeneity of the set.

If the original set of items measures two or more factors, however, the final set of items selected on the basis of high item-

test correlations may contain one, two, or more factors, depending on the number of items representing each factor in the original collection. There is no assurance that the final set of items will measure only a single trait (Mosier, 1936; Sletto, 1937). If the item selection is to be accomplished through the use of the item-test coefficient, an efficient solution would be realized if the homogeneous subsets of items representing the different factors in the test were first determined, and then the several scores on the subsets and the item-subtest correlation were used for the selection of the items (Wherry and Gaylord, 1943; Davis, 1947a).

For purposes of prediction, the relation between the items used as predictors and an external criterion is determined. This relation is usually represented either by one of the correlation coefficients or an approximation thereto, or by some type of regression coefficient (Davis, 1946a; Adkins, 1947; Thorndike, 1949). One procedure treats each item as an individual test and neglects the interitem correlations. More efficient procedures using all the relevant data have been developed by Horst (1934b) and Toops (1941).

The sampling variation in item-discrimination statistics is appreciable even for samples as large as 400 cases, although the difficulty indices of items may be fairly stable (Davis, 1946b; Travers, 1942). Furthermore, unless the distribution of validity coefficients is significantly greater than that expected by chance, there is little reason to select any particular sample of items from the total test (Merrill, 1937). These sampling problems are sufficiently serious to warrant a questioning of the often mechanical application of item-analysis techniques in test construction.

Weighting without the use of a dependent variable. The basic discussions of this linear weighting problem are presented by Burt (1936), Kelley (1947), Richardson (1941a), and Wilks (1938). In general, there is no one "best" method of weighting; the differ-

ent methods accomplish different objectives. The methods may involve the simple addition of arbitrary numerical values, the use of values representing the judgments of experts, or some function of the intercorrelations of the scores and of their reliability coefficients.

The distinction between effective and nominal weights is important to the weighting problem. The nominal weights are the coefficients, W_j , of the variables in the linear equation, $T_i = \sum_j W_j X_{ji}$. The effective (or functional) weights have been defined as "the proportion of the total variance of the composite T_i that is contributed by the particular (weighted) variable $W_j X_{ji}$ " (Richardson, 1941a). The effective weight of a variable depends upon the nominal weight of that variable and its standard deviation as well as upon the weighted correlations of the variable with each measure (including itself) in turn. The correlations are weighted by the dispersions of the several measures, and the self-correlation is defined as unity.

The simple addition of scores, as in the case of a set of test items, is sufficiently accurate for the combining of large numbers of variates. The rationale for this simple procedure is that, as the number of positively correlated variables increases, the correlation between any two sets of weighted scores approaches unity and the effect of differential weighting tends to disappear. However, if the number of measures to be added together is not large, the dispersions and intercorrelations of the measures will influence significantly the effective weighting.

The method of weighting scores inversely as their standard deviations is a common practice. If the tests are considered to be of equal importance and the dispersions to be artifacts of the arbitrary characteristics of the test, then the addition of the *standard scores* of the individuals is appropriate. Richardson (1941a) has pointed out two important characteristics of this method. In the first place, if the number of variables is

three, or greater, the variance contributions of the several variables to the composite are not necessarily equal, even though standard scores are added (i.e. the nominal weights are unity). Differential weighting will occur unless the variables are equally correlated. The second point is that, in so far as the differences in the variances of the measures reflect differences in internal consistency (and reliability, in this sense), the addition of standard scores will, in effect, increase the relative weight of the less reliable tests, since the variance of the composite scores is directly related to the internal consistency of the set of measures.

If the set of measures can be regarded as parallel forms of a single test, such that the intertest correlations corrected for attenuation are unity, the measures may be weighted in terms of a function of their respective reliabilities (Kelley, 1947). This procedure is justified on the grounds that an increase in the size of the sample increases the reliability of the composite. The effective contribution of each measure so weighted to the composite is directly proportional to its reliability coefficient and inversely proportional to its error variance (Richardson, 1941a).

A related problem is that of weighting the measures so that the reliability of the *composite* will be maximal. The solution, which deals with a property of the composite, is not the same, however, as that obtained when the assumption is made that the intrinsic correlation coefficients are unity. Thomson (1940) has shown that weighting for the case of maximum battery reliability is a function of the reliabilities and of the intercorrelations of the measures.

Another theoretically important method of determining a set of weights is applicable to the combination of positively correlated attributes that are considered as separate aspects of a single variable. The same solution can be arrived at through three approaches; the scores may be weighted so that: (1) the dispersion of the composite is

as large as possible (Horst, 1936); (2) the variations between the weighted scores for each individual are minimized (Edgerton and Kolbe, 1936), and (3) the composite score for each individual best represents his standing on all the measures of the composite (Burt, 1936; Hotelling, 1933). Horst (1941) indicates that the units of measurement must be considered in these (principal axes) solutions. Since the least-squares determination of the principal axes requires the solution of the characteristic equation, the problem becomes computationally cumbersome for more than five or six measures. However, this weighting procedure has a sound rationale and is considered appropriate for the combination of a series of measures that represent different aspects of the underlying variable.

The computational difficulties associated with the principal-axes solution have led to the introduction of weighting in terms of the correlation of the variable with the average centroid axis of the system or according to the contribution to the total variance of the composite (Burt, 1936; Richardson, 1941a). Burt (1936) points out that another approximation can be secured by assuming that only one variable is being measured and by using a single-factor solution for the weights. These solutions will not differ greatly, but the accuracy of the centroid weighting as an approximation to the method of maximum variance may not be close (Edgerton and Kolbe, 1936). The centroid method is computationally feasible for relatively large numbers of variables for which either the intercorrelations of the measures or their correlations with the sum of the variables are available. The item-analysis procedures, using the item-test correlation coefficient (an internal criterion), represent applications of this method (Richardson, 1941a).

Another method of weighting measures representing various aspects of success utilizes the judgment of a "competent" group of individuals regarding the relative importance of the several elements (Horst, 1941;

Toops, 1945*b*). These judgments can be expressed in a number of ways. If there are two or more judges, each may be required to apportion among the several components of the activity a given set of numbers or "bids." The number assigned to each element represents the judge's evaluation of the importance of that aspect. The judges, in turn, can be weighted by some estimate of their competence or experience. The final set of weights can then be reduced proportionately to any desired total. The bids, in turn, may be adjusted for the intercorrelations and reliabilities of the measures. These "rational" weights can now be considered as representing the desired effective contributions of the separate measures to the composite value, but the nominal weights must still be determined. The determination of the nominal weights requires the analysis of a set of simultaneous equations that express the nominal weights as a function of the dispersions and intercorrelations of the variables and of the effective or rational weights (Horst, 1941; Bechtoldt, 1947). The error often made in the use of rational or intuitive weights lies in considering these judgments as nominal weights rather than as the effective weights.

Training

DAEL WOLFLE

American Psychological Association

The psychology of training is the applied psychology of learning. If an investigator's primary interest is in the processes by which knowledge or skill is acquired, then his studies are classified under the heading of *learning*. But, if his purpose is to investigate the teaching that goes on in school, in industry, or in a military establishment, his work is classified under the heading of *training*. Since training is the applied aspect of learning, much that is pertinent to this chapter has already been discussed in other chapters (see especially Chapter 17).

There are several excellent sources of information about learning and training. Hunter (1934) and McGeoch (1931, 1933, 1942) provide a systematic background and extensive bibliographies. Viteles (1949) discusses industrial training. Henmon (1930) and Stroud (1940) have reviewed the literature on learning in school situations. Bray (1948) and several of the reports of the Army Air Forces Aviation Psychology Program (see Flanagan, 1948) give information about military training programs of World War II. Flanagan and a number of collaborators (1948) have reviewed the literature on training in World War II, and Wolfle (1946) has summarized the principles of learning that were most useful in the training of military specialists.

FACTORS DETERMINING THE EFFECTIVENESS OF TRAINING

A number of general principles of learning have emerged from laboratory studies and from industrial, military, and school experience. Six of them are discussed in this chapter. These six principles are concerned with variables that can be manipulated under practical training conditions. They are:

1. Knowledge of results.
2. Avoidance of habit interference.
3. Variety of practice materials.
4. Methods used in training.
5. Knowledge of principles involved.
6. Effectiveness of guidance.

Knowledge of Results

Laboratory studies are unequivocal in emphasizing the importance of giving a subject as specific and as immediate information as possible concerning the outcome of his efforts. An excellent illustration of this principle is found in a study by Trowbridge and Cason (1932). In a repetition of one of Thorndike's line-drawing experiments, they found no improvement in 100 attempts to draw a 3-inch line unless the subjects were told whether or not their attempts had been satisfactory. The results are given in Table 1. These data also demonstrate the value of making the information as exact as

TABLE 1

EFFECT ON LEARNING OF GIVING SUBJECTS DIFFERENT AMOUNTS OF INFORMATION ABOUT RESULTS ON EACH TRIAL (AFTER TROWBRIDGE AND CASON, 1932)

Information Given Subjects after Each Trial	Average Errors in Inches		
	First 30 Trials	Middle 40 Trials	Last 30 Trials
None (control group)	0.75	0.86	0.80
Nonsense syllables	1.11	1.07	1.05
"Right" or "wrong"	0.92	0.67	0.49
Exact information	0.24	0.14	0.12

possible. Subjects who were told the amount and direction of error in each trial improved much more than did subjects told simply that each trial was "right" or "wrong."

learning situations the relation between length of delay and effectiveness is described by an exponential or negative growth function.

There is good evidence that knowledge of results can be as valuable in acquiring industrial or other practical skills as in learning laboratory problems. Biel et al. (1944), in training men to use Army gun directors, found it desirable to use a checksight through which an instructor could follow the target and know at all times how accurately the tracker was keeping the gun on target. When the instructor sounded an electric buzzer to indicate that the tracker was off target, men learned to track more

FIG. 1. Relation between amount of delay in reinforcement (knowledge of results) and strength of habit formed. The points represent the amount of learning for constant numbers of reinforcements. The delay in reinforcement was different for each of eight groups of albino rats. As the delay increased, the amount of learning decreased. (After Hull, 1943; data from Wolfe, 1934.)

The subject should be told his results not only as precisely as possible, but also as soon after each trial as possible. This principle applies to both animals and men. Thus the data for rats shown in Fig. 1 demonstrate a rapid loss in effectiveness as the delay increases. Hull (1943) analyzed a number of studies on this problem and came to the general conclusion that in typical

accurately than when they were not told their results. The experimental data are presented in Fig. 2. Lindsley (1943) reports that a group of radar operators who were not enlightened about their progress on successive trials became less and less accurate as practice went on for 6 days.

The knowledge of results in training programs should be automatic, immediate, and

meaningfully related to the task being learned. Two studies of the learning of radio code illustrate how this kind of information can be given to men in training.

A man's first task in becoming a radio operator is to learn the sound patterns (dots and dashes) that represent the 10

FIG. 2. Effect of knowledge of results in learning tracking. The solid lines represent practice given with knowledge of results (a buzzer sounding whenever the tracker was off target); the dashed lines represent practice given without knowledge of results. With both groups of subjects improvement occurred when knowledge of results was provided; practically no improvement occurred without it. (After Biel et al., 1944.)

digits and the 26 letters of the alphabet. In the past, many methods have been used to teach this basic information. Keller (1943, 1945) developed an improved method based on the assumption that learning would proceed most rapidly if the learner was told immediately after hearing each character just what that character was.

A double row of squares (see Fig. 3) was provided for each set of characters. When the first character was sent, for example *R*, the student wrote its name in the first box of the upper row. Three seconds later when

the instructor named the character, the student did nothing if he had written *R*. Then, having heard the character, having tried to name it, and having been told what it was, he heard it, and named it, again. When the student did not recognize a letter, as in the third box, or made a mistake, as in the fifth, the instructor's naming of the letter allowed immediate correction. This was called the code-voice method of teaching radio code.

The code-voice method also capitalized on the superiority of whole over part methods

R	R	-	V	F	L				
		V		L					

FIG. 3. Sample row of the record sheet used in the code-voice method of teaching radio code. When the trainee hears a letter, he writes it in the upper box. If he makes an error or does not recognize a letter, he writes the correct letter in the lower box when the instructor names it 3 seconds later. (After Keller, 1945.)

by including "whole-learning" as one of its features. The previous Army method had divided the 36 characters into several groups. One group was learned, then a second, and so on, until all were mastered.

The superiority of the code-voice method of teaching the characters over the method previously used in the Army is evident in Table 2. Instead of requiring an average of

TABLE 2

SUPERIORITY OF CODE-VOICE METHOD OF TEACHING INTERNATIONAL MORSE CODE OVER PREVIOUS ARMY METHOD (AFTER KELLER, 1945)

Training Method	Number of Men	Hours Required to Pass 5 Words per Minute		Per Cent Who Failed to Pass 5 Words per Minute
		Mean	S.D.	
Code-voice Standard Army (Z-tape)	253	26.57	7.93	3.4
Standard Army (Z-tape)	74	34.78	15.47	15.0
	446	40.87	22.78	

35 or 40 hours of practice to attain a speed of 5 words per minute, men trained by the code-voice method averaged less than

27 hours of drill. Instead of 15 per cent of them failing altogether to attain this speed, only 3.4 per cent failed to qualify.

An excellent demonstration of a teaching device that automatically informs the learner of his correct and incorrect responses is the code-actuated typewriter devised by Bennett and Langmuir (Bennett, 1945). This typewriter prints in ordinary type exactly what the student radio operator sends in code. The letter *M*, for example, consists of two dashes. If the operator sends two dashes of the correct length with a pause between them approximately one-third as long as the dashes, the typewriter prints *M*. The absolute length of these dashes is unimportant. The typewriter records accurately so long as the dots, and the pauses within a letter, are one-third as long as the dashes.

When the student operator makes an error, the typewriter tells him just what he has done wrong. If his first dash for an *M* is too short, the typewriter prints *A*, the symbol for which is a dot and a dash. If the second dash, instead of the first one, is too short, the typewriter prints *N*. If the space between the two dashes is too long, the typewriter prints *TT*. If the operator makes both the first dash too short and the pause too long, the typewriter prints *ET*. When the pauses, the dots, and the dashes of any character are all correct, the operator has the immediate satisfaction of seeing the correct letter appear.

The use of this typewriter illustrated another desirable feature of training devices: radio men accepted it and liked to practice on it.

The illustrations used so far have dealt with the acquisition of skill. In some training the major emphasis is not on skill but on acquiring a body of knowledge. In such cases examinations are useful. To be of greatest aid to learning, examinations should give precise information regarding the nature of errors. The better tests used to diagnose difficulties in the learning of school

subjects attempt to provide this kind of information.

In constructing either an examination or a scoring device, it is necessary to consider the purpose for which it will be used. Sometimes motivation of the learner is of primary importance. Successive scores should then show improvement. Sometimes the major purpose is to discriminate accurately among a group of trainees in terms of the level of skill that each has attained. It is well known that, when discrimination among different ability levels is the purpose, the difficulty of the examination should be set at the point where the average member of the group receives a score of 50 per cent. The same principle applies to scoring devices: they should be so set that the average member of the group gets a score of 50 per cent. By making the scoring device adjustable, as Kappauf (1945b) did in designing a photoelectric instrument for measuring the accuracy of gunners in training, it is possible to adjust scoring limits to secure an average score of 50 per cent for any group of trainees.

The two objectives of motivating the men and discriminating among them may sometimes conflict. If successive scores are obtained on a group that is learning a task, higher scores on later examinations show the trainees that they are improving. But higher average scores (above 50 per cent) decrease the accuracy with which various levels of skill can be differentiated. Both objectives can sometimes be achieved by giving the trainees examinations of increasing difficulty but reporting to them increasingly higher scores. In other situations, requiring the same level of accuracy at successively higher speeds may satisfy both objectives.

Avoidance of Habit Interference

Learning is always slower if one has to learn several alternative responses to approximately the same situation. This interference with learning has been experiment-

ally studied under the headings of habit interference, negative transfer, and proactive and retroactive interference. The interference may occur in the learning of what is usually thought of as a single task, or it may arise in the successive learning of similar tasks.

Viteles gives an interesting personal account of habit interference. In preparation for research on the selection of streetcar motormen, he took the normal training given to new men. After preliminary schoolroom training, he was sent out on a regular run with an experienced motorman as his tutor. The next day he had a different tutor. For 10 days he continued, each day with a different motorman teaching his own preferred methods of handling the streetcar controls. The effect of being taught to respond to similar situations in a variety of ways, some of which were wholly antagonistic to each other, was, as Viteles summarized, "to create interference in habit formation—a condition which retards the development of skill, lengthens the training period, and promotes an uncertainty of response which continues after the close of the training period" (1932, pp. 396–397).

Habit interference arises when partially overlapping stimulus patterns are expected to elicit different responses. If a situation containing elements a, b, c, \dots, n is intended to elicit one response and a situation containing elements h, i, j, \dots, z is supposed to elicit another, confusion arises because of the presence of the common elements $h \dots n$ in the two situations; either situation may lead to either response. Whether the two "responses" constitute alternative methods of performing an act, as in Viteles' experience, or are different acts with different purposes, depends upon one's definition of *response* and is irrelevant for this discussion.

The amount of overlap between the two stimulus situations may vary between complete identity and complete dissimilarity. Likewise, the degree of similarity in the two responses may range from identity to com-

plete dissimilarity. No thorough research analysis of all interrelations of these two variables has been made. But the study by Bruce (1933), coupled with the other work that has led to the principles of stimulus generalization and response generalization, justify the following hypotheses:

1. The greater the similarity between the two stimulating situations, the greater should be the similarity between the two responses if habit interference is to be avoided.

2. The greater the similarity between the two responses, the greater should be the similarity between the two stimulating situations if habit interference is to be avoided.

From these hypotheses it follows that both the stimulating situations and their responses should be made either as little alike as possible or as much alike as possible. In the first case, the absence of overlap will mean that two noninterfering, and also non-reinforcing, habits will be learned. In the second case, the similarities between the two stimulus-response situations will mean that the principles of generalization and positive transfer will facilitate learning. An outstanding example is the adoption of the standard gearshift in automobiles of different makes. The resulting ease with which a driver can switch from one make of car to another should serve as a lesson for industrial designers.

McGeoch (1942) concluded that habit interference is greatest when the learning of the second habit system is incomplete. It is then in competition with a well-established habit elicited by a similar stimulus situation. Under these conditions the old instead of the new response may occur.

The amount of interference between two activities is in part a function of the degree of proficiency attained in both of them. Negative transfer appears to be at a maximum when the degrees of learning of the first and second activities are similar (Siipola and Israel, 1933). The little experimental evidence on this point is in agreement with the experience of airplane pilots that they

are not disturbed by the different locations and operations of the controls when they first start to fly a new type of plane, but that interference, occasionally with disastrous results, is more likely to occur after they think they have become thoroughly accustomed to the second set of controls.

The reason for greater interference when both sets of habits are of about equal strength is obscure. Apparently minor factors can shift the balance from one habit system to another when the two are of nearly equal potency.

If training goes on long enough, habit interference may completely disappear (McGeoch, 1942, p. 429). Harlow (1949) has demonstrated this point in training a group of monkeys on a long series of similar visual discrimination problems. After learning a number of such problems, many subjects needed only one trial to find out which object was correct in any new problem; subsequent trials were then made correctly until another new problem was introduced.

In training situations in which habit interference is likely to develop, certain safeguards may be used to minimize its disturbing effects:

1. Careful analysis of the skill to be learned and indoctrination of all teachers in the same methods of teaching will eliminate part of the interference of the kind described by Viteles.

2. Beginning training on a later habit system only after the preceding ones are fairly well established will reduce the amount of interference.

3. Either standardizing both the stimulating situations and the responses as much as possible or making them as different as possible will eliminate interference.

Variety of Practice Material

Variation of stimulus conditions has regularly been employed in learning experiments to prevent the subjects from learning something in which the experimenter was not interested. In discrimination studies the cor-

rect stimulus appears sometimes on the right and sometimes on the left in order to keep the subject from learning a position habit. The order of pairs of words in a paired-associates study is varied to keep the subjects from learning on the basis of position in the series. For the same reason, practice material used in training typists or radio operators is varied. In all these illustrations, variation of irrelevant parts of the task forces the learner to respond to the critical aspects of the stimulating situation.

A number of military schools violated this rule during World War II. Men in training were given an inadequate variety of targets to track, casualties to repair, messages to record, or radar images to interpret. The result was that, although they learned to respond correctly to the particular materials used in training, they were not able to respond adequately to the somewhat different situations encountered later on the job. As a general rule, practice materials should vary in as many dimensions and over approximately as wide a range as will the situations to be encountered when the learning is to be applied.

Although emphasis is here placed upon the importance of varying practice material, it must be recognized that variation decreases the speed of learning. Wolffe (1935) has demonstrated that the speed of learning decreases regularly as the extent of variation in the practice material increases. Figure 4, curve A, plots the slopes of the learning curves for five groups of subjects learning a high-relief finger maze. All trials given group 1 were on the same maze. Subjects in group 2 were presented with two mazes. The alleys of one were 10 per cent longer than the corresponding alleys of the other. Variation in size increased until group 5 had randomly arranged trials on mazes of five different sizes. The learning curves for each group were plotted on semilogarithmic paper and were fitted by the equation $Y = a - bX$, in which Y represented the error scores, and X the trial number. The

slopes of these curves, the b values, are plotted in Fig. 4.

Curves B and C show comparable data for two other experiments of the same type. Curve B summarizes an experiment by Grether and Wolffe (1936) in which groups of rats learned a visual brightness discrimi-

FIG. 4. Relation between amount of stimulus variation and rate of learning. In each of three experiments, different groups of subjects were taught essentially the same problem. Each group learned the problem with different amounts of stimulus variation during the learning trials. The ordinate values are slopes of the learning curves ($Y = a - bX$). (The slopes plotted in curve B were divided by 10.) (After Wolffe, 1935, 1936; and Grether and Wolffe, 1936.)

nation problem under different degrees of stimulus variation. Curve C (Wolffe, 1936) is from a study in which human subjects learned paper-and-pencil mazes in which the pathway within each unit of the maze was systematically varied.

All three curves demonstrate that increasing the amount of stimulus variation decreases the rate of learning.

On the other hand, if training is prolonged and monotonous, variety in the practice materials may speed up learning instead of retarding it. Seashore et al. (1944) attempted to combat monotony in the training of radio operators by using a great va-

riety of drill materials. Men trained under these conditions learned more rapidly than did men having less varied drills.

Relatively little consideration has been given the problem of how variation of practice material influences the transfer of a learned response to new situations. Luborsky (1945) found in an aircraft recognition class that previously unseen and briefly exposed silhouettes of airplanes were recognized more accurately if five different silhouettes were used during training than if only three were used. It seems probable that variation of the material used during learning will generally increase the range of conditions under which the learned act can be correctly applied.

All stimuli on any continuum may be represented by points on a line such as that drawn in Fig. 5. The curve above the line represents the likelihood that any given stimulus will elicit the response being learned. This curve will be at a maximum for the stimulus used during training. How it falls off on either side of its maximum is the problem of stimulus generalization, which has been investigated systematically by Hovland (1937a, b). The data of Hov-

FIG. 5. Curve of stimulus generalization. The height of the curve shows the likelihood that a response will be given to stimuli, on the stimulus continuum, that are different from the one used during training.

land's experiments were well fitted by curves concave upward, similar to the traditional forgetting curve. His data, however, do not warrant the conclusion that the curve on each side of the training stimulus is concave upward over its entire course. The closest point to the stimulus that Hovland investigated was 25 jnd away. What shape the curve takes within the range between 1 and 25 jnd is still unknown. A wealth

of psychophysical experiments suggests that the complete curve is probably inflected on each side. It has therefore been given a bell-shaped form in Fig. 5.

If training is given at several points on the stimulus continuum, there will be several curves of stimulus generalization. Exactly how they will reinforce one another has not been carefully investigated. As a starting point, we may assume that the several curves will summate, approximately as is

Methods Used in Training

In any learned act there is both a method of doing the job and a product or end result of the work. Under many circumstances learning proceeds more rapidly if emphasis is placed upon the process to be learned rather than upon the product to be achieved. Athletic coaches pay attention to this distinction and customarily emphasize correct *form* in athletic skills. Despite occasional unorthodox champions, it is generally as-

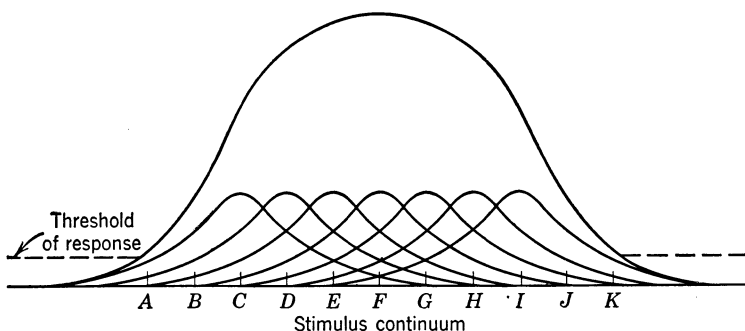

FIG. 6. Summation of several response generalization curves to produce a superthreshold response tendency over a wide range of the stimulus continuum. The upper curve is the summation of the individual curves of stimulus generalization.

shown in Fig. 6.* This figure indicates that the response tendency remains above the threshold level over a wider portion of the stimulus continuum than it does when training is confined to a single point, the condition represented in Fig. 5.

The optimal range of variation to employ during training is unknown, but well worth investigating. Until experimental results provide information, it is probably safe to advise variation over a major portion—but not over the entire extent nor at every point within it—of the range within which generalization is desired. For example, if Fig. 6 is used as an illustration, practice given at several places within the range from point C to point I should prove satisfactory if application over the range from A to K is desired.

* Hull (1943, p. 195) has used a similar curve to explain how several subthreshold stimuli may summate to superthreshold values.

summed that the best performance can be achieved by athletes who use the “proper” muscular coordination. The difference between product and process is especially clear in swimming, where a number of different strokes have been developed and where races are run and records kept in terms of each. A swimmer who used the crawl would be disqualified in a breaststroke event, even if he won the race.

The kinds of learning in which it is advantageous to emphasize the methods used and those in which it is advantageous to emphasize the end products have never been clearly differentiated. However, in tasks that depend to a considerable extent upon symbolic or intellectual components, it is usually advantageous to give the learner information about the best methods of working on his task.

Woodrow (1927) measured the memory span of three groups of subjects and the

ability of each group to memorize poetry, prose, a set of facts, a list of historical dates, and words from a Turkish-English vocabulary. Four weeks later all three groups were given a parallel set of tests of ability to memorize. During the intervening weeks one of the groups served as a control and received no training or practice. The second (practice) group was given 90 minutes of practice in memorizing poetry and 87 minutes of practice in memorizing nonsense syllables. The third (training) group was given 76 minutes of instruction on effective methods of learning, 25 minutes of practice in memorizing nonsense syllables, and 76 minutes of practice in memorizing poetry.

The practice group did not surpass the control group by a significant amount on any of the final tests. On the other hand, the group given training in how to memorize surpassed both of the other groups on every test by amounts that gave *p* values at the 1-per-cent level or better.

The method of learning a maze was found by Husband (1931) to influence the rate of improvement and by Wolfe (1935) to influence the extent to which variation interfered with learning. A comparison of "verbal" and "motor" learners is given in Fig. 7. When the same maze was used on every trial, verbal learners progressed about one-and-a-half times as rapidly as motor learners. When mazes of five different sizes were used in training, verbal learners progressed two or three times as rapidly as motor learners. It is a plausible hypothesis, and one worth testing, that the savings to be gained by employing better methods of learning increase with an increase in the difficulty of the task.

Lindahl (1945) has demonstrated that careful analysis of an industrial process may improve the learning of beginners as well as the production of experienced workers. The task studied was that of contact disc cutting in which a thin abrasive wheel in the cutoff machine is used to slice thin discs from the end of a tungsten rod.

The cutoff machine depends for successful operation upon the speed, form, rhythm, and pressure pattern of the hand and foot action of the operator. Failure to apply foot pressure properly results in damage to the discs, excessive breakage and use of wheels, and wastage of material. [1945, pp. 420-421.]

By comparing paper tape recordings of the foot movements of individual operators with their work records, he selected the pat-

FIG. 7. The relation between amount of stimulus variation and relative efficiency of verbal and motor learning methods. The ordinate values represent the ratios of the slope of the learning curve for verbal learners divided by the slope of the learning curve for motor learners. Greater ordinate values represent relatively greater superiority of verbal over motor methods. (After Wolfe, 1935.)

tern of foot movement shown in Fig. 8 as a standard to be taught to new workers.

Figure 9 shows the course of improvement of a sample worker; after 239 hours of supervised operation his foot action closely approximated the standard pattern.

Weekly production records for new employees trained by this method were compared with production records of older employees. With 11 weeks of training the new employees reached the level of performance of those who had been on the job for 5 months. After 10 weeks of operation the newer trainees were breaking fewer wheels than were other operators with an average of 9 months of experience.

English (1942) reported an experiment conducted in 1918 on one of the factors involved in success at rifle shooting.

Recruits are instructed to squeeze the stock of the rifle as well as the trigger, the whole hand participating in the movement as if in squeezing a sponge. Unfortunately, they do not adequately respond to these excellent and clear verbal instructions. [1942, p. 3.]

The stock of a rifle was hollowed out at the place where the last three fingers should

his squeeze reaction. This continued until he could fire invariably with a proper squeeze. [1942, p. 4.]

Concentrated training on the proper method of squeezing the trigger produced satisfactory learning in subjects who had failed to learn when attention was directed at the target.

FIG. 8. A view of the disk-cutting cycle. (From Lindahl, 1945.)

press. A rubber bulb and tube were inserted and covered with a wooden plate supported by springs. To casual inspection the stock appeared normal. But a correct squeeze depressed the wooden plate. Air forced out of the bulb activated a tambour on a kymograph or changed the level of liquid in a U-tube.

The recruit was thus enabled to compare visually his own squeeze with that of an expert. If his squeeze was inadequate, he continued to practice firing, at first watching the tube, then aiming at a target without watching the tube but informed each time of

FIG. 9. Disk cutter foot-action patterns of a trainee, showing improvement with training. The records were made after 9, 45, 141, and 239 hours of supervised operation. (From Lindahl, 1945.)

The advantage of teaching correct processes may also show up when workers are transferred to new jobs. When he later tested their ability to work on a somewhat different assembly task, Cox (1934) found

that specialized training designed to teach effective work methods to lampsocket assemblers was more effective than an equal amount of time spent in unguided practice.

It cannot be concluded, however, that emphasis on process is always desirable.* A skilled act involves both motor and sensory components. On the motor side, skill consists of precise timing, coordination, and control of effort. On the sensory side, it requires a response to small changes in stimulation. In some acts the controlling stimuli are self-initiated. The cutoff operators studied by Lindahl and the riflemen studied by English are examples. Although these subjects utilized other sensory data, their skill consisted of precise movements that were in large part controlled by the kinesthetic impulses aroused by the movements.

In some other acts the controlling stimuli are not self-initiated. Examples are: learning to follow in ballroom dancing, learning to parry an opponent in boxing or fencing, or learning the pointer-matching skills required by some kinds of military fire-control equipment. Skill in these acts consists of coordinating one's movements with cues that are not self-initiated.

The way in which we learn these two kinds of skill and the best methods of teaching each may be quite different. Careful experimentation in this area is needed before we can know the best methods of teaching all possible skills.

Knowledge of Principles Involved

Learning is generally faster and transfer is generally greater if the learner understands the principles underlying the task on which he is working.

In a frequently cited experiment Judd (1908) trained two groups of boys to shoot at a submerged target. Boys given an explanation of refraction did not learn any

more rapidly than did boys not given that explanation, but they adapted more quickly to a change in the depth of the target.

Hendrickson and Schroeder (1941) have reported a similar experiment. Three groups of 14-year-old boys (thirty in each group) learned to shoot an air rifle at a submerged target, 6 inches below the surface of the water. After satisfactory performance was achieved, the target was raised to a point 2 inches below the surface. Further trials were given until a satisfactory score was achieved. Scoring was lenient enough so that, once they discovered the fact that a correction for refraction was necessary, all the boys were able to achieve good scores. Marksmanship was not involved, in other words.

The control group was given no information concerning refraction. A second group (experimental group A) was given a written explanation of refraction. The third group (experimental group B) was given the same explanation plus the specific information that changing the depth of the water changed the amount of refraction.

The results in terms of the mean number of trials required to make a satisfactory score are given in Table 3. The amount of

TABLE 3

EFFECT OF KNOWLEDGE OF PRINCIPLE INVOLVED ON RATE OF LEARNING AND AMOUNT OF TRANSFER (FROM HENDRICKSON AND SCHROEDER, 1941)

Group	Mean Number of Trials Required		Gain in Trials	Per Cent Improvement
	At 6 in.	At 2 in.		
Control	9.10	6.03	3.07	34.1
Experimental A	8.50	5.37	3.13	36.5
Experimental B	7.73	4.63	3.10	40.3

transfer from the 6- to the 2-inch depth is shown for each group by the average number of trials saved and by the percentage of improvement. None of the differences was large enough to be taken with complete con-

* Renshaw and Postle (1928) reported that detailed instructions on a pursuitmeter task interfered with learning.

fidence (critical ratios varied from 0.49 to 2.34), but all were in the direction expected on the assumptions (1) that providing the boys with information about the principle of refraction would speed up learning and (2) that, the more specific their knowledge, the more effectively would it aid learning and transfer.

Waters (1928) and Katona (1940) investigated the relative value of different methods of teaching college students to solve simple reasoning problems. Showing the student the solution to one or two of the problems aided him very little in the solution of subsequent ones. Telling him the general principle upon which the problems were based aided somewhat more. Giving him a selected series of problems that enabled him to work out the principle for himself resulted in the most rapid learning or the greatest amount of transfer to later problems.

The findings of Waters and Katona point out a difficulty with the experiments of Judd and Hendrickson and Schroeder: knowledge of the principle upon which a problem is based does not mean that the subject can proceed to employ the knowledge successfully. The principle must be in a form and at a level the learner can comprehend.

McGeoch concludes a summary of the transfer of general principles from one activity to another with the statement:

General principles are one of the most important vehicles of transfer, but the acquisition of a principle does not guarantee that it will be used wherever it is applicable. . . . The probability that [it] will be much higher if the subject is taught, or given a *set*, to apply the principles learned and is taught to analyze similarities between old and new situations. [1942, pp. 422-23.]

The Effectiveness of Guidance

Does it help a person to learn a motor task if he is guided through it several times during the early stages of learning? This question was investigated by Carr and several of his students, using both human and

animal subjects on several different tasks. Various kinds of guidance were given in different amounts and at different places in the series of learning trials. Guidance was found to be an aid, provided it was not overdone. Two to four guided runs through a maze aided learning if given early in the series of training trials. The effectiveness of guidance decreased as its amount increased and as its point of introduction got farther away from the beginning stages of practice. This reduction in effectiveness was great enough that, if given at the wrong time or in too large amounts, guidance interfered with learning. Sample results from Koch (1923) and Ludgate (1923) are presented in Figs. 10 and 11.

An interesting result of these studies was the finding that giving guidance in the learning of one maze increased the amount of transfer to a second maze. Whether this result would appear with other learning materials is unknown.

Two conclusions from the studies on guidance are probably applicable to a wide variety of situations: (1) "The most effective results were generally secured by giving a small amount of tuition relatively early in the process of learning" (Carr, 1930, p. 204); (2) all the experiments showed that, despite its benefits, guidance cannot completely replace actually doing the job to be learned. If a trainee is to acquire skill, he must perform the task himself without outside aid.

Interaction among the factors determining the effectiveness of training. The factors influencing the effectiveness of training are many. A change in motivation may completely nullify the effects of an improved instructional method, or it may overcome the effects of less satisfactory teaching methods. Differences in the way men are selected for a task may require radical changes in the kind and amount of instruction necessary to prepare them for useful work. Changes in the design of the equipment they use may alter selection requirements and necessitate

changes in the kind of instruction. The industrial worker's motivation is partially determined by the whole social situation of employee-employer relations and of labor union attitudes and regulations.

contrast, found that the specific method of teaching did not matter. Keller was using a normal Army population being trained under Army conditions. Taylor was teaching a group of very superior civilian volunteers. The average level of ability, the distribution of practice, and the motivation were quite different for the two groups of subjects. What a student learns is partly determined by his teachers and their teaching methods, but probably to a much greater

FIG. 10. Effects of guidance on number of trials required to learn a maze. In general, two or four guided trials given at the beginning of training decreased the total number of trials required to master the maze. (After Koch, 1923; Ludgate, 1923.)

The interaction of all these factors frequently makes it difficult to determine the effect of changing a single feature of the whole training situation. As reported above, Keller (1945) found that a change in the method of teaching International Morse Code produced substantially fewer failures and more rapid learning. Taylor (1943), in

FIG. 11. Effect of location of four guided trials on the number of errors made in learning a maze. In all three studies, guidance given on trials 1 to 4 resulted in fewer errors than when no guidance was given and fewer than when the guidance was introduced later in the series. (After Koch, 1923; Ludgate, 1923.)

extent his learning is determined by his ability, motivation, and work habits. The variance of performance due to these differences may be great enough to mask small effects due to different teaching methods.

In spite of the fact that interaction is the rule rather than the exception, appropriately designed experiments can provide a good deal of information on the nature of different kinds of learning—information that will permit the planning of more effective training programs for industrial and military personnel.

ADMINISTRATION OF A TRAINING PROGRAM

An effective training program requires the solution of both administrative and psychological problems. Ghiselli and Brown (1948) and Viteles (1949) provide a general introduction to these problems and discuss a number of the social and personal adjustment aspects of industrial training that are not touched on in this chapter. Two publications of the War Manpower Commission (1945*a*, *b*) are based upon extensive experience in training war workers. Brief guides by Gardiner (1943) and Maxcy (1943) on how to train workers quickly illustrate the type of literature prepared for industrial use. Cushman (1940) and Hayes (1940) discuss the problems of teaching foremen or other industrial workers to serve as instructors of new employees. Hayes' paper discusses methods by which foremen can enhance morale, motivation, and cooperation within the plant. Morgan (1945) has outlined what he considers the most desirable organization for the training department of an industry.

Three problems of administering a training program that can in large part be answered by psychological techniques are:

1. What should be taught?
2. What teaching aids can be usefully employed?
3. How long should formal training continue?

Determination of what is to be taught. Selection of what to teach obviously depends upon what the learners are to do with the skill or knowledge acquired. Unless

this information is available, trainees are likely to be given too much training on some points, not enough on others, and inappropriate instruction on still others. In order to avoid giving inappropriate training, job analyses have frequently been made to obtain exact descriptions of the duties to be performed and hence the skills to be acquired. Zerga's bibliographies (1943, 1944) on job analysis and on motion and time study can be used as a starting point for investigating the literature in this field.

Whether information on job analysis is used in planning training or not, the training is likely to get out of date unless constant effort is made to modify the training course to correspond with changes in the job. The introduction of new equipment or new work methods should lead to immediate examination of the training program to see what changes should be made in it.

The typical job analysis is made by a job analyst who observes the worker and records what he does and how he does it. It is, in a sense, an external description of the work being performed. As such, it supplies useful information on which skills are used most frequently, which sequences of movements are most economical, and what the trainee will be called upon to do at the conclusion of his formal training.

From the standpoint of research on training, a different kind of job analysis, one that describes the task in terms of its psychological components instead of in terms of its work units, could frequently contribute additional information of value. By making such analyses psychologists were able to suggest a number of improvements in the training of World War II military specialists. Lindsley's work on Navy radar-operator training is an example (Lindsley, 1945, and quoted in detail by Bray, 1948).

The use of training aids. Blackboards, models, book illustrations, lantern slides, and demonstrations have long been used as training aids. Since in the judgment of hundreds of teachers these devices are important aids

to learning, World War II with its tremendous pressure to save training time saw the development of a great variety of more elaborate aids: working models, cutaway models, multicolored charts with transparent overlays, electric circuits spread out on large panels, and many, many motion pictures. There had been a few research studies, but the wartime development was founded more on enthusiasm than on evidence. That enthusiasm, however, provided the stimulus for postwar research on the usefulness of training aids. When the reports of these studies become available, we should begin to have more systematic knowledge of how best to include training aids in a training program.

Dale and Gibbony (1948) and the American Council on Education catalogue (1948) list a number of references useful to anyone seeking either specific audiovisual aids or information about the use of such materials.

A second kind of teaching aid is a synthetic trainer, a device that provides a substitute for practice under actual operating conditions. Perhaps the best known example is the Link Instrument Trainer which provides an airplane pilot with an opportunity to gain experience in controlling an airplane without leaving the ground. Other synthetic trainers have been designed to train aircraft pilots, bombardiers, navigators, gunners, radar operators, submarine crews, and other types of military specialists. Some of these trainers have peacetime applications to justify their continued use and development.

A synthetic trainer involves many of the problems of an entire training program. Kappauf (1945a), Viteles (1945), and Wolffe (1945) have discussed the psychological factors involved in the design and use of synthetic trainers. It is necessary to include a scoring system that will provide a trainee with knowledge of the results of his practice. It is necessary to avoid habit interference. It is necessary to provide an adequate variety of practice materials.

A synthetic trainer should keep the trainee informed of his progress. Automatic counters, tape records, timers, photoelectric scorers, and similar devices usually make it possible to provide knowledge immediately upon the conclusion of each trial or practice period. Ideally, the scoring device should provide specific information concerning the nature of the pupil's errors.

The scoring system should be so designed that the tolerance limits of acceptable performance can be adjusted to the level of skill of the man being trained, as noted previously.

A trainer should present the same psychological problems that the learner will encounter later in performing his task. If it does not, the validity of the trainer will be low and the trainee will experience habit interference when he transfers from the trainer to the supposedly similar equipment he is being taught to handle.

A synthetic trainer must provide an adequate variety of practice material. This requirement is not difficult to meet if its importance is recognized when the trainer is being designed. For then it is easy to prepare a sufficient number of alternative templates, cams, films, or other devices for controlling the tasks set by the trainer. Variety can sometimes be provided by making it possible to begin practice at any point within the problem or sequence of problems set by a particular cam, film, or other controlling device.

The validity of a synthetic trainer can never be taken for granted, but must always be determined experimentally. Determination of the validity of a trainer follows the methods for measuring transfer of training from one situation to another. (Gagné, Foster, and Crowley, 1948, have systematically compared these methods.) If there is positive and appreciable transfer from the trainer to the actual situation, the validity of the trainer is established. The value of practice on the trainer need not be

so great as the value of an equal amount of time spent in practicing on the actual equipment, for frequently that equipment is unavailable or is too expensive or too dangerous to be used by beginners. But, unless there is some transfer, the trainer has no value.

A number of studies of trainers and training aids are now being conducted in university and other research laboratories under the auspices of the United States Navy's Special Devices Center (Mead, 1949).

The duration of training. Accurate performance records may be used to determine the appropriate time at which to stop training. In some situations formal training can be stopped before the learning curve reaches an asymptote because an acceptable level of proficiency has been reached or because the men will be put onto productive work where learning can continue. Ghiselli and Brown (1947), for example, found in a study of accident records of streetcar motormen and motor coach operators that accident rates continued to decline steadily throughout the first 17 months of operation. The men had all had from 2 to 4 weeks of training before being put onto regular runs and were, at the end of that time, judged ready for regular operation. Yet learning continued; the average number of accidents at the end of 17 months was less than half the average for the first month of regular operation.

Performance records may show that an inadequate amount of time has been devoted to training. Baldwin and Lindsley (quoted by Bray, 1948) studied the Army Air Force training program for radar bombing operators. They found that giving between three and four times the customary amount of training resulted in a large increase in bombing accuracy.

In general, a learning curve for a group as a whole or for each individual shows when an acceptable level has been reached. Men can then be transferred from a training to a production status.

PROBLEMS OF CONDUCTING RESEARCH ON TRAINING

In planning research on training, the investigator encounters all the problems of laboratory research and more besides. Thorndike (1947) has discussed these problems under the headings used below.

Defining the research problem. In research on a practical training problem, the problem itself should be sharply defined. Will x hours of such-and-such kind of practice on trainer A produce a higher or lower average score on criterion y than will an equal amount and distribution of practice on trainer B ? Will trainees who see this motion picture spoil less material than trainees who spend that hour in normal shop work?

Precise definition of the research problem to be studied is necessary in order to determine:

1. What criterion will be most appropriate.
2. What administrative difficulties are likely to interfere with the study and how they can be circumvented.
3. What experimental design will secure the maximum amount of information concerning the question at issue.

Criteria of training success. If research on training is to be conducted, the effects of training must be measured. Two general types of criteria may be used—a criterion internal to the training, or one external to it. An internal criterion is one that measures improvement or changes within the course itself. The examinations in academic courses, the learning scores in most laboratory experiments, or skill in using a synthetic trainer are internal criteria. An external criterion is one that is outside the course itself. The combat efficiency of military personnel is an external criterion of the adequacy of the preliminary military training. Success on the job is an external criterion of industrial training.

Research on training is frequently planned in coordination with research on selection.

In both cases a criterion is necessary. Frequently the same criterion can be used to measure the efficiency of a selection device and the effectiveness of a training program. The ultimate aim of both selection and training is job proficiency. Consequently, the external criterion of success on the actual job is always to be preferred as a criterion. There are, however, two situations in which an internal criterion may be justified.

1. Sometimes the training situation corresponds so exactly to later work situations that an internal criterion is the equivalent of an external one. This is the case in a test of typewriting speed; whether the test is given one day on a school typewriter or the next day on an employer's typewriter is of relatively little moment.

The equivalence of internal and external criteria must always be demonstrated. It cannot be assumed.

2. Sometimes no satisfactory external criterion is available. Trainees scatter to a variety of jobs. They work under different supervisors. Different conditions determine how well they succeed in their work. Any of these factors may make the use of an external criterion extremely difficult. Under such circumstances, the experimenter may have to use an internal criterion. If he does, he must recognize it as a substitute that allows him to measure the effects of whatever factors he has studied on the training itself. It does not allow any measurement of their effects on later performance.

Whichever type of criterion is employed, it must be made as free as possible from systematic bias. As Thorndike (1947) writes:

Since . . . a comparison is being made of the systematic effect of two or more distinct procedures, it is imperative that the criterion measure be unbiased. That is, there must be no possibility that the criterion test is being administered under conditions which permit one group to have an advantage relative to the other. . . . Any biases associated with a particular school, a particular flight, a par-

ticular group of instructors, or the attitude of the group of instructors toward the two groups are likely to affect the groups differentially. The biases may become systematic rather than random. When this happens, the validity of the experimental results is lost. Measures of proficiency based upon subjective ratings and evaluations are particularly suspect from the point of bias. Changes from time to time and place to place are the rule rather than the exception. Furthermore, in an experiment being carried on at a given time and place it is entirely possible that raters may be biased in favor of one rather than the other of the methods under study and that they may prejudice their ratings accordingly. One is led to conclude that it is particularly in training experiments that complete objectivity is needed in the criterion measure. [P. 145.]

It is possible to use a variety of criteria that satisfy Thorndike's statement concerning objectivity. The most valuable criterion depends upon the particular circumstances of each study and the nature of the task being investigated. A few examples will illustrate the range of possibilities. Total number of units of work accomplished in a given time is a standard scoring method. Stopwatch timing, photoelectric timers, and other mechanical or electrical timing devices provide objective scores that for many tasks are obviously related to success. The percentage of total time that an operation is being correctly done can be fairly well approximated in many instances by using the percentage of a periodic series of short samples during which the operation is being performed correctly. Comparisons of the path of arm or foot movements with a standard obtained by kymographic or similar recording methods is sometimes useful. Specially constructed gauges, templates, or similar devices for measuring specific aspects of work turned out are objective and easy to use. Check lists of specific items done or omitted, objective scales for rating performance, and many of the measuring devices

developed by test experts are useful in measuring performance.

Having adequate criteria against which to evaluate training research is so essential that, unless criteria will be available at the end of the experiment, research should be dropped.

Administrative problems of training research. A psychologist engaging in research on training in an industrial or military setting encounters many more problems of administrative coordination than does the laboratory investigator.

Sometimes there is difficulty in explaining the purposes of the study to the supervisors and in enlisting their support for it. An unsympathetic officer or a foreman who feels that his status is being threatened by the investigator's work can ruin a research study.

The cooperation of the trainees must be secured. Properly motivated and instructed, laboratory subjects are usually willing to do a great variety of things that they might not otherwise do. But industrial workers are working in a world of pay rates, union rules, complexly determined attitudes toward management, seniority rights, and other personal, social, and economic factors that determine how they will respond to the experimenter's instructions and requests.

Overcoming these administrative problems requires cooperation on the part of the investigator, strict honesty with the men regarding the uses to be made of the findings, and sometimes a high order of selling ability. It is usually easier to enlist the necessary cooperation, as McQuitty (1948) and Taft (1946) have pointed out, if the investigator knows a good deal about the total working situation. A period of indoctrination into the problems, customs, regulations, and working habits of the plant may frequently be a desirable prelude to any research; a period of military indoctrination may be advantageous as a background for engaging in military research.

Despite the difficulties faced by a psychologist conducting research on training, he can proceed with the knowledge that if his studies are properly designed they will have two values. The first is practical: research can increase the effectiveness of specific training programs. The second value is more fundamental. Present knowledge of the principles of learning is largely of a qualitative sort. Properly conducted research will contribute quantitative information on the limits of each principle, its optimal conditions of application, and the nature of its interaction with others.

Engineering Psychology and Equipment Design

PAUL M. FITTS
Ohio State University

Traditionally the design of machines has been a responsibility of engineers, and the discovery of the most effective procedures for selecting and training men to use them has been a task for psychologists. The demands of World War II, however, raised many unusual problems of equipment design — problems that drew experimental psychologists into active collaboration with physicists and engineers (cf. Stevens, 1946). By the end of the war psychologists were assisting in the design of such varied equipments as radar consoles and scope faces, instrument dials, binoculars, stereoscopic heightfinders, gunsight reticles, underwater sound-detection devices, voice communication systems, signal systems, gunsight controls, aircraft cockpits, combat information centers, and synthetic training devices. Since the war, research of this nature has continued on a relatively large scale. Much of the material in the present chapter is taken from this recent work.

Psychological research on equipment design has been identified by various names: applied experimental psychology, applied psychophysiology, man-machine systems research, biotechnology, psychotechnology, human engineering, and engineering psychology. Convention favors the name *engineering*

psychology, since it conforms to the practice followed in naming other specialized areas such as educational, clinical, personnel, and industrial psychology. Hereafter, engineering psychology and equipment-design research will be used synonymously.

It is the purpose of the present chapter to summarize psychological facts and principles of particular significance for equipment design and to indicate theoretical questions raised by the study of man's behavior in using the mechanical devices of our technological society.*

PROBLEMS AND METHODS

The methods employed in research on equipment problems are primarily those of experimental psychology. Problems of method peculiar to this new research field are far too numerous to permit even a listing here. They range from criterion problems to problems of electronic circuitry, from questions of how to handle skewed distributions of error frequencies in dial reading studies to questions of how to measure stimulus-response relations in continuous tasks.

* Since this chapter was written there has been published a volume, *Human Factors in Undersea Warfare*, by the Panel on Psychology and Physiology, Committee on Undersea Warfare, National Research Council, which treats some of the problems here presented.

This chapter was written while the author was Chief of the Psychology Branch, Aero Medical Laboratory, USAF Air Materiel Command.

Many areas of equipment-design research call for systematic, large-scale programs planned to attack problems of demonstrated importance. Several effective survey techniques are now available for discovering and assessing these problems. These survey techniques are not procedures that one would use in carefully controlled experiments so much as techniques for identifying, analyzing, and defining problems within the field of engineering psychology.

The discovery and definition of critical problems in designing man-machine systems. Different elements in a complex man-machine system contribute to the overall error variance of the system in accordance with a well-known statistical relation (Chapanis, 1949). If the total variable error in a system is represented by σ_T , then additive components a, b, c, \dots of the system contribute to this total in accordance with the relation

$$\sigma_T^2 = \sigma_a^2 + \sigma_b^2 + \sigma_c^2 + \dots \quad (1)$$

provided the errors contributed by each of the components are uncorrelated. Otherwise the relation is

$$\sigma_T^2 = \sigma_a^2 + \sigma_b^2 + \sigma_c^2 + \dots \pm 2r_{ab}\sigma_a\sigma_b \pm 2r_{ac}\sigma_a\sigma_c \pm 2r_{bc}\sigma_b\sigma_c \pm \dots \quad (2)$$

It is apparent that the relative importance of the root-mean-square error contributed by any component increases quadratically with its relative size. It follows that improvement in the more accurate elements of a system will produce only a negligible reduction in the total variable error of the system. For example, if the machine components of a particular man-machine system contribute a root-mean-square error of 10 and the human components contribute an error of 50, and the two are unrelated, the variable error of the total system is only 51. In this case only a 2-per-cent improvement in the system would be gained by eliminating all the variable errors of the machine components. It is possible, in other words, to analyze the errors in complex

machine operations and industrial processes, and to determine the relative size of the error variance contributed by men, by machines, and by interaction effects.

Similarly, correlation techniques can be used to identify sources of difficulty in technical tasks. Carter and Dudek (1947), for example, secured records from standardized navigation flights. Applying factor-analysis and multiple-correlation techniques, they found that three principal factors—heading, speed, and wind effect—determined the accuracy of navigators' position reports. The most important single source of error lay in the determination of compass deviation. This error was then traced to a particular instrument, the astrocompass.

An activity-sampling technique can sometimes be used to advantage in analyzing the activities of men engaged in complex tasks. In one instance Christensen (1949) recorded at 5-second intervals the operations performed by aerial navigators and radar operators during 15-hour flights. An analysis of the resulting data enabled him to determine where the greatest amount of time could be saved by new equipment and by revised operating procedures.

Another useful procedure is the critical-incident technique. This technique was used by Fitts and Jones (1947*a, b*) in surveying psychological problems relating to aircraft equipment. They asked pilots for descriptions of specific errors or difficulties experienced in operating controls and in responding to instruments. These descriptions of critical experiences were classified and enumerated. The results for instrument-reading errors are given in Table 1. Findings from several experimental studies of problems revealed by this survey will be discussed later. A procedure similar to the critical-incident technique is that of analyzing errors in equipment use. Reports by Ford (1949) and Grether (1949) illustrate this approach.

As a further step in defining problems, it is desirable at times to ask experienced persons to rate the importance and fre-

TABLE 1

CLASSIFICATION OF 270 ERRORS MADE BY AIR-CRAFT PILOTS IN RESPONDING TO INSTRUMENTS AND SIGNALS (MODIFIED SLIGHTLY FROM FITTS AND JONES, 1947b)

	Relative Frequency
1. <i>Misinterpreting multi-revolution instruments.</i> Mistakes in comprehending information presented by two or more pointers or by a pointer plus a rotating dial viewed through a "window."	18
2. <i>Misinterpreting direction of indicator movement (reversal errors).</i> Improper interpretation of an instrument indication with the result that subsequent actions increase rather than reduce an undesirable condition.	17
3. <i>Misinterpreting visual and auditory signals.</i> Failing to respond appropriately to hand signals, warning lights or sounds, or radio range signals.	14
4. <i>Errors involving poor legibility.</i> Difficulty in seeing numerals, scale markings, or pointers clearly enough to permit quick and accurate reading.	14
5. <i>Failing to identify a display.</i> Mistaking one instrument for another or confusing pointers on a multiple-pointer display.	13
6. <i>Using an inoperative instrument.</i> Accepting as valid the indication of an instrument that is inoperative or operating improperly.	9
7. <i>Misinterpreting scale values.</i> Difficulty in interpolating between numbered scale graduations or failure to assign the correct value to a numbered graduation.	6
8. <i>Errors associated with illusions.</i> Difficulties arising out of a conflict between body sensations and information given by visual displays.	5
9. <i>Omitting the reading of an instrument.</i> Failing to refer to an instrument at the proper time.	4
Total	100

industrial tasks. For the most part, systems studies such as these are relevant to experimental psychology only in so far as they indicate problems for experimental study. In this respect, however, they have made an important contribution to research on equipment design.

Numerous authors have attempted to classify and assign importance to problems within the field of engineering psychology. Representative discussions are found in publications by Bartlett (1947), Bray (1948), Brown and Jenkins (1947), Chapanis, Garner, and Morgan (1949), Fitts (1947), Grether (1947a), Kappauf (1949), McFarland (1946), Mead (1948), and Morgan (1947).

The major distinction made by the present writer is between display problems, i.e. questions of how best to present information to the senses, and problems of the design of control systems, i.e. questions of how best to utilize human motor output, and how to secure good dynamic characteristics in complete controller systems.

One further point should be emphasized. Research in engineering psychology must concern itself with the behavior of individuals in complex and continuous tasks, particularly tasks in which skill is exercised in the rapid interpretation of instruments or signals and in the accurate control over sources of external power. Furthermore, machines usually must be designed with reference to many complex and sometimes conflicting considerations. In the present chapter, therefore, emphasis is given to experimental data relating to complex skills, to interaction effects, and to human performance in a variety of different tasks.

DESIGN OF VISUAL DISPLAYS

A display is any device that can be used for presenting information to individuals by visual, auditory, tactual, or other exteroceptive channels. The requirements of good

frequency of use of different components, processes, or 'links' in a system.

Much emphasis has been given in recent years to systems research. Systems studies have often been concerned with such practical problems as the optimum number of human operators that should be assigned to work in a particular system, the optimum number and kind of equipment components, and the optimum arrangement of men and machines. Motion and time engineers, attempting to discover the most efficient methods of work, have collected similar data and reported "link values," "therblig values," process charts, and time charts for many

visual displays are the matters with which we are here concerned.

Significance of different visual discrimination processes. The literature on visual discrimination includes reports of performance in many different tasks, varying from the detection of light energy to the recognition of complex patterns. Performance on these visual tasks is influenced by many parameters. This is illustrated by a study of highway signs by Forbes and Holmes (1939). After determining the maximum distance at which 24-inch-roadside warning symbols could be recognized with unlimited time, they had subjects drive along an unfamiliar road and call out all signs as soon as they were observed. Calls occurred at distances of from 200 to 400 feet, in contrast with the 800 or more feet at which similar symbols were recognized on the previous tests.

It is important to distinguish two aspects of visual discrimination. One concerns the *time* required for the completion of discrimination and response. In *visibility* studies the subjects are allowed to take as much time as they desire before responding, and accuracy alone is the criterion of efficiency. In *legibility* studies the subjects are instructed to minimize the overall time required to complete a response, and effectiveness is judged by speed as well as by accuracy.

The second aspect concerns the *nature* of the discriminatory response. *Detectability* studies require only detection of the presence of a stimulus. *Identifiability* studies require identification of the stimulus object. Detection of a stimulus is sometimes the only requirement in visibility studies; at other times identification is required. Identification is generally required in legibility studies.

In engineering psychology legibility and the identification of complex patterns are usually of greater interest than are visibility and detectability. However, in the interest of the systematic organization of topics, the simpler processes will be considered first.

Design Problems Involving Visibility

Since adequate visibility is a prerequisite for all visual displays, a few illustrations will be given to show the application of visibility data to equipment-design problems.

Size, brightness, and contrast. The design of radar (radio detection and ranging) equipment raises many problems of visual discrimination. Radar operators are often forced to search for weak signals at near-threshold levels where such factors as the size, brightness, and contrast are critical. Pulses of electrical energy are sent out by the radar and reflected back by the distant target, whereupon they are amplified and usually made to modulate the intensity of a beam of electrons in a cathode-ray tube (CRT) in such a way that corresponding to each target there appears a bright spot or a 'pip' on the face of the tube. In practice, radar reflections are almost always accompanied by 'noise,' so that the real targets are partially or completely obscured by a background of random brightness variations on the face of the CRT.

The visibility of radar signals, either with or without a noise background, has been shown to vary with CRT brightness in about the same manner as does the visibility of laboratory test objects (Williams, Bartlett, and King, 1948). A slight loss in visibility was found for small values of CRT bias (bright traces), but it was discovered that this was due to loss of sensitivity of the phosphor screen with resulting loss of contrast at higher beam intensities.

The brightness adaptation of the eye and the level of brightness of the area surrounding the target are factors that influence the visibility of displays such as those on a radar scope. Hanes and Williams (1948) found that for weak radar signals the lowest contrast thresholds and the shortest detection times occurred when the test and adapting illuminations were approximately equal in brightness. These results were obtained for adapting brightness levels ranging from 0 to

1858 foot-lamberts and for screen intensities ranging from 0.00009 to 0.204 foot-lambert. Similar results have been reported from several related studies. For optimum detection of low-contrast 'pips' the CRT should be adjusted until the background brightness of the tube is in the neighborhood of 0.1 foot-lambert. Interestingly enough, ambient illumination as bright as the screen background has no detrimental effect on CRT target visibility and may actually improve it, by permitting the maintenance of relatively uniform retinal adaptation at a level near the optimum.

A preliminary study of visibility of CRT signals as a function of their size was made by Bartlett and Williams (1947). The smallest image size employed subtended 1 minute by 12 degrees of visual angle at a viewing distance of 12 inches. It was found that very dim targets could be discriminated more readily if the eyes were near the scope face (6 inches) than if they were farther away (24 inches). This finding was true for dark or moderately bright CRT backgrounds but did not hold when noise was present. Detection of targets viewed against a noise background involves pattern perception, of course, rather than simple brightness discrimination. The role of stimulus size apparently varies, therefore, depending on whether the task involves the visibility or the identifiability of a target.

The detection of a low-intensity image that is viewed amid a cluster of relatively bright noise pips is much more difficult than the identification of the same image when it is seen against a uniform background. Payne-Scott (1948) discussed the importance of this point and suggested procedures for simplifying the radar operator's tasks. One of her suggestions was to increase the number (N) of samples of noise per unit of time, thereby obtaining a more even distribution of noise over the surface of the tube face. Engineers can vary approximately fifteen design characteristics that have an effect on the sampling rate of a radar set or

on the size, brightness, or contrast of the blip.

Although the ability of an operator to detect radar images can be predicted fairly well from existing visibility data, it is often advisable to determine visibility under conditions that permit the study of the special interaction effects and the limiting conditions peculiar to radar displays.

Color. The wavelength of the light reflected by a display is sometimes an important design factor. Monochromatic red light is especially advantageous when it is necessary to read instruments and at the same time to preserve dark adaptation. This is true because the visual receptor elements that mediate night vision are relatively insensitive to red light (see Chapter 24). It was not until late in World War II, however, that red light came into general use for the illumination of instrument panels.

Since the eye is not color corrected it cannot bring all wavelengths of light into simultaneous focus on the retina. This suggests that monochromatic light should give better visibility than light of mixed wavelength. Kappauf (1949) concluded that the evidence on this point is contradictory. Of monochromatic lights, however, yellow provides the best acuity.

Visibility of numerals and letters printed in various color combinations has been found to depend primarily on brightness and contrast, rather than on color (Sumner, 1932; Preston, Schwankel, and Tinker, 1932). Data collected by Eastman Kodak Company (1944) now make it possible to compute the equivalent brightness contrast of two monochromatic fields that are of the same apparent brightness. Thus color differences can be expressed as equivalent brightness differences.

Pattern discrimination is a function of the ability to detect gradients of brightness, color, and saturation. Few displays except those employed in color motion pictures and color television, however, employ all three factors. The science of camouflage, of

course, makes extensive use of all three factors in attempting to destroy pattern vision for objects by making them blend in with their background or assume deceptive configurations.

Discrimination of velocity and acceleration. If an individual can respond to the velocity and acceleration of a moving object,

Discrimination of three coordinates from cues on a cathode-ray tube. Numerous efforts have been made to obtain more than two parameters of information from a single image on a CRT, particularly the location of objects in three-dimensional space.

Any two of the three coordinates necessary to locate an object in space can be

FIG. 1. Four possible ways of displaying three dimensions of information on the two-dimensional surfaces of cathode-ray tubes. In A and B the size and length, respectively, of the blip are utilized to indicate the relative magnitude of the third dimension; in C and D two separate coordinate systems are employed.

i.e. respond in anticipation of its future course, he can perform many perceptual-motor tasks much more effectively than if he responds only to the object's position from moment to moment. Hick (1948b) found that the ability to detect a sudden change in the velocity of a moving spot on a CRT obeys Weber's law approximately; the mean threshold was about 12 per cent of the initial velocity under favorable conditions.

represented by the position of the CRT image with reference to a polar or rectangular grid system superimposed on the tube face. Difficulties arise, however, when we try to add the third dimension. The use of stereoscopic devices has been considered, but most efforts to solve this problem have made use of changes imposed on the image itself, such as changes in its size, brightness, color, or pattern, or variation in its temporal characteristics, such as flicker rate. Several of

the many possibilities are illustrated in Fig. 1. Thus we see that man's ability to make relative or absolute discriminations of stimulus values can be utilized in the design of 'three-dimensional' displays.

Discrimination of angular position. On many circular instruments, values are indicated by the angular position of a hand or cursor. Sometimes it is necessary for individuals to judge directly the angle formed by two such objects or lines, or by one object with respect to the vertical and horizontal. This ability has been studied with the aid of lines projected on a large unstructured circular screen (Kaufman et al., 1947; Rogers et al., 1947; Reese et al., 1948).

The average error of 33 subjects in judging the bearing of a line of light was 2.8 degrees. Subjects adjusted a marker to a designated bearing more accurately than they estimated the bearing of a marker that had already been adjusted; but adjustment required more time than estimation.

The introduction of a known reference line enabled observers to reduce their errors in estimating bearings that were as far as 20 to 30 degrees from the reference line. When no visual reference was provided, observers relied on subjective estimates of the vertical and horizontal. Estimates were most accurate at the 0- and 90-degree points, and somewhat better at 45 degrees than at other bearings in the 0- to 90-degree sector. On the basis of these and related findings, a grid system of 24 bearing markers spaced 15 degrees apart was recommended for use on large display screens (Kaufman et al., 1947). Such a grid system includes all the salient or 'natural' anchor points (0, 30, 45, 60, 90, etc., degrees).

Problems Related to Pattern Discrimination

Standards for legibility studies. The lack of standard procedures and standard units has seriously limited the generality of the results from legibility studies. Fortunately, however, agreement has been reached regarding certain units of measurement and

conditions of experimentation, through the work of a subcommittee of the Armed Forces-NRC Vision Committee (1947). The recommendations formulated by this subcommittee are summarized in Table 2.

Size of numerals and letters. Burnham, in 1892, concluded that printed characters should have a minimum height of 1.5 millimeters. This is equivalent to the size of small letters printed in 10-point type. Interestingly enough, subsequent work supports this early observation. Paterson and Tinker (1940), for example, found that the use of 6- and 8-point type retards speed of reading, but that 9-, 10-, 11-, and 12-point type are about equally legible when each is used with an appropriate line width. Most journals and textbooks are printed in 10- or 11-point type. Readers have been found to prefer this size.

Reading speed is retarded if type is too large (Buckingham, 1931). Paterson and Tinker (1942, 1943, 1944) have shown that the average number of words covered per eye fixation is less for very large type than for type of an optimum size. Although fixations are somewhat shorter for large than for small type, the net result in one study comparing 10-point and 14-point type was found to be a 14-per-cent increase in perception time for the larger type. This is not strange when it is considered that 14-point type occupies 87 per cent more printing space than 10-point type.

Paterson and Tinker, who have systematically investigated such typographic variables as size, style of type, width of line, space between lines, margins, columnar arrangement, space between columns, color of print and paper, and paper surface, stress the importance of interactions between these variables. They emphasize that interaction is the rule rather than the exception, and they caution against drawing conclusions about optimum values for any variable that has been studied in isolation.

Size of instrument dials and cathode-ray tubes. The question of optimum size arises

TABLE 2

STANDARDS RECOMMENDED BY THE ARMED FORCES-NRC VISION COMMITTEE FOR USE IN RESEARCH ON VISUAL DISPLAYS

A. Subject Variables			
Variable	Unit of Measurement	Standard	Remarks
1. Visual acuity		20/20 or better	Follow testing manual issued by AF-NRC Vision Committee.
2. Color vision		'Normal'	Use any standard pseudo-isochromatic chart.
3. Mental ability		None specified	Define population used with respect to sex, age, education, work experience, intelligence scores, and measures of perceptual, verbal, numerical, and motor abilities.
B. Stimulus ('Controlled') Variables			
4. Distance	Feet and inches	13 inches	Representative of normal reading distance.
		28 inches	Representative of instrument-reading distance.
		20 feet	Standard distance for visual acuity measurements.
5. Size	Visual angle		Express in degrees, minutes, and seconds.
6. Height of numerals	Inches	$\frac{3}{32}$, $\frac{1}{8}$, $\frac{3}{16}$	For minor, intermediate, and major numerals and letters on instruments to be viewed at 28 inches.
7. Stroke width of numerals	Inches	0.015, 0.020, 0.025	For minor, intermediate, and major numerals and letters on instruments to be viewed at 28 inches.
8. Length of scale graduations	Inches	$\frac{3}{32}$, $\frac{5}{32}$, $\frac{7}{32}$	For minor, intermediate, and major graduations on instruments to be viewed at 28 inches.
9. Width of scale graduations	Inches	0.015, 0.020, 0.025	For minor, intermediate, and major graduations on instruments to be viewed at 28 inches.
10. Pointer length	Inches		Tip should reach the inner end of minor scale graduations.
11. Pointer width	Inches	$\frac{3}{32}$	
12. Style of numerals and letters		Aeronautical Design Standard No. AND 10400	Wrico or LeRoy lettering guides are acceptable substitutes.
13. Color or hue	Millimicrons		Specify dominant wavelength if possible; otherwise match with Munsell scale.
14. Saturation	Millimicrons		Specify wavelength distribution if possible, otherwise match with Munsell scale.
15. Brightness	Foot-lambert	30 foot-lamberts for day simulation; 0.1 foot-lambert for night simulation	Use MacBeth Illuminometer or comparable photometric instrument. Brightness should be specified for the white area, whether figure or ground.
16. Illumination	Foot-candle		
17. Color of figure and ground		(1) Black on white, (2) white on black	(1) For general use. (2) For instruments designed for night lighting.
18. Contrast	$\frac{DI}{I + DI}$		Maximum possible contrast is recommended. <i>I</i> in this case is the lesser of the two brightnesses.
19. Adaptation level		Sufficient time for eyes to adapt to test level	See Hecht, Haig, and Chase, 1937.
20. Exposure time	Seconds	0.1 second	When a single eye fixation is desired.
21. Style of type			Follow recommendations in Paterson and Tinker (1940), pages 156-157.

also in the design of scale markings, numerals, pointers, overlays, radar scopes, and many other items. Here an important consideration is whether the operator has plenty of time for reading, or whether he must check a display very quickly.

Check-reading requires rapid inspection in order to detect deviations outside the normal range. Under conditions that permitted subjects to respond to the patterns formed by a group of instruments, White (1949) found that a panel containing 16 instruments of 1¾-inch diameter was check-read somewhat more rapidly and accurately than panels of either larger or smaller instruments. Results for 24 subjects are given in Table 3.

TABLE 3

Size of Individual Dials in Inches	Average Check-Reading Time in Seconds	Per Cent of Trials in Error
1	0.67	5
1¾	0.65	3
2¾	0.69	6

The differences between the 1¾- and 2¾-inch dials were significant at better than the 5-per-cent level. Eye-movement records also indicated that fewer fixations were required to check the dials of intermediate size.

Studies of the size of radar scopes in relation to speed of target detection have also indicated an optimum size range. This size is considerably less than that employed in some present-day radar sets (Horton, 1949). Where the use of a larger scope results only in distributing the existing signal over a larger surface, little gain in legibility is to be expected with scopes larger than about 6 inches in diameter. However, if CRT displays are designed to be viewed from a distance, or by several observers at once, as in the case of home television, larger sizes are often desirable.

Sleight (1948), using a 0.12-second exposure time, determined errors in reading linear, circular, and other types of scales to the nearest graduation mark. All scales covered

a range of from 0 to 10, and the distance between adjacent scale division marks was constant. The average number of errors made by 60 subjects and the maximum visible dimensions of each scale are given in Table 4. All differences in error frequency

TABLE 4

Type of Scale	Maximum Dimension in Inches	Per Cent of Trials in Error
Open window	1½	0.5
Round dial	2½	10.9
Semicircular	4½	16.6
Linear-horizontal	7	27.5
Linear-vertical	7	35.5

were significant at the 1-per-cent level. It can be seen that there was a close relation between the maximum visible dimension of a scale and the observer's ability to read it during an exposure shorter than the time required for an average eye fixation. For such short exposures it appears that the best scale is the one that enables the reader to anticipate most precisely where to find the pointer.

Grether and Williams (1947) reported that there was no systematic relation between speed of reading and dial size for dials ranging in diameter from 1 to 4 inches when subjects had to call out numerical values. Kappauf and associates (1947, 1948) found no significant differences in quantitative-reading speed between 1.4- and 2.8-inch dials, but they reported a marked loss of speed for a 0.7-inch dial. They also found that a general slowing of response accompanied any increase in the overall range of values depicted on a scale. For rapid detection of pattern changes or rapid reading of scales, it can be concluded that there is generally an optimum size of display.

A different principle holds when reading speed is not important. If similar information is presented on a large and on a small dial, then more accurate readings can usually be made from the larger dial. The precision of reading is then primarily a function of the

C

FIG. 2. Instrument dials employed in studies of legibility as a function of the spacing between scale markings by (A) Loucks (1944a), (B) Grether and Williams (1947), and (C) Kappauf, Smith, and Bray (1947).

arc distance separating each unit of the scale.

Spacing of scale marks. It is possible to vary the distance between scale marks as well as the overall size of a display (cf. Fig. 2).

Errors in reading a scale to an exact numerical value have been expressed (1) as

FIG. 3. Dial-reading errors for various scale intervals expressed as a relative value. Data are for 20 subjects at each point. (From Grether and Williams, 1947.)

a percentage of the distance between scale divisions, (2) as an average error computed as arc distance along the scale, reported either in inches or in the units represented by the scale, and (3) as the proportion of readings in error by more than some arbitrary amount. The first of these measures indicates relative accuracy of interpolation between two scale marks. Results from Grether and Williams' study (1947), in which subjects read dials to the nearest tenth of an interval, have been plotted in Fig. 3 to reveal accuracy of interpolation. Relative errors of interpolation are much greater for very small intervals. The minimum relative error was reached at about 0.5 inch per scale

division. Weber's law holds approximately over the range of graduation intervals from this point on. Once Weber's law becomes operative, of course, nothing is to be gained by making divisions any larger. In fact, the data suggest that relative accuracy may actually become somewhat poorer with very large separation between scale marks.

Accuracy relative to the distance between scale marks, however, is not so important for practical purposes as is the problem of minimizing the absolute size of the reading error. The question here is, given a dial of a particular size, how close together should scale marks be placed to provide maximum reading precision? When absolute accuracy is the criterion, and adequate reading time is permitted, best results are achieved by the use of closely spaced scale marks, such as those used on a slide rule.

FIG. 4. Dial-reading error for various scale intervals expressed as an absolute value. (From Grether and Williams, 1947.)

Grether and Williams (see Fig. 4) found that absolute accuracy increased down to the most closely spaced scale tried. Kappauf and his associates obtained similar results, but they found evidence for a loss in absolute accuracy for very small graduation intervals. It appears that maximum relative precision in reading circular scales increases as arc distance between scale marks increases,

up to a scale separation of about 0.5 inch for instrument-panel (28-inch) reading distance. But maximum absolute accuracy increases as the distance between marks decreases down to approximately 0.05 inch (about 6 minutes of visual angle). These specific values are undoubtedly subject to considerable variation with changes in pointer design, lighting, the thickness and length of scale marks, the range of values covered by the scale, and other factors. Maier (1931), for example, reported greatest accuracy when graduation marks were 25 per cent as thick as the interval between marks.

In several instances Loucks (1944*a, b, d*), using a short-exposure technique, found a significant advantage in favor of dials on which some of the scale division marks had been removed. For example, of the two dials shown in Fig. 2A with 0.05- and 0.25-inch separation between scales, the one with the fewer scale marks gave significantly fewer reading errors. He also found that a dial with numerals at every scale division was superior to one with every fifth division numbered, provided the dial was viewed for as long as 1.5 seconds, but that the opposite was the case when 0.75-second exposures were used. This is consistent with Ford's (1949) discovery that the introduction of fine scaling on a CRT display resulted in an increase in scale-interpretation errors but a reduction in precision errors when readings were made in moderately rapid succession.

Patterns for signs and geometrical symbols. Geometrical figures differ considerably in legibility. Straight lines have been found to be more legible than curved ones (Mackworth, 1944). The triangle, the rectangle, and the square have been reported to be more easily recognized under conditions of low illumination and in peripheral vision than circular and hexagonal forms (Collier, 1931; Helson and Fehrer, 1932; and Whitmer, 1933).

The use of geometrical symbols and pictographic markers in place of verbal symbols

often improves legibility and interpretability. Arrows indicating directions, for example, are better than RIGHT and LEFT, since many individuals are momentarily non-plussed when asked to turn to the right or left. Symbols must be chosen carefully, however. For example, Lauer (1947) found that under average daylight conditions the word STOP on a standard octagonal highway marker could be recognized before the shape was identified, whereas square or diamond-shaped highway signs could be identified from nearly twice the distance at which legends on them could be read.

Optimal form of letters and numerals. Studies of the visibility and legibility of isolated letters have given varied results. For example: Webster and Tinker (1935) found that American Typewriter type was visible at a greater distance than Scotch Roman type, but that the latter could be read about 5 per cent faster. They attributed this to the fixed spacing of typed copy, rather than to the style of individual characters.

There is little difference in the legibility of lower-case Roman and lower-case italic type, but most readers prefer the former. All-capital printing, however, results in about 12-per-cent slower reading than lower-case printing (Paterson and Tinker, 1940). In spite of this fact most decals and emergency instructions on instrument panels and machines are printed in all-capital type.

Studies of the relative visibility of different letters of the alphabet were undertaken as early as 1881 by Javal, a French oculist, who was interested in selecting characters to be used in testing eyesight. Roethlein (1912) carried out a very extensive study of the visibility of isolated characters, using sixteen different type faces. The results of all her work gave the following average rank order to the various upper- and lower-case letters of the alphabet, from most to least legible: WMLJI ATCVQ PDOYU FHXGN ZKERBS, and mwdjl pfqyi hgbkv rtncu oxaesz. Tinker (1928) reported that the correlations between results from thirteen

different studies of the legibility of upper-case letters ranged from -0.58 to $+0.89$. For lower-case letters the range was $+0.48$ to $+0.88$. The letter *L* was frequently at or near the top in legibility, and the letter *G* was frequently at the bottom. Tinker concluded that the maximum of legibility is represented by the old Roman capitals, which are made up almost entirely of straight lines and sharp angles.

FIG. 5. Relation between stroke-width of numerals and the distances at which they can be read for two contrast relations. Data are for two observers. Note that relatively narrow white-on-black strokes gave optimum visibility. (From Berger, 1944a.)

The relative legibility of different numerals depends on the criterion employed as a legibility measure, the style of the numerals, and the figures with which they are associated. The numerals 0, 3, 6, and 9, all of which have curved outlines, are often confused with one another. In most studies the numeral 7 has been reported to have good legibility and visibility.

In the well-known Snellen test chart, the width of strokes is the same as the width of enclosed white spaces. Several investigations (Aldrich, 1937; Berger, 1944b; Bartlett, 1947; Lauer, 1947) have shown that a narrower stroke than this is desirable for best visibility. Recommendations for the width of strokes have varied from about 12 per cent to 25 per cent of the width of the letter or from approximately 8 per cent to 17 per cent of letter height. Aeronautical

standards for white-on-black numerals now call for a line width equal to 12.5 per cent of the numeral height when numerals are over $\frac{1}{8}$ inch in height, and a line width of 16.7 per cent of the height for smaller numerals. Berger (1944a) showed clearly that the stroke-width ratio giving maximum visibility varies considerably between white-on-black and black-on-white (see Fig. 5), and that white letters should have narrower strokes than black letters. Widths of lines for maximum visibility under the two contrast relations were 7.7 and 12.5 per cent, respectively, of numeral height. Loucks (1944b) found that for best legibility the stroke thickness should be increased for low brightness levels.

Designs specified for white numerals used on aircraft instruments are shown in Fig. 6C. Also shown are a set of black numerals

FIG. 6. Numeral designs recommended for optimum legibility by (A) Berger (1944a), (B) Mackworth (1944), and (C) the Aeronautical Board.

developed during the war by Mackworth (1944) for use on air-raid plotting boards, and numerals designed and patented by Berger (1944a). Berger's numerals shown in Fig. 6A were designed to give optimum and equal visibility at a distance, when printed with white lettering on black, and diffusely lighted from the front. Both Mackworth and Berger made greater use of straight strokes than is customary in com-

monly used numeral forms. The slanting lines of Berger's numerals are usually at approximately 45 degrees.

The ratio of height to width of letters and numerals has been the subject of a few studies. Lauer (1947) concluded that block letters of equal height and width have best visibility. It is generally agreed that, when available width is limited, little or nothing is gained by using very tall characters. Aeronautical design standards, which require

Carmichael and Dearborn (1947) and will not be discussed here.

The role of meaning in the recognition of all types of patterns must not be overlooked. Words can be identified more quickly than single letters (Luckiesh and Moss, 1937), for example, and common first names can be read at distances where last names cannot be recognized (Walls, 1943).

Pointer position pattern as an aid to improved check-reading. Warrick and Grether

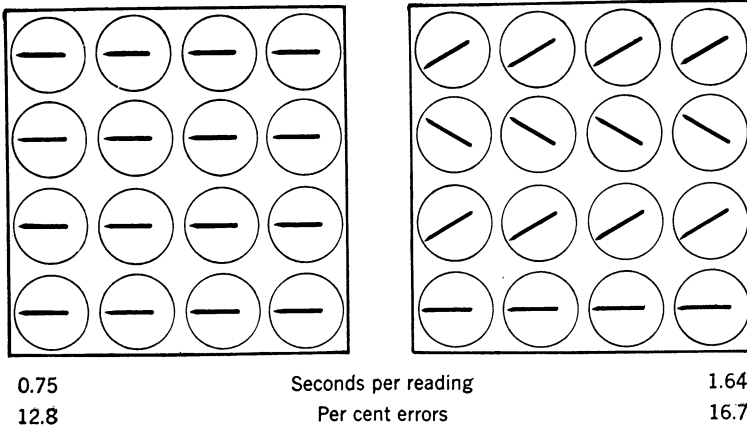

FIG. 7. Instrument-panel arrangements that gave short check-reading times. (From White, 1949.)

a height-width ratio of 1 to 1 for the letter *W*, a ratio of 1.3 to 1 for *A*, *M*, and *L*, and a ratio of 1.5 to 1 for all other letters and numerals, appear to represent sound practice.

Proper spacing between letters is important for good visibility. A distance between letters equal to about half the average width of a letter was found to be optimum in one case (Lauer, 1947). Forbes and Holmes (1939) advocated graded spacing, depending on whether strokes of adjacent characters paralleled each other as in *NM* or *VA*, one stroke diverged as in *VN*, or both strokes diverged as in *VT* or *AA*.

Other problems involving pattern arrangement of printing, such as line width, spacing between lines, width of margins, and columnar arrangement, have been treated in detail by Paterson and Tinker (1940) and by

(1948) have shown that a significant gain in speed of check-reading results from patterned arrangement of instrument pointers. They found that if 16 instruments were arranged in a rectangular pattern, with the pointers of all instruments aligned at some cardinal position (such as 9 o'clock), as is shown in Fig. 7, the entire panel could be checked for deviations and a response switch operated in $\frac{3}{4}$ second. When the pattern was broken up into subgroupings of 4 instruments, response times increased to approximately 1.6 seconds. However, the latter condition still represents a marked gain over most present-day instrument panel arrangements.

Pointer design. Loucks (1944c), using standard black aircraft instrument dials with $1\frac{1}{8}$ -inch pointers, tried painting various lengths of the tip white. A pointer $\frac{3}{32}$ inch

in width and painted white for nearly its full length was found to give fewer dial-reading errors for short exposure intervals than pointers with $\frac{7}{16}$ -inch and $\frac{9}{16}$ -inch white tips. Loucks also found that a standard $\frac{1}{8}$ -inch long pointer could be reduced in width from $\frac{3}{32}$ inch to $\frac{1}{32}$ inch with no loss in legibility. The narrower pointer actually gave somewhat fewer errors when made to fluoresce under ultraviolet low-level illumination. This finding agrees with an earlier report by Maier (1931) who recommended that the pointer of stop-watch dials be narrower than the width of the scale marks. A narrow pointer has the further advantage that it covers up a smaller portion of any numeral that happens to lie beneath it.

The amount by which a pointer should overlap the scale, especially when scale-division marks are of different lengths, is a further problem. Vernon (1946) reported that dial-reading errors increased when the tip of the pointer was more than 0.5 inch from the scale. Parallax resulting from the height of the pointer above the scale is an additional factor that may lead to errors.

Number preferences. Kappauf (1949) has pointed out that strong preferences seem to exist for certain numbers and that this carries over into scale-reading tasks, especially if subjects must interpolate between scale divisions. Individuals appear to favor readings of 0, 2, 5, and 8 when interpolation is by tenths. Preferences can be controlled to some extent by training, and by designing displays that require a minimum of interpolation.

Black-on-white versus white-on-black. The relative merits of black characters on a light background, versus the converse arrangement, have been variously reported by investigators employing different criteria and different values for the interacting variables. The majority of studies employing visibility criteria have yielded results favoring the use of dark numerals on a bright background (Holmes, 1931; Lauer, 1933; Sumner, 1932; Taylor, 1934). However, Berger

(1944*a, b*) found that, if strokes of optimal width were used, bright numerals could be recognized under daylight illumination at about 9-per-cent greater distance by his 4 subjects than could dark numerals. Starch (1914) and Paterson and Tinker (1931, 1940) found faster reading with black print on white, and Taylor (1934) found that the use of black print led to fewer eye fixations per line than did the less familiar white type.

Two factors that influence the relative visibility and legibility of bright and dark characters are (1) irradiation and (2) the level of adaptation of the eye. Of course, width of lines interacts with the black-white relation.

Meaning and familiarity also play an important role in determining the relative superiority of dark versus bright stimulus objects. The factor of familiarity would be expected to favor black-on-white. Taylor (1934), using a visibility criterion, found that, the less meaningful the stimulus material, the more marked was the superiority of black-on-white printing, as indicated in Table 5. Thus it appears that familiarity

TABLE 5

Stimulus Material	Per Cent Superiority of Black-on-White
Words in sentences	11
Isolated words	17
Nonsense words	23
Isolated capitals	24
Combinations of letters <i>i</i> and <i>l</i>	33

with a particular stimulus pattern partially cancels out the advantage of the more familiar contrast relation.

Design of Quantitative Displays

The equipment-design problems considered in the preceding sections have been primarily concerned with visual discrimination processes. We turn now to questions that involve the ability to comprehend, interpret, or understand the information presented by visual displays. Errors of interpretation re-

sult from many complex and interacting factors, and they arise to some extent in the use of all types of displays. They are frequently large in magnitude and serious in consequence. Their elimination is often the most important consideration in the design of a display.

Direct display of numerical data. Quantitative data are commonly displayed either by means of counters and other devices that present numerical symbols directly, or by the position of a pointer on a scale. The advantages of the first of these methods are so obvious as scarcely to require elaboration. Whenever direct-reading displays have been compared with scale-and-pointer combinations, it has been found that individuals can obtain numerical information more rapidly from direct numerical displays. The latter are also relatively free from interpretation errors.

Why then does the design of quantitative displays present a problem? It is because displays must often serve multiple functions. Displays must be designed so that, in addition to being easy to read quantitatively, they will show the rate and direction of change of a variable, and will provide the sensory cues necessary for the performance of psychomotor tasks. For such multiple purposes a pointer-scale indication is often superior to a direct-reading numerical display. For example, it was found that an indicator could be turned to a new bearing more quickly when the cue for the response was the position of a cursor on a scale than when it was the value shown by a counter (Chapanis, Garner, and Morgan, 1949).

Interpretation of scales. Vernon (1946) investigated several systems for marking off scales. Errors in reading appeared to be influenced more by the values represented by major scale divisions (the modulus chosen for the scale) than by the values represented by the minor scale divisions. Relatively few interpretation errors arose when a scale modulus of 1, 10, 100, etc., was used. An optimum scale design was found

to be one with a major numbered graduation mark at each ten, and minor unnumbered division marks at each unit; or else one graduated by 100's and 10's or by some equivalent ratio. In a study of clock dials Grether (1948a) found that omission of numerals at any of the hour positions led to an increase in comprehension errors. It can be concluded that all major scale divisions should be numbered if possible.

Vernon found that scales having a modulus of 4 gave many errors. So did those with a modulus of 2 or 20, if the intervening spaces were marked off into fifths. Minor graduations that represented units of 2 were found to be satisfactory when the modulus of the scale was 10 and each major division was numbered. Other studies, however, have revealed that individuals may confuse minor scale divisions that increase by 2's with those that increase by 1's, particularly when minor division lines change in values from one part of the scale to another or when different scales are read in rapid succession. Chapanis (1947), using a polar-coordinate presentation, had subjects interpolate between range rings when values from 1000 to 10,000 yards were assigned to each ring. Readings with the 1000, 2000, and 10,000 scales were most accurate; those with the 3000 and 6000 scales were least accurate.

Scales that increase from right to left, or counterclockwise, are particularly susceptible to directional errors, such as reading 21 in place of 19 or reading 22 in place of 18. Christensen (1948) found that the use of a 'staircase' scale, on which the lengths of minor scale graduation marks increased in proportion to their numerical values, reduced the frequency of this particular error significantly. Whenever possible, however, counterclockwise scales should be avoided.

Interpretation of wide-range instruments. Instruments can be arranged on a continuum with respect to the number of discriminable differences they provide. At one end are the all-or-none indicators, such as *stop* or *go* signs, which provide only two categories of

information. At the other end are displays, such as watches, that can be read in thousands of discrete steps. A watch, for example, if read to the nearest second, indicates a total of 43,200 different time steps during a 12-hour period.

read with an error of exactly 1000 feet. Bray (1948) reports that a serious error made in directing artillery fire was one of exactly 100 mils. Both these errors occurred because observers had to make a gross and then a vernier reading, in one

FIG. 8. Nine instrument designs for indicating quantitative values over a wide range. Some results are given for speed and accuracy of reading by two groups of subjects differing widely in experience. (From Grether, 1949.)

Devices for displaying large ranges of information include single dials with several concentric pointers, e.g. watches with sweep second hands, several one-pointer dials with different sensitivity, e.g. gas, water, and electric meters, and long scales affixed to moving tapes. Most of these devices use broken or divided scales that require the reader to combine data obtained from several sources, and they all are subject to errors of comprehension. It will be recalled (see Table 1) that the type of error described most frequently by aircraft pilots was one of misreading multiple-pointer instruments. The aircraft altimeter, for example, was often

case from separate moving pointers, in the other case from separate moving scales.

Following up the results of the critical-incident study described earlier, Grether (1949) investigated nine different designs (see Fig. 8) for presenting wide-range data in an effort to improve the altimeter. It is obvious from Fig. 8 that the differences between designs as revealed by group performance were much greater than the differences produced by several years of experience in using particular instruments.

Errors in reading the conventional three-pointer altimeter were classified into seven categories. These categories are given in

Table 6, together with the frequency counts for each in the pilot and college populations. Specific errors illustrating each category are

TABLE 6

CLASSIFICATION OF ERRORS MADE IN READING A MULTIPLE-POINTER INSTRUMENT *
N = 97 USAF PILOTS AND 79 MALE COLLEGE STUDENTS (SEE FIG. 9 FOR EXAMPLES)

Type of Error †	Per Cent of Errors	
	Pilots	College Men
A. Misinterpreting the value of a scale division.	5.8	7.1
B. Interchanging numerals.	4.0	5.5
C. Reading a value from a major scale division before it is reached.	4.4	3.7
D. Omitting the value indicated by one of several pointers.	0.3	2.3
E. Reading a value from a major scale division after that division has been passed.	0.3	2.3
F. Repeating the value indicated by a pointer.	1.0	0.8
G. Other complex, unclassified errors.	0.9	1.5

* Subjects read a sensitive aircraft altimeter, on which three concentric pointers represented hundreds, thousands, and tens of thousands of feet, respectively.

† Error descriptions have been modified slightly from those used by Grether (1949).

shown in Fig. 9. In only two of the seven types of errors was the frequency substantially less for the experienced pilot group. This finding demonstrates that design is often more important than training as a factor in instrument reading.

In the study under discussion the fastest and most accurate quantitative readings were made from the direct numerical display. The two designs that permitted the next best performances were the one combining a single pointer and a counter, and the one using a movable tape.

In practical situations the choice among designs will depend on considerations in addition to those of speed and accuracy in quantitative reading — considerations such as suitability for 'check-reading' and for quick detection of rate of change or direction of change of a variable.

Graphs and tables. Relative speed and accuracy in reading values from graphs, double scales, and tables are dependent upon factors that are similar to the ones discussed in the preceding sections. Reading a graph is similar in many respects to interpreting the value shown by a pointer on a scale. Table reading resembles the reading of a direct numerical display, although at times it may also require interpolation.

Carter (1947) had subjects work identical problems with various kinds of tables and graphs. The type of problem was found to interact significantly with the type of display. Problems requiring no interpolation were in all cases solved more quickly by the use of a table, regardless of the complexity of the numerical function. Problems requiring single or double interpolation, on the other hand, were solved much more rapidly by the use of graphs. Results for the function $y = x^2/c$, with c taking on four values, are given in Table 7. Note that

TABLE 7

Type of Problem	Problems Solved per Minute	
	Graphs	Tables
No interpolation	5.5	11.32
Single interpolation	4.4	2.6
Double interpolation	3.8	0.8

interpolation problems required very little more time than noninterpolation problems when subjects used a graph, but required fourteen times as long as noninterpolation problems when they used a table.

Characteristics of good quantitative displays. The foregoing facts support the hypothesis that the probability of an error in comprehension increases directly with the number of separate stimulus-response operations required of the subject.* Such an hypothesis has already been proposed to ac-

* A specific theory relating error frequency and number of S—R connections was proposed by W. F. Grether in a staff meeting of the Psychology Branch, USAF Aero Medical Laboratory.

count for the differential effect of short exposures on the legibility of instrument scales. It also offers a plausible explanation for the

based on units, tens, hundreds, or thousands, rather than on intermediate values, and the large number of errors made in

FIG. 9. Types of errors made in reading a three-pointer instrument (see Table 6). (From Grether, 1949.)

superiority of counters over scale-pointer combinations, the superiority of uniform over logarithmic or other nonlinear scales, the advantage of scales having a modulus

reading instruments that require a synthesis of information from several sources. Grether (1948b) has suggested that absolute errors in interpolating between modulus points on a

scale often increase inversely with the number of minor scale divisions, and that errors of comprehension increase directly with the number of minor divisions. Ford (1949) has reported experimental evidence that this happens. In a good all-purpose display we must compromise between these two opposed considerations, remembering that comprehension errors are usually large, whereas interpolation errors are usually small.

Displays for Spatial Relations

The advent of the air age with its tremendous speeds has made the display of spatial information of critical importance. The designing of displays to represent spatial relations such as direction, distance, and relative motion is, however, one of the most complex problems in engineering psychology. Numbers can be used to represent altitude, distance, and other spatial relations, of course, but there are many situations in which an overall 'pictorial' display is needed, rather than sets of numbers. Displays are needed to provide cues for the direct perception of spatial relations and for the performance of perceptual-motor tasks, such as the flying of an aircraft without any vision outside the cockpit.

Although it might seem that an ideal display would be one that exactly reproduced all the cues normally utilized in space perception, such a display would be difficult, if not impossible, to devise. And even if a complete situation display were provided, in some situations the unaided human eye would not be able to make all the necessary discriminations without supplemental information. An automobile driver, for example, relies on his speedometer for an indication of speed even when visibility is perfect.

Two solutions are possible. One is to provide both pictorial displays and supplemental quantitative displays. The other is to depict the essential spatial relations in a way that provides more precise information than is gained through unaided vision. One aspect of this second problem is to determine

whether a schematic display gives a 'natural' indication, i.e. an indication to which the correct response is a *population stereotype* as demonstrated by its frequency of occurrence in the general population.

Population stereotypes in responding to directional cues. Several studies of direction-of-motion stereotypes have been carried out at Cambridge University (Vince, 1944; Vince and Mitchell, 1946; Mitchell, 1947, 1948). The motions of displays and controls were those made by pivoted pointers and levers. Responses were made to discrete stimuli appearing in rapid succession. When the operator tried to cause the display to move upward, it was found that the control movements from most to least effective were upward, forward, right or left, backward, and downward. Similar results were obtained when the operator's task was complicated by requiring him to carry on two concurrent activities. In general the effect of direction-of-motion relations was less marked in continuous than in discontinuous tasks, and less marked for the preferred than for the nonpreferred hand. Experimental

TABLE 8

RELATIVE EFFICIENCY OF DIFFERENT MOVEMENTS OF A CONTROL LEVER IN RESPONSE TO AN UP-AND-DOWN DISPLAY MOVEMENT (FROM MITCHELL, 1947)

N = 10 SUBJECTS FOR EACH RELATION

Relation between Control Lever and Marker	Average Number of Errors during 60 Trials	
	In a One-Hand Task	In a Two-Hand Task
1. Upward control movement caused marker to move upward.	3.0	4.2
2. Forward (away from body) control movement caused marker to move upward.	4.5	5.3
3. Rightward control movement caused marker to move upward, combined with results obtained when a leftward control movement caused marker to move upward.	7.0	9.2
4. Backward (toward body) control movement caused marker to move upward.	6.8	11.1
5. Downward control movement caused marker to move upward.	8.0	11.9

results from one study are summarized in Table 8.

Fitzwater (1948) discovered that, when a clockwise movement of a control lever re-

studied by Warrick (1947*a, b*). In one experiment responses were recorded while subjects were attempting to move a light to a center position on a display. All responses

FIG. 10. Population stereotypes for movements made in centering a light on a linear display by means of a rotary control. In arrangement A the control was in the same plane as the display; in B the control and display were in different planes. The light could be centered by turning the knob in either direction. The directions actually used by the subjects are tabulated. Note the preponderance of clockwise responses. (From Warrick, 1947*a*.)

sulted in clockwise rotation of a pointer (in the 12 o'clock sector), a significantly higher score was obtained in a continuous compensatory-pursuit task than when the same control movement caused a counterclockwise rotation of the pointer.

Population stereotypes in the operation of a variety of rotary controls in response to both linear and circular displays have been

were rewarded, because the light could be centered by movement of the control in either direction. The apparatus and the results are shown in Fig. 10. Similar stereotypes were recorded by Carter and Murray (1947) for responses made in controlling the movements of a spot on an oscilloscope tube.

When controls and their associated displays were located on panels at right angles

to each other, as shown in Fig. 10B, many individuals reacted to the same stimulus sometimes with a clockwise response, sometimes with a counterclockwise response. When displays were made in the shape of an arc, the subjects adjusted the controls more rapidly when they were required to rotate them clockwise in order to move the displays in a clockwise direction around the arc. For example, if it were desired to move

servers usually attribute motion to the light rather than to the frame and report that the direction of motion is opposite to what really exists.

Figure-ground relations. It is known that figure and ground relations sometimes become reversed. Such a reversal apparently occurs when an aircraft pilot switches from "contact" to "instrument" flight. As long as the pilot can see the earth, he perceives his own aircraft to be banking, climbing, or diving with respect to the stationary earth below. However, as soon as outside vision is excluded, the visible parts of his own aircraft, such as the instrument panel and cockpit enclosure, become the fixed background with reference to which the small moving parts of the instrument displays appear as figures.* He now responds in terms of an 'aircraft reference' principle.

Several observers have reported figure-ground reversals when watching the ground from a banking aircraft (MacLeod, 1940; Moore, 1940; Webster, 1940). When the earth was viewed through a near-by window, so that it subtended a relatively large visual angle, the aircraft was perceived to be in a bank; however, when a relatively small area of the earth was seen through a distant window, the aircraft was perceived to be level and the earth tilted.

The original flight attitude indicator, which was the prototype of most attitude instruments still in use, was designed with an "artificial horizon" bar that remained parallel to the earth's horizon during the roll of the aircraft (Fig. 12). It was thought that this use of the external-reference principle would give the pilot the impression that he was actually looking at the horizon and thereby reduce his "mental effort" (Poppen, 1936). It turns out that if the horizon bar is perceived as figure (instead of as part of the background) and is responded to in accordance with the population stereotype,

* Some experienced pilots, however, state that they have succeeded in preventing this reversal from taking place.

FIG. 11. Apparatus for studying the stereotypes of subjects in adjusting different arrangements of rotary controls and semicircular displays. (From Warrick, 1947b.)

the light on the display shown in Fig. 11A to the right (counterclockwise), the control was moved counterclockwise by most individuals. However, performance was not so stereotyped with this arrangement as it was with that shown in Fig. 11B.

Responses to directional cues are determined in part by configurational properties of the total visual field. Responses may depend upon whether the control is located to the right or left of the display, whether the control and display movements can be projected onto the same plane in space, whether control and display movements are rotary or translatory, and upon the dominance of various parts of the visual field. Duncker (1939), for example, showed that if a fixed point of light is observed within an oscillating rectangular frame, ob-

the pilot will move his control in the wrong direction and make a reversal error. Pilot reports show that this frequently happens during the early stages of flying training (Fitts and Jones, 1947b). Similar errors have been reported by men operating submarine diving controls where the same principle is used. Furthermore, two experimental studies (Browne, 1945; Loucks, 1947), agreed in showing that novices make fewer errors in responding to an artificial

FIG. 12. An artificial horizon used to give orientation information to pilots. The indication shown is that of a diving turn to the right. The long white line is a gyro-stabilized bar that represents the position of the earth's horizon.

horizon that must be interpreted in accordance with the aircraft-reference principle than to an indicator that must be perceived as a part of the background and interpreted in accordance with the external-reference principle.

Set and change of set in responding to directional indications. The important role of "set" in the interpretation of directional cues can be illustrated by one of the conditions investigated by Warrick (1947b). Subjects alternately adjusted two rotary controls, each of which governed a related semi-circular display. When clockwise rotation of the controls resulted in clockwise movement of the controlled objects, performance was superior to that recorded when clockwise control movements gave counterclockwise display movements. However, when a mixed arrangement was used, i.e. when a change of set was required between successive responses to the two controls, overall per-

formance was inferior to that recorded under either of the two uniform conditions. Interestingly enough the greater number of errors in the change-of-set task was made in adjusting the control that operated in accordance with the population stereotype. An obvious conclusion from this finding is that all controls that must be operated in a rapid sequence should conform to a uniform direction-of-motion principle.

It must not be overlooked, however, that certain shifts in set can be made with little or no confusion if the total situation is favorable. For example, an individual who knows he is steering with a wheel seldom experiences any difficulty when he shifts his hand from the top to the bottom of the wheel, even though this requires a right-left reversal of his control movements.

Error information versus correction information. It has been proposed that a display should indicate how to correct an error rather than indicate the nature of the error itself. This proposition implies that behavioral processes are simplified if attention is directed to the movement to be made rather than to the error to be corrected.* This hypothesis has not been verified, however. Evidence cited earlier indicates that most individuals habitually respond to the movement of an indicator by executing a movement in the opposite direction. The typical individual apparently interprets a display as if it were an indication of error and responds to it as if to drive the error in the opposite direction. As a result of long experience it has been decided that the Landing Signal Officer on an aircraft carrier, for example, should hold his signal flags up when the approaching pilot is too high. Displays in most cases should indicate the direction of the error, not the direction of the movement to be made in correcting it.

Ambiguity of directional cues from circular displays. Rapid and accurate direc-

* This distinction is not comparable to that traditionally made between sensory and motor set.

tional responses cannot be made equally well to indications from all sectors of a rotary display. Warrick and Grether (1948) studied the ability of subjects to check-read panels of 16 circular instruments and to interpret as too much or too little the deviations shown by any instrument that deviated from a normal reading. When the normal pointed position was at 9 o'clock on the dial, performance was superior to that recorded when the normal position was at 3 o'clock.

Fitts and Simon (1950), utilizing a compensatory dual-pursuit apparatus, required subjects to keep the pointers of two instruments centered by operating two rotary controls. Pointer alignments at the 12, 3, 6, and 9 o'clock positions were compared. In the case of horizontal and vertical separation of the two circular instruments, the 9 and 12 o'clock positions, respectively, were found to give consistently higher performance scores than the 3 and 6 o'clock positions. Likewise, Connell and Grether (1948) and Long and Grether (1949) found a greater number of errors in verbal reports of the direction of change represented by a pointer movement when the movement occurred in the right or bottom quadrants of a circular dial than when it took place in the left or top quadrants. The inferiority of the right and bottom quadrants, as revealed by such findings, may be due to the conflict, in this part of a circular dial, between the principle of up or right to indicate an increase, and the principle of clockwise to represent an increase.

Moving pointer versus moving scale. A change in the magnitude of a value can be shown by movement of a pointer, by movement of a scale behind a fixed lubber line, or by simultaneous movement of both pointer and scale. The problem of designing a compass for use on a vertical instrument panel will serve to illustrate some of the directional ambiguities that are met in connection with each type of display.

A scale that moves behind a window or fixed lubber line permits the operator always to look at the same point in making a reading. An instrument designed in this way cannot be check-read easily, however, because the numbers on the scale must always be read before a response can be made. Furthermore, if scale values increase in a clockwise direction, then the scale must move in a counterclockwise direction in order to indicate an increase, whereas, if the scale is designed so that it rotates clockwise to indicate an increase, then values on it must increase in a counterclockwise direction. Neither alternative is a satisfactory one.

It is easy to check-read a moving-pointer instrument when the pointer is in the left or upper parts of the dial, but when the pointer is in the bottom or right quadrants reversal errors may sometimes occur, as was shown in the preceding section. Long and Grether (1949) and Loucks (1949a), assessing verbal and motor responses, respectively, to moving dials, moving scales, and moving pointers, found that a moving pointer in the upper half of a compass-type dial results in the fewest ambiguous responses.

Grid and coordinate systems. Two-dimensional coordinate systems are used on maps, graphs, television screens, and many other projection surfaces. Rectangular and polar coordinates are most common, but other systems are possible. Few studies have been made of the ability of individuals to interpret these various systems.

Compasses, maps, and terrain displays can be azimuth-stabilized; i.e. north can be made to appear always at the same point, such as the top; or they can be heading- or course-stabilized; i.e. the direction in which the reader is traveling or looking can be made to appear always at the same point, such as the top. Maps can be used with north at the top, or they can be rotated as the user turns. The advantages of the two systems with respect to the maintenance of orientation are still not clearly defined. Loucks

(1949b) found that novices became more seriously disoriented when using a rotatable map with a fixed-scale compass indicator than when using a fixed map. Much may depend on which principle one has been trained to use, and on whether an immediate motor reaction or a deliberate intellectual response is required.

Variations in magnitude. It is generally accepted that an increase in magnitude or a change from "off" to "on" should be represented by movement of an indicator or of a control device in a clockwise direction if motion is rotary; if motion is translatory, then by movement of the display or control upward, forward, or to the right. Although little experimental work is available on this topic, common practice seems to be sound. Clocks, thermometers, speedometers, and nearly all types of scales follow this convention. The directions employed in control movements are not so well standardized, however. Controls that follow opposite principles can be found on radios, stoves, locks, and many other common devices. These exceptions often lead to confusion. Switch positions on central telephone switchboards and in electrical substations, on the other hand, are standardized. Here one of the most useful principles is the use of the center or neutral position for "off."

Characteristics of good qualitative displays. Qualitative displays should conform to population stereotypes. The required interpretation should be in harmony with the configurational properties of the environment in which the display is to be used. The display should also conform to the sets required in interpreting related displays. The movement of a display should correspond wherever possible to the direction taken by the error and not the direction appropriate for corrective action.

Undoubtedly these requirements reflect the nature of the processes by means of which men orient themselves. In the design of qualitative displays, as was true for quantitative ones, the best display is one in

which the fewest processes must intervene between the stimulus and the appropriate response. This topic is too complex, and too little is known of the processes involved in maintaining orientation, to permit formulation of any general theory to guide display design. There is need for a theory of spatial orientation that will synthesize the various findings in this area and provide a basis for a deductive approach to future design studies.

AUDITORY DISPLAYS

An on-off or pulsed signal, such as that produced by a policeman's whistle, is the simplest type of auditory display. It is possible, however, to transmit quite complex information by means of a temporal pattern of these on-off signals. Information may also be transmitted by amplitude, frequency, phase, or some other type of modulation of a carrier signal. Auditory signal systems make use of all these possibilities.

Auditory signals are almost always accompanied by other sounds (noise) that carry no useful information. Signal-to-noise ratio is the commonly used measure of the amount of noise interference present. In terms of statistical concepts of communication theory, noise level can be thought of as the probability that any discriminable signal does not represent transmitted information but is simply a fluctuation in the background. Because of the pervasiveness of unwanted sounds, the following discussion will deal primarily with auditory discrimination in the presence of noise.

As a means of introducing some of the design factors that influence signal intelligibility, it will be of advantage to take as an example a particular signal system. The low-frequency radio range will serve this purpose.

Discrimination of aural radio range signals. Radio range signals are produced by beamed radio signals modulated at 1020 cps

and turned periodically on and off. The signal in one beam is on when that in the other is off, in such a way that, where the beams are of equal strength, a steady tone is heard. American radio ranges use the code letters *A* (dot-dash) and *N* (dash-dot) to identify the two beams. Pilots fly at assigned alti-

somewhat with the level of background noise.

The meaning of such data for a pilot flying a radio range is represented graphically in Fig. 13. Under the ideal conditions of no static, a pilot with normal hearing should be able to fly a course that would deviate

FIG. 13. The effect of static on the effective width of the aural radio range. (From Flynn et al., 1945.)

tudes along the edge of an air lane at a position where they are just able to detect the *A* or the *N* signal. They are separated from aircraft going in the opposite direction by the zone of steady tone, the width of which is inversely proportional to their ability to discriminate auditory signals.

Signal-to-noise ratio is one of the principal factors determining the discriminability of auditory signals. In one study (Flynn et al., 1945) the minimum intensity difference that permitted discrimination between *A* and *N* signals was found to vary from about 0.5 decibel at a favorable signal-to-noise ratio (50 decibels) to about 2.5 decibels at an unfavorable ratio (-10 decibels). The optimum signal intensity, however, varied

approximately 1.5 degrees from the center of the beam. This course is represented by dotted lines. At 150 miles from the range station he should be 4 miles off course. The solid lines in Fig. 13 represent the extent to which he might be driven off course by the presence of static. Thus at 150 miles with 50 microvolts of static he would have to be 16 rather than 4 miles off course in order to be sure that he was flying on the correct side of the beam.

It has been reported (Flynn et al., 1945) that a suitable filter permits a pilot to follow radio range signals in approximately 10 decibels more static than is possible without the filter (see Fig. 14). When a circuit is to be used for both code and voice reception,

the best practice is to provide for the optional use of a band-pass filter for attenuating frequencies other than the code frequency, and a narrow band-elimination filter for attenuating the code sound when it is desired to use the system for voice communication.

Effect of signal pattern. Another way to improve signal intelligibility is to choose signal patterns that can be discriminated easily from one another. At one time an *E* (dot)

FIG. 14. Mean threshold values for discriminating *A* and *N* code as a function of signal-to-noise ratio. Note the superior performance resulting from the use of a selective filter. (From Flynn et al., 1945.)

and *T* (dash) keying system was employed on radio ranges used in Great Britain. Browne (1943) compared the number of errors made in recognizing the British *E-T* signals with the errors made with the American *A-N* system and found the latter to be superior. He also concluded that there is an optimum speed of transmission (approximately 24 letters per minute) above or below which accuracy of recognition suffers. The speed with which an individual can interpret code sounds, rather than speed of sending, is the factor that usually limits transmission rates.

Seashore and Kurtz (1944) analyzed 29,000 errors made by students in copying dot-dash code and determined the order of difficulty of code characters and the frequency of confusion between different pairs of characters. As was shown to be the case

with numbers, Seashore and Kurtz found definite preferences or population stereotypes for copying certain characters. Students tended also to write letters in place of numbers. It is of interest to note that the *E-T* pair was found to be more frequently confused than was the *A-N* pair.

Flybar. An interesting attempt has been made to devise auditory signals that can be substituted for visual cues in complex perceptual-motor tasks. The system has been called "Flybar"—flying by auditory reference—because of its application to aviation. It was first demonstrated as feasible in flight by de Florez (1936). Further research was undertaken at the Harvard Psycho-Acoustic Laboratory in order to determine how well continuous control adjustments could be made in response to different signal combinations, and how many simultaneous auditory signals could be responded to successfully (Forbes, 1946).

Various complex auditory signals were tried. Combinations of separate tones proved to be unsatisfactory, since subjects often become engrossed with one signal to the exclusion of the others. One moderately successful complex signal was devised. It combined the following three indications: (1) a "turn" signal that could be made to appear to sweep from right to left, or vice versa, by reason of an intensity shift between the two ears; (2) a "bank" signal that could be made to appear to tilt by means of a change in pitch of the carrier tone during each sweep; (3) an "air speed" signal that took the form of a "beep" at a rate that varied from 2 to 22 per second. This three-in-one signal was reported to be realistic and relatively easy to interpret. Subjects successfully 'flew' a Link instrument trainer on a straight course with only these auditory cues for guidance.

Voice communication systems. A great many psychological considerations enter into the design of equipment used for the detection, transmission, and reproduction of human speech sounds. In fact, this is the

most important area in the design of auditory displays. But since the factors that influence the intelligibility of speech have been covered in earlier chapters, discussion of voice communication systems is omitted from the present chapter. For a further summary of research on a great variety of psycho-acoustic problems in the design of communication systems, the reader is referred to Miller, Wiener, and Stevens (1946).

Visual versus Auditory Displays

Developments such as Flybar, which substitutes auditory for visual cues, and new devices such as television and facsimile, which substitute visual displays for speech sounds, raise the question of the relative advantages of visual and of auditory displays. This general problem touches the display of all types of information.

Each sense modality has certain inherent advantages and disadvantages for the detection and analysis of different kinds of information. Audition is more nearly a continuous sense than vision; vision is basically selective and intermittent. As a consequence, audition is well adapted for the detection of warning stimuli that may arise at any moment from one of a variety of sources, whereas vision is well suited to the selection of and concentration on particular stimuli to the exclusion of others. Many other differences exist. Craik (1947), for example, pointed out that the ear is better than the eye in distinguishing a constant pattern from a varying background, such as the beating of a submarine's propellers in the total pressure pattern picked up by a sonar device.

Simultaneous use of two sense modalities. There are some tasks, such as the search for weak radar signals, in which simultaneous use of both visual and auditory displays may provide mutual reinforcement. The display of different information to different sense modalities, either simultaneously or in alternation, has been suggested by various writers. One of the chief arguments ad-

vanced in favor of this idea is that use of auditory cues in complex control tasks should lighten the heavy work load often carried by the eyes. This contention is plausible, but experimental data are lacking on important assumptions underlying it. In particular it has not been demonstrated in perceptual-motor tasks that it is easier to respond to a combination of visual and auditory data presented simultaneously, than to respond to the same information presented entirely by means of visual displays. Display systems employing two sense modalities may necessitate rapid fluctuation of attention between the two sense fields. If this is true, and if human perception is essentially a one-channel system, then the use of a mixed system may actually increase rather than reduce the load on the operator, at least for tasks that profit from continuous attention. However, once a skill reaches the level at which it becomes essentially automatic, it is possible that bimodal sensory control may become quite efficient. The hypothesis of a psychological refractory period, discussed in a later section, proposes that central or motor processes, rather than receptor processes, limit the speed of responses in continuous tasks. If this is true it is a further reason for doubting the advantage of bimodal displays. The judicious combination of visual and auditory displays in various kinds of tasks remains, however, an interesting, if relatively unexplored, possibility.

Visible speech. Recent developments indicate that it is feasible to transform electrical patterns of speech into two-dimensional visual intensity patterns (and perhaps patterns of color) which can be 'read.' This development is discussed in Chapter 26.

The converse of visible speech is the conversion of visual stimuli into an auditory pattern so that the blind can read or find their way about by the use of auditory cues. Considerable research is being directed at this problem.

TACTUAL DISPLAYS

Many of the skilled movements made in machine operation are guided by touch. It is desirable, therefore, to improve tactual displays as well as visual and auditory ones. One of the most obvious possibilities is to provide machine controls with knobs of distinctive shapes. Studies have been conducted to determine the advantages of shape coding and to discover what shapes provide adequate recognition cues.

Shape coding of control knobs. It has been shown (Weitz, 1947) that use of shape-coded

control knobs lessens the amount of interference between conflicting position habits when an operator changes from one arrangement of controls to another. It is an advantage in this situation for the same knobs to be used on corresponding controls in the new arrangement as were used in the old one.

In order for coding to be effective, shapes must be used that can be distinguished easily from one another. An investigation by Jenkins (1947a) revealed some of the factors affecting recognition of control knobs.

FIG. 15. Eleven knob shapes that are readily identified by touch. (From Jenkins, 1947a.)

If two objects of the same shape are mounted differently—for example, if one cube is mounted with a flat side up and another cube is mounted so that a corner is up—the two are often confused. The orientation of a shape by itself, it appears, is not a distinctive tactual cue.

It was also found that there are families of shapes, the members of which are frequently confused with one another, although they may be distinguished readily from shapes belonging to other families. For example, most shapes with sharp corners and plane surfaces, regardless of the exact number of sides, apparently belong to the same family. Eleven knob shapes that were recognized with practically no errors, even when subjects wore gloves and grasped the knob for only a second or so, are shown in Fig. 15.

Size and color coding of controls. Size and color coding have been proposed as further means for facilitating the identification of controls. Although multiple cues are theoretically desirable, neither size nor color offers a very practical means of coding controls. Size is a less useful cue than shape because one can recognize a great many more shapes of a standard size than one can identify different sizes of a standard shape. The use of color is limited because it is effective only when the operator looks at the control he is about to use, and then only when levels of illumination are sufficient to permit cone vision. Color, however, has many uses in coding both displays and controls as to function. The location of controls and their mode of actuation also serve as an important means of identification.

DESIGN OF CONTROL SYSTEMS

Man has progressed in the art of control from a state in which he used hand-held tools to fashion the products of civilization to a stage in which, by adjusting delicate control devices, he directs complex machine proc-

esses and governs the flow of energy to distant places. Man's role in a technological society is thus becoming more and more one of guiding and directing. Although the tools and simple machines employed by craftsmen can probably be improved somewhat, engineering psychology today should concern itself in large measure with the design of devices that permit individuals to exercise precise control over large sources of energy.

It is fitting, therefore, that psychological problems in the design of controls be introduced by a discussion of the transfer and application of force through mechanical and electrical systems. This brief excursion into the field of engineering may give the reader a better understanding of the problems met by engineers who must design control systems in which human beings perform critical acts. It will also introduce the reader who is unfamiliar with control theory to a point of view that holds considerable promise for the fundamental study of perceptual-motor behavior.

Dynamic Aspects of Mechanical Systems *

Transmission of forces through elastic bodies. The characteristics of an elastic system that are important in absorbing, dissipating, or transmitting the forces acting on it are its mass, its stiffness or rigidity, and the friction developed during its movement. These characteristics are referred to as system constants. The behavior of an elastic system depends on these constants as well as on the forces applied to it. This is true for simple mechanical systems that transmit forces only, and for control systems in which an input signal of low energy governs the output of an amplifier or some other device that provides a source of additional energy.

Lag and oscillation. Two important problems that arise in designing control systems

* The assistance of R. C. Gibson, Department of Electrical Engineering, USAF Institute of Technology, in formulating this section is acknowledged.

are lag and oscillation. Lag is evidenced by a time delay between the input and output sides of a transmission or control system. In systems subjected to cyclical inputs delay time often is expressed as the fraction of the cycle by which the output lags behind the input (phase lag). Lag is a universal characteristic of human motor behavior. It

The relation between the input and the output of a control system can be expressed as a function of time by means of a *system equation*. If such an equation is available, then the amount of lag and oscillation can be determined for any specified input. System equations can be employed to describe the behavior of large, complex systems, or of

FIG. 16. Response curves illustrating different amounts of oscillation due to different damping ratios. Curve 1 illustrates overdamping, curve 2 critical damping, and curves 3 and 4 underdamping.

consists of reaction time plus movement time.

Oscillation is evidenced by an output that overshoots the correct position one or more times before it settles down. Oscillation, or "hunting," often results when high corrective forces are developed by or act upon members with large effective mass and relatively small energy-dissipating elements. As lag is reduced by the use of large initial forces, application of the exact amount of braking force needed to stop the movement at a precise point becomes more difficult and therefore oscillation tends to increase. If, after the initial disturbance, oscillation builds up in a control system, then the system is unstable. Response curves with different amounts of oscillation are illustrated in Fig. 16.

small units of a system. Often these equations can be determined for a total system even though the characteristics of some of its units are unknown.

System equations. A diagram of a simple system containing a mass, a spring, and a damper is given in Fig. 17A. If a time-varying force $f(t)$ is applied to the mass M , the internal opposing forces in the system may be equated to the applied force as

$$Kx + F \frac{dx}{dt} + M \frac{d^2x}{dt^2} = f(t) \quad (3)$$

where x represents the position of the mass with respect to its rest position, dx/dt the velocity of the mass, and d^2x/dt^2 the acceleration of the mass at any instant. A special case, often called the transient solution, results if the mass is displaced from its rest

position and released at a time arbitrarily called zero. Then the subsequent behavior of the system can be described by an equation of the form

$$Kx + F \frac{dx}{dt} + M \frac{d^2x}{dt^2} = 0 \quad (4)$$

The mass may overshoot its rest position and proceed to oscillate with a decreasing

miliarly known as current. The transient performance of the mechanical system can be duplicated in the electrical circuit by making $e(t) = 0$ and placing an initial charge across the condenser at $t = 0$.

Once a system equation is set up, it can be solved by two general types of operations. One is to measure directly each of the constants in the system. This is not always

FIG. 17. Diagrams of (A) a simple elastic mechanical system, and (B) an analogous electrical circuit.

amplitude but a constant frequency (as a car does after hitting a single bump), or it may return to its former position slowly without oscillation, depending upon the relative values of the system constants of K , F , and M .

The dynamic behavior of a simple electrical circuit such as that shown in Fig. 17B can be described by the equation

$$Cq + R \frac{dq}{dt} + L \frac{d^2q}{dt^2} = e(t) \quad (5)$$

in which K , F , M , x , and $f(t)$ are respectively replaced by capacitance C , resistance R , inductance L , electric charge q , and electromotive force $e(t)$. The term dq/dt then represents the time rate of change of electric charge and is more fa-

possible. The other approach is to apply known inputs to the system, to record the resulting outputs, and to infer the relative magnitudes of the system constants from these input-output data. In practice it is convenient to determine certain ratios between the system constants, such as the undamped natural frequency $\sqrt{K/M}$, and the damping ratio $F/2\sqrt{KM}$. Response curve 2 in Fig. 16, for example, has a damping ratio of 1 and is said to be critically damped. Curves 3 and 4 have damping ratios of less than 1 and are said to be underdamped. At present the methods commonly used by engineers in the determination of system equations from analysis of the relation between input and output depend

upon an assumption of linearity. The concept of linearity as it applies to the human being is discussed in a later section.

Attempts have been made to describe the behavior of isolated muscle preparations and of intact human limbs by system equations (see Gilson, Walker, and Schoepfle, 1944; Fenn, 1938). The homeostatic processes and general neural activities of the body are also subject to analysis as rhythmic, dynamic processes (see Hoagland, 1949; McCulloch, 1949); so are certain aspects of receptor processes (see Main, 1950).

We have considered a few of the dynamic characteristics of simple physical systems and have seen that certain aspects of human behavior can to some extent be described in a manner analogous to that followed for physical systems. It may be possible, therefore, to analyze the total complex of human perceptual-motor behavior in this way. The human organism is a most complex example of a dynamic system combining electrical, chemical, and mechanical elements. As Searle and Taylor (1948) point out, it is likely that present equations, complex as they are, are still too simple to represent the processes involved in perceptual-motor tasks. Nevertheless the physical systems just described provide a suggestive model for the dynamic aspects of human controller tasks.

Control systems with feedback. The transmission links and control systems discussed thus far have been 'open' or one-way systems. To use a human analogy, these open systems resemble a patient with *tabes dorsalis* who can send signals to his arm muscles but, unless he watches the resulting movement, receives no return signals to tell him what his arm is doing. The most important, and for psychologists the most interesting control systems, however, are those with feedback loops. These are commonly called servo or slave systems. The behavior of a servo is governed, not by the input signal alone, but by the difference between the input and some function of the output. Before considering servo systems and the

dynamic aspects of total human controller tasks, however, it will be well to examine some of the more limited aspects of human motor behavior relating to the design of control systems.

Time and Force Patterns of Human Motor Responses

Every human motor response involves a distribution of force in time and space. This force is generated in the muscles and is transmitted to tools, levers, switches, steering wheels, and other objects by elastic transmission systems, the limbs. If we include only the limbs, the system is an open one that can be described adequately by reference to its equivalent mass, damping and stiffness. When we add sensory and neural processes the system becomes one with complex feedback loops. It is relatively simple to eliminate exteroceptive sensory feedback during motor performance, but it is exceedingly difficult to eliminate interoceptive feedback. Proprioceptive feedback loops are always active during normal motor responses.

Discrete corrective movements. If an individual moves his arm quickly from one point to another, he may undershoot or overshoot the point of aim. If the arm is carrying a heavy load, if damping or braking force is inadequate, or if the tenseness (gain or stiffness) of the muscles is too great, the time plot of the response may reveal a series of underdamped oscillations such as are shown in curves 3 and 4 in Fig. 16. The corrective responses made by skilled subjects to discrete stimuli may resemble curve 2 of Fig. 16, which shows no oscillation. But usually there is a succession of more-or-less discontinuous movements. Each movement may represent a separate effort to reduce the error to a subthreshold magnitude. Woodworth (1899) called the first of such a series of corrective movements an "initial impulse" and found that it lasted about 0.2 second. The phase during which discrete secondary corrective movements were made

he called "current control." Most subsequent investigators have made a similar classification of the elements in adjustive movements. Woodworth reported a value of about 0.5 second for the interval between the initiation of successive adjustments during current control in a one-dimensional task. This figure agrees with later findings on the frequency characteristics of successive corrections during continuous one-dimensional tracking tasks.

Movements during continuous perceptual-motor tasks. Stetson (1905) classified rhythmical movements as slow or fast. In slow movements, groups of opposing muscles contract with uneven tension. In fast movements, both groups of opposing muscles may be under tension ("moving fixation"), or they may contract in alternation or "ballistically." When ballistic movements are made at a maximum rate the limb is literally thrown back and forth, single muscle contractions serving to check one movement and to initiate the next. Stetson and McDill pointed out that slow or controlled movements can be modified at any point in their course, but that this is not true for fast movements, especially ballistic or free movements like beating time with a baton. They observed that ". . . such a rapid movement cannot be subject to control after it is once started; movement elements occurring at the rate of 10 per second are the units; at most then movements can be modified not oftener than ten times in a second" (1923, p. 23). They concluded further that fast movements are predetermined by the preliminary adjustment or set of the individual.

Peters and Wenborne (1936), studying the time patterns of rapid arm movements executed in moving a stylus along a spiral path, concluded that control was accomplished by means of a series of more or less separate and successive variations in rate, and that these separate "motor impulse effects" were completely determined by processes that preceded each phase of the movement.

In certain situations a sequence of several movements appears to be released as a unit. Dodge (1907) thought that several eye movements were triggered off as a unit when one was reading, and Woodworth (1899) concluded that the same was true of arm movements in a dotting task. Barnes and others (1940), recording eye movements during the performance of skilled factory work, observed that, in acts ("therbligs") requiring visual guidance, the eyes left the scene of action 0.06 to 0.24 second before the action was completed.

FIG. 18. Section of a tracking record showing three types of responses to a continuously moving target. *A* and *C* are successive position corrections; *B* is a 'rate tracking' response. (From Ellson, Hill, and Gray, 1947.)

Visually controlled aiming and tracking behavior usually shows a cyclic pattern with a mean frequency of about 2 responses or half-cycle waveforms per second when the tracking is in one dimension (Bates, 1947; Craik, 1947; Ellson, Hill, and Gray, 1947; Hick, 1948a; Tustin, 1947; Vince, 1948a).

Ellson, Hill, and Gray (1947) identified two types of tracking in a one-dimensional following-pursuit task in which the subject used a position control system. "Rate-tracking responses" appeared after the operator had achieved a relatively small position error, and they were evidenced by a rate of movement of the control handle that approximately matched that of the target (see Fig. 18). "Position-tracking responses" were evidenced by single or successive half-cycle waveforms, which were taken to be indicative of discrete control movements. It would appear, then, that skilled movements in continuous tasks are not under continuous visual control but, like the elements in dis-

crete corrective movements, are triggered off in units.

Acceleration patterns during rapid control movements. Acceleration records sometimes reveal fluctuations in force that are too small or too rapid to be detected from simple

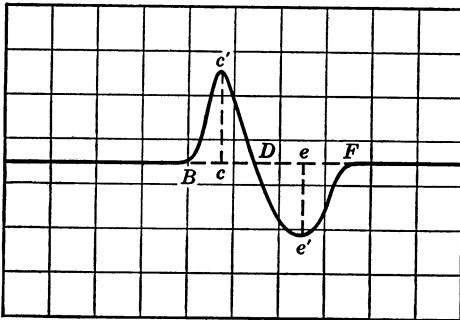

Smoothed samples of typical records of position, rate, acceleration, and rate of change of acceleration ("jerk") for a 9-inch movement to the right are shown in Fig. 19. The essential nature of the movement, which was initiated after a reaction-time lag of 0.44

FIG. 19. Smoothed records of the (1) position, (2) rate, (3) acceleration, and (4) jerk (rate of change of acceleration) of a hand control for rapid corrections made in a tracking task. *A-B* is reaction time; *B-F* is movement time. (From Taylor and Birmingham, 1948.)

position curves. For this reason Taylor and Birmingham (1948) recorded the output from an accelerometer that was mounted on a relatively long (76-inch) control lever. Subjects watched a spot of light on an oscilloscope and tried to keep it centered by compensatory movement of the control lever. The spot jumped to one side or the other by an amount equal to 1.5, 3, or 6 degrees of visual angle; the appropriate response was a movement of $2\frac{1}{4}$, $4\frac{1}{2}$ or 9 inches, respectively, in the opposite direction.

second and lasted for about 0.34 second, was described as follows:

... For approximately the first 0.07 sec. force in the direction of motion was applied at an increasing rate, then it was applied at a decreasing rate for another 0.07 sec., then braking force was applied at an increasing rate during the next 0.10 sec. and finally the negative force was applied at a decreasing rate for the last 0.19 sec. of the response. [P. 793.]

There were no ballistic-type movements in which agonists and antagonists showed short

bursts of activity with intervening periods of no applied force. Movements appeared instead to be guided by continuously varying forces. Ellson and Hill (1947) likewise found no evidence of ballistic-type movements in muscle potential records taken during tracking. Evidence from several studies (de Montpellerier, 1937; Taylor and Birmingham, 1948) indicates that the time devoted to the positive and negative phases of the acceleration curve varies with the nature of the control task, such as the relative importance of starting a movement quickly or of stopping it accurately.

Reaction time in perceptual-motor tasks. The delay time before a movement is initiated by a trained subject in response to a stimulus has been found to be independent of the rate, extent, or direction of the specific movement required by the stimulus, and also to be independent of speed-up instructions. It is difficult to measure the reaction time to particular stimuli occurring during continuous tasks, but reaction times to discrete stimuli in a series have been reported at values ranging from 0.23 to 0.50 second (Brown and Slater-Hammel, 1949; Ellson and Hill, 1948; James, Nichols, and Phillips, 1947, p. 360; Taylor and Birmingham, 1948; Tustin, 1947).

Proprioceptive reaction time is of particular interest here. Craik (1947) reported an experiment in which a lever had to be moved rapidly against a stiff spring so as to correct a misalignment. After individuals had learned the 'feel' of the control and were making fairly accurate movements, the spring tension was altered between responses so that they would tend to over- or under-shoot. Under these conditions about 0.15 second elapsed after the beginning of a movement before the individual modified his response pattern to meet the changed resistance. Vince (1948*b*) obtained a figure of 0.16 second for proprioceptive reaction time in a somewhat similar experiment. Hick (1949), however, has questioned these short times and has shown that the inertia and

elasticity of the limb are important factors whenever force must be increased in response to a second stimulus.

In many perceptual-motor tasks, especially those in which information must be secured from several different displays, the latency and perceptual span of vision are important factors. Dodge (1907) postulated the necessity of a "clearing-up" process which he believed precluded a succession of adequate visual fixations under 0.1 second each. Eye fixations in reading seldom are shorter than 0.2 second. More difficult discriminations than those made in reading impose even slower rates on the visual sampling process. Fitts, Jones, and Milton (1950), for example, found that aircraft pilots fixated individual instruments for 0.6 second on the average when making a blind landing. Travis (1936) found that the mean latency of eye movements in following a suddenly-appearing target was 0.20 second with a standard deviation of 0.02.

In general, then, it appears that responses to proprioceptive stimuli and simple following movements of the eyes take place in an interval approximately that required by simple sensory reactions, but that eye fixations and muscular responses during perceptual-motor tasks are often longer.

Psychological refractory phase. The hypothesis of a psychological refractory phase has been developed in reports from Cambridge University (Craik, 1947, 1948; Hick, 1948*a*; Vince, 1948*a*) and by some earlier workers (see Telford, 1931). For tasks requiring rapid corrective movements, this hypothesis holds that if two stimuli, S_1 and S_2 , occur in rapid sequence, then the response called for by S_2 cannot be initiated until the primary movement in response to S_1 has been completed or until an appropriate time interval has elapsed. The exception has been proposed, however, that if S_1 and S_2 occur nearly together in time they may be responded to as a pair. The fact of cyclic motor responses in continuous tracking tasks has been cited as indirect

evidence in support of this hypothesis. The most direct evidence, however, comes from experiments in which two discrete stimuli have been presented in rapid sequence.

Measuring the time required to initiate movements in each of two directions, and using stimuli separated by intervals varying from 0.05 to 1.6 seconds, Vince (1948a) found that responses to S_2 were delayed when S_2 followed S_1 by less than 0.3 second (approximately the reaction time). Ellson and Hill (1948), however, repeated Vince's study without finding support for the hypothesis.

It appears from the scanty data now at hand that there is often a real refractoriness when two stimuli occur closer together than a tenth of a second. At these very short intervals acceleration records reveal no changes in the typical force patterns elicited by S_1 for periods of at least $\frac{1}{10}$ second, regardless of the time of occurrence of S_2 (Warrick, 1948, unpublished data).

It is interesting to speculate that a refractory phase of greater than $\frac{1}{10}$ second may be a necessary condition for the learning of certain tasks. On the one hand, discontinuity and refractoriness may be characteristic of situations that favor the modification of behavior. For example, while an individual is learning a new skill he may respond, wait for knowledge of results, then respond again. On the other hand, in situations in which habitual modes of response are utilized he may respond continuously or nearly so. This point is also germane to the topic of linearity, to be discussed later.

Optimum Rates and Forces of Movements

Some tentative conclusions may be drawn regarding the optimum rates of movement and the optimum forces to be employed in operating controls. With the present state of knowledge, however, generalizations in this area must be made with caution.

Proprioceptive feedback. The ability of individuals to produce or discriminate variations in force, extent, and duration of movements, and in particular to utilize proprio-

ceptive feedback, underlies their ability to insert these functions into a control task. Fullerton and Cattell (1892) concluded that the extent of a movement is more accurately judged than its force, and that force in turn is judged more accurately than duration. Woodworth (1901) found that discrimination of force and of extent, although related, are separate functions. Hollingworth (1909) found that the discrimination of extent and duration are also independent.

Others have suggested that one type of proprioceptive feedback is primary, and others secondary. Morgan (1917) reported that force applied in pulling a weight was judged in terms of the duration of the movement. Hick (1945b) suggested that, when an individual is operating a tracking control against viscous friction or its equivalent, better performance may result if he concentrates on generating a constant force rather than a constant rate. It has been proposed by Bates (1947) that force can be looked upon as the body's basic output quantity. In accordance with this hypothesis, he reasoned, velocity should be considered the single integral and displacement the second integral of force, and hence to generate a given velocity or a given displacement should in theory be a more complex operation than to generate a desired force.

The question of the body's basic output quantity has an important bearing on the design of control systems that provide optimum proprioceptive feedback: whether, for example, it is better to require large displacements with small variations in force, large variations in force with small displacements, or large variations in the duration of control acts without reference to their extent or force. Examples of each principle and of combinations of these can be found in many common control devices. Of even more general significance is the question of the relative importance of interoceptive versus exteroceptive feedback in control tasks and the optimum combination of the two. Visual control probably is very

important while an individual is learning a new perceptual-motor task. As performance becomes habitual, however, it is likely that proprioceptive feedback or 'feel' becomes the more important.

Aeronautical engineers have followed the rule of thumb that 2 to 8 pounds of force applied to the controls should produce a maneuver involving an acceleration of $1g$. The gradient by which back pressure in a control system increases is especially critical in flying high-speed aircraft where a power boost is added to the controls and where there is a lag before the aircraft responds to the control movements (Orlansky, 1949).

Relation between speed and accuracy. Woodworth (1899) studied the relation between speed of movements and the accuracy with which they could be executed. When less than 0.5 second per movement was permitted, responses made with the eyes closed were about as accurate as those made with the eyes open. Slower speeds gave greater accuracy but about 1.5 seconds per response was sufficient for the completion of all secondary corrections. Still slower speeds failed to increase accuracy. Movements controlled by internal feedback alone (eyes closed) were about equally accurate at all speeds. In this case accuracy was determined chiefly by the initial response rather than by secondary adjustments. When the rate of each movement was constant, accuracy diminished as the interval between movements was increased. This was attributed to the fact that the delay between movements led to greater variability of the primary response and hence to a loss in accuracy. For stereotyped, repetitive movements, shortening the interval between responses resulted in increased uniformity. Woodworth concluded, "the path to skill lies in increasing the accuracy of the initial adjustment" (1899, p. 59). Vince (1948b) repeated and amplified Woodworth's study with similar results.

When subjects were urged to respond quickly but were allowed sufficient time to

complete all secondary adjustments, Brown and Slater-Hammel (1948) found that the time for the initial movement was decreased, the time for secondary movements in some cases was significantly increased, and the correlation between primary and secondary movement times was negative. In subsequent studies by Brown et al. it was found that left-right movements gave shorter primary movement times than did inward-outward movements, but gave longer secondary movement times. These results confirm the assumption, based on the analogy of the mechanical system discussed earlier, that there is an optimum gain or stiffness for any response and that efforts to produce higher rates may lead to unfavorable muscular tenseness and loss of fine control.

Optimum rates of movement. The optimum rates of control movements are determined in part by such factors as the maximum rate of muscle contraction, the maximum rate of innervation, and the effect of fatigue. The maximum frequency attainable in repetitive movements of single limbs (such as tapping the finger or wagging the tongue) is approximately 10 per second. Fenn (1938) pointed out that the period of reciprocal movements is similar for different parts of the body and suggested that frequency is limited by the speed with which excitation and inhibition can be made to alternate in the central nervous system without a loss of precise control over the magnitude of the force. It should also be noted that an appreciable time—about 0.04 second in the human arm—is required for maximum tension to develop in a muscle.

High rates of movement are commonly required by handwheel controls. Winding movements are a combination of reciprocal movements properly distributed in phase. Their maximum rate is approximately half that of simple back-and-forth movements of similar amplitude. The rate that results in most accurate control depends on handwheel diameter, inertia, friction, and other design features, and on the type of target course.

Helson and Howe (1943*a, b*) concluded that there is always an optimum maximum speed. The maximum speeds recommended for different types of handwheels varied from 140 to 200 rpm. Some relations between tracking accuracy and speed of turning are shown in Fig. 20 for handwheels of 2.25 inches and 4.5 inches radius. Error in performance was measured in terms of the time that would be required for the target to move from the point of aim to its actual po-

FIG. 20. Accuracy of tracking as a function of speed of handwheel turning. The two curves are for handwheels of 4.5- and 2.25-inch radii and are based on data from 14 subjects. (From Helson and Howe, 1943*a*.)

sition. Accuracy improved steadily with increasing handwheel speeds up to near the human breakdown point. The effect of handwheel diameter was relatively small. This finding agrees with the observation that variations in the amplitude of rhythmic movements have only a small effect on rate (Bryan, 1892; Stetson, 1905).

Optimum gear ratios. The ratio between the amplitude of movement of a control and that of its related display is important for tasks in which a control is adjusted intermittently. Jenkins and Connor (1949) investigated different gear ratios, using an apparatus that permitted variation in amplification over a range of 350 to 1 as well as variation both in control knob diameter and in the accuracy required in the adjustment of a pointer. Time was measured for the initial movement* (called "travel time") and for

* The time measurement was taken from the beginning of the pointer movement to the point

secondary movements (called "adjusting time").

The duration of the initial movement decreased as the gear ratio increased, until an optimum was reached where the pointer movement was large relative to that of the control wheel. Secondary adjustment time was at a minimum, however, when the pointer movement was small relative to that of the control wheel. The form of these relations (Fig. 21) was such that a ratio could usually be chosen to minimize the overall time required for primary plus secondary adjustments. This optimum ratio was approximately 1 revolution of the control knob for 1 inch of pointer movement. Variations in knob diameter made little difference in time scores. It should be men-

FIG. 21. Travel time and adjustment time for making discrete settings of a pointer by means of a rotary control, as a function of gear ratio. Points are the means of three subjects. Gear ratio is here defined as the pointer movement, in inches, per revolution of the control wheel. Minimum overall time was obtained for ratios between 1 and 2. (From Jenkins and Connor, 1949.)

tioned that quite different gear ratios may be optimum for other control tasks.

Searle and Taylor (1948) found that, when the ratio of hand movement to pointer movement in a linear tracking task was changed, individuals tended to compensate for the

where it reached the correct position, regardless of whether or not the correct position was overshoot; thus underdamped responses gave the shortest time.

change and to produce a constant rate of pointer movement; i.e. they moved the control at a much higher rate when it was less sensitive.

Friction and inertia in controls. Friction that is independent of the speed of control motion (coulomb friction) often has an adverse effect on performance, particularly if it is large in relation to the mass, stiffness, and viscous friction in the system, but it

Helson and Howe's studies of handwheel tracking are given in Table 9. Character-

TABLE 9

EFFECTS OF INERTIA AND HANDWHEEL DIAMETER ON TIME-ERROR SCORES IN TRACKING (FROM HELSON AND HOWE, 1943b)

N = 12 Operators

Handwheel Speed in Rpm	Large, Light Handwheel, 21 Psi	Large, Heavy Handwheel, 200 Psi	Small, Light Handwheel, 25 Psi	Small, Heavy Handwheel, 197 Psi
	2.0	10.7	6.6	11.1
2.8	9.4	5.6	8.9	4.9
6.2	7.3	4.4	6.7	4.0

20.0	8.0	4.8	5.3	3.5

FIG. 22. Effect of friction on accuracy of tracking with a light handwheel of large diameter (six subjects). Other results indicate that the effect of friction is less marked when a heavy handwheel is used. (From Helson and Howe, 1943b.)

can seldom, if ever, be eliminated entirely. Helson and Howe (1943b) showed that coulomb friction increased the irregularity and average error of handwheel tracking. The effect was least pronounced when high velocities and large inertias were involved. Typical results are given in Fig. 22. For situations involving jolting, there is some evidence that coulomb friction actually has a beneficial effect (Hick, 1945a).

Friction that is proportional to the rate of movement (viscous friction) has been found, in contrast to coulomb friction, to be of advantage in many control systems. Inertia, in the form of either a heavy control or a heavy load moved directly by the human operator, may also improve performance in many situations. Some typical results from

istic tracking records with different inertias are shown in Fig. 23. Accuracy improved as inertia was increased over a wide range of values. The limit to this favorable in-

FIG. 23. Two typical tracking-error records, showing the smoothing effect of inertia. (From Helson and Howe, 1943b.)

crease was reached sooner for small handwheels, presumably because excessive force was required to accelerate loads with a control of small radius.

The beneficial results of viscous friction and of inertia are due to several factors. Friction and inertia tend to minimize the effects of small fluctuations in force and to damp out high-frequency oscillations. This effect becomes especially important under conditions of jolting and vibration. The

operation of a control against viscous friction and inertia also provides a basis for discriminating small changes in the rate and acceleration of the load. This corresponds to the feedback of first- and second-derivative information, respectively, and enables the human controller to detect smaller variations in the position of the load than would otherwise be possible.

An open rotary transmission system is shown for comparison in Fig. 24B. The torque developed in this open system by the spring when θ_i is turned is equal to $K(\theta_i - \theta_o)$. This torque is opposed by the load and the viscous damping, J and F , so that

$$K(\theta_i - \theta_o) = F \frac{d\theta_o}{dt} + J \frac{d^2\theta_o}{dt^2} \quad (8)$$

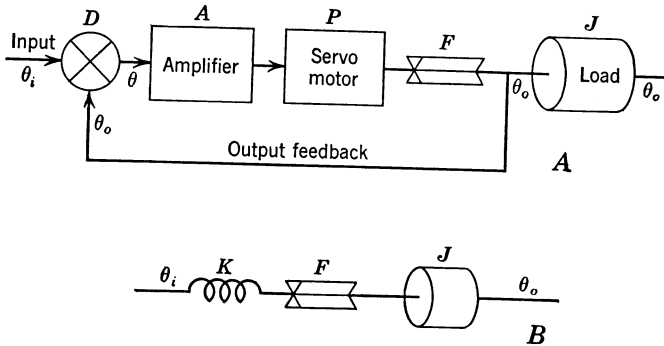

FIG. 24. Diagram of (A) a servo system with a single feedback loop, and (B) an open rotary transmission.

Operational Analysis of Motor Behavior

For some of the dynamic aspects of complete perceptual-motor processes, a simple servo system with feedback will serve as a model (see also Chapter 5).

A diagram of a servo system is shown in Fig. 24A. K and F represent stiffness and damping and J is the moment of inertia of the load. Energy for the servo motor P is supplied by the amplifier A . The error signal θ , which goes to the amplifier, is the difference between the input θ_i and the output feedback θ_o , i.e. $\theta = \theta_i - \theta_o$. The torque developed by the motor is equal to $AP\theta$. This torque is opposed by the load and the damping, J and F , on the output so that

$$AP\theta = F \frac{d\theta_o}{dt} + J \frac{d^2\theta_o}{dt^2} \quad (6)$$

or, since $\theta = \theta_i - \theta_o$,

$$AP\theta_i = AP\theta_o + F \frac{d\theta_o}{dt} + J \frac{d^2\theta_o}{dt^2} \quad (7)$$

Note that equations 7 and 8 are identical if $AP = K$. The amplifier and motor of the servo are, therefore, mathematically equivalent to a spring, except that the servo utilizes an external power source that is governed by the error. Note further that equations 7 and 8 are identical in form to those written for the systems in Fig. 17. It should not be construed from this, however, that all control or transmission systems are governed by this simple equation, but only that systems that are physically quite different, such as systems with and without feedback, may be mathematically identical.

As is true of the open transmission system considered earlier, a servo system is subject to lag and oscillation. If feedback is continuous, however, the amplifier is kept informed of the lag and oscillation in the output, and it governs the power supplied to the motor accordingly.

Servos may be continuous, as the one just described, or they may be intermittent. A

special case of the intermittent system is the definite-correction or sampling servo, which measures the error at regular intervals and after each measurement applies a correction proportional to the error. Servos can be designed to act on different characteristics of the error signal. One possibility is to make the signal to the amplifier include integrals of the error as well as the error itself. This would predispose a system to disregard sudden changes in input and cause it to respond in part to the past history of the error. Another possibility is to make the input include derivatives of the error. This would predispose the system to respond to rates of change of the error and thereby cause it to anticipate the future course of the error. (For further discussions of servomechanisms see Brown and Campbell, 1948; James, Nichols, and Phillips, 1947; Lauer, Lesnick, and Matson, 1947; MacColl, 1945).

If we now substitute the human sense receptors, nervous system, and muscles in place of the servo, we have a somewhat analogous system. Input is the desired condition that the individual sets himself to achieve. Feedback is provided through the eyes, the ears, and the interoceptive channels from muscles, tendons, and joints. Error is the difference between the desired and the observed condition.

Linearity. The mathematical procedures for treating linear physical systems are widely used, but the mathematical treatment of nonlinear systems is so laborious that it is common practice to employ linear approximations provided the output of a system contains less than 10 per cent nonlinear elements. Consequently a practical consideration in applying operational analysis to human behavior is the question of the linearity of the human system. This is also a question of general theoretical interest.

For the present purpose it will suffice to define a linear system as one for which the superposition theorem holds. This theorem states that the response to any complex input is equivalent to the sum of the separate

responses that would be made to the components of that input. In other words, it is possible to predict the response curve of a linear system to a complex time-varying input by summing the response curves given to separate components of the complex input (see Ellson, 1949).

It is well known that the human being is basically a nonlinear system. Among the most marked nonlinearities of human responses are the discontinuities associated with learning and change of set. A human being can adjust many of his 'system constants' to suit the task at hand. He can set himself to use different kinds of feedback. He can vary the tenseness of his muscles, the range of forces employed, and the timing of his responses. Phenomena such as sensory thresholds, sensory adaptation, and fluctuations in attention and motivation introduce still other nonlinearities. In spite of these obvious exceptions, however, there appear to be some situations in which human motor output is approximately linearly related to input.

It has long been known that some quick corrective movements require approximately the same time, regardless of their extent (see Stetson and McDill, 1923). For example, it requires about the same time for a man to write his name, regardless of whether he uses large or small strokes of the pen. We have already seen that the time required for successive movement responses in tracking is relatively independent of their amplitude. Some data illustrating this relation are shown in Fig. 25. These facts are consistent with the hypothesis of linearity, since response curves for the execution of large movements have a form approximately equivalent to that obtained by superimposing curves made in executing movements of smaller extent.

In testing for linearity it is common practice to record the output of a system in response to sinusoidal inputs. In a linear physical system, such as an alternating-current amplifier, the output contains only those

frequencies that exist in the input. Ellson and Gray (1948) recorded human motor responses in following a simple sinusoidal stimulus motion. Subjects were able to match both the frequency and the amplitude of the stimulus up to a breakdown point in the neighborhood of 3 or 4 cps. Up to this point, therefore, human responses are essentially linear.

FIG. 25. Relation between duration and amplitude of control movements in a continuous pursuit task. Data are for 10 subjects. (From Ellson, Hill, and Gray, 1947.)

Experiments with discrete responses, of either a following or a compensatory nature, also throw light on the question of linearity. Large movements usually require somewhat more time to complete than do small movements (Brown and Slater-Hammel, 1949; Taylor and Birmingham, 1948). In the strict sense, therefore, these responses are non-linear. It has also been noted that individuals tend to overcorrect for small distances or forces and undercorrect for large ones. This has been called the range effect. In a statistical sense individuals appear to cause the amplitude of responses to regress toward the mean of the range of responses of which they are members. Woodworth (1899) concluded that constant errors in judging the extent of a movement are minimal when several movements of similar extent are made in sequence, and Ellson and Wheeler (1949) showed that the direction

of the constant error is determined by whether the response is larger or smaller than other responses in the series.

Ellson and Gray (1948) made the interesting suggestion that human responses may be more linear for complex and unpredictable inputs than for simple and predictable ones.

In summary, successive responses made during continuous tracking are approximately linear in the sense that they have an approximately constant duration. Responses to simple sinusoidal target motions are approximately linear as long as the frequency does not exceed about 3 cps. (With these simple repetitive inputs, however, the results are probably accounted for by the subject's ability to recognize and compensate for repetitive stimulus patterns.) Discrete corrective responses, in contrast to continuous ones, have been found to be definitely non-linear, movement time increasing somewhat as the extent of the movement increases.

System equations for the human controller. An objective of the study of human control dynamics is the determination of mathematical expressions for the stimulus-response relations in continuous sensory-motor tasks. Psychologists have not yet attempted this quantitative formulation of human behavior in controller tasks, but several engineers have proposed tentative system equations of this nature.

Raggazini (1948) and his associates required subjects to try to keep a spot centered on an oscilloscope by moving a set of control handles. In this type of compensatory-pursuit task the stimulus contains two components — the predetermined motion imposed on the target by the experimenter, and the motion produced by the tracker as he moves the control handles. At intervals, unknown to the tracker, Raggazini stopped the movement of the spot on the oscilloscope, opened the circuit so that the tracker had no control over the spot, and recorded the movements imparted to the control handle by the tracker during the next few seconds. In this 'open-loop' situation the stimulus remained

fixed, but the subject presumably continued for a short time to behave as he would in a continuous 'closed-loop' control task. Raggazini decided on the basis of data obtained in this way that human tracking responses can be approximated by linear equations.

The equation proposed by Raggazini to describe the human response in this particular tracking task is

$$H = \left[\left(ap + b + \frac{c}{p} \right) e^{-p\tau} \right] A \quad (9)$$

where A is the position of the stimulus as a function of time, and H is the motion of the operator's limb as a function of time. Equation 9 is written in operational form and is equivalent to the following equation written in a form more familiar to psychologists.

$$H = \left(a \frac{dA}{dt} + bA + c \int A dt \right) \text{ delayed by one reaction time } \tau \quad (10)$$

Equation 10 is a differential equation similar to equation 3 for the simple mechanical system. In the differential form there is no convenient notation for expressing the time delay introduced by the operator's response time, which makes the operational form of equation 9 preferable if an actual solution is desired. The terms a , b , and c are proportionality constants. Their relative values indicate the extent to which subjects respond to target rate, target position, and the integral of target position, respectively. Although his equation contains both derivative and integral terms, Raggazini concluded that derivative control is more difficult for individuals to develop than integral or proportional control and that orders of derivative control higher than the first are probably negligible.

This equation, then, states simply that the position of the operator's control handle at any moment is a function of target rate, target position, and the integral of target motion, all at some instant τ seconds earlier in time.

It has been proposed by Tustin (1947) that human responses contain basic elements that are linear or nearly so, plus subsidiary elements that take the form of random disturbances. If these disturbances are in fact random, then a "nearest linear law" may be determined. In order to arrive at a first approximation of this law, Tustin employed a following-pursuit task in which he imposed on the target a complex motion consisting of a fundamental frequency and two higher harmonics. This complex motion was

FIG. 26. Records of target displacement, control-handle displacement, and tracking error during two successive test runs by the same subject. (After Tustin, 1947.)

used in the hope that the subjects would not recognize the repetitive nature of the task. The subjects sat in a rotatable power-driven turret and operated three different types of rate-tracking controls. Simultaneous records of the target motion, the displacement of the operator's control handles, and the tracking error (discrepancy between turret and target) were obtained.

Records of control-handle movements for repeated segments of the same target motion were found to be quite similar. In Fig. 26 the target course, handle motion, and error curves are indicated for two successive runs by the same tracker. The similarity of successive records of handle movement is striking when it is remembered that the target error, to which the tracker was presumably responding, contained all the random elements that he himself had inserted, plus discrepancies introduced by the gun turret's servo system.

Records of handle position $h(t)$ and of error $e(t)$ were analyzed to determine the amplitude and phase differences of the subject's responses to the three frequencies contained in the complex target motion. For each frequency the ratio of amplitude of handle motion to amplitude of error signal was determined as well as the associated phase difference between handle motion and error. As a matter of convenience Tustin here considered the velocity of the tracker's hand motion rather than its position. He concluded that handle velocity was related to the stimulus, or error, in the following manner:

$$ph = [K(pT + 1)\epsilon^{-0.3p}]e \quad (11)$$

or when expressed in differential notation

$$\frac{dh(t)}{dt} = \left(KT \frac{de(t)}{dt} + Ke(t) \right)$$

delayed by 0.3 second (12)

Integrating equation 12 we obtain

$$h(t) = [KT e(t) + K \int e(t) dt]$$

delayed by 0.3 second (13)

which agrees with equation 10 if we let $b = KT$, $c = K$, $\tau = 0.3$ second, $A(t) = e(t)$ and $a = 0$, remembering that Raggazini felt that the derivative term in equation 10 was unimportant.

The fact that two engineers, using different tasks and analyzing their data by different techniques (transient and frequency analysis) reached similar conclusions is an encouraging indication that some aspects of behavior may be amenable to mathematical prediction. This approach may well be supplemented by other approaches such as that of Helson (1949) whose U-hypothesis "expresses the fact that organisms can adapt to a fairly wide range of stimulus values and function optimally within this range."

Effectiveness of Various Human Response Systems

The large differences between muscles with respect to strength, method of attachment

to the limbs, and frequency of use lead us to expect significant differences in the efficiency with which various control tasks can be performed by fingers, arms, legs, or other body members. This expectation is confirmed by the finding that the arms gave higher scores than the legs in a continuous-pursuit task requiring precise and rapid compensatory movements (Grether, 1947b).

Studies of controls for computing gun-sights furnish evidence that a large improvement in overall performance is possible through proper choice of the kinds of movements required for azimuth and elevation tracking, for ranging, and for triggering (Johnson and Milton, 1947; Bray, 1948). Engineers will be able to take full advantage of this freedom in designing control systems, however, only when the relative superiority of the various limbs, joints, and muscle groups has been fully determined.

The common notion that two hands are better than one is supported by data on position tracking with winding wheels (Helson and Howe, 1943c; Hick and Clarke, 1946) and for position tracking with a sight aimed directly at a moving target (Ellson and Craig, 1948). However, Brown, Slater-Hammel, and Bilodeau (1948) found that accuracy in making discrete corrective movements was not significantly different with one and with two hands, and that speed of primary movements was slightly less for both hands. The relative advantage of the independent movement of two separate controls versus the two-dimensional movement of a single control, when the task is to govern the movement of an object in two dimensions, has not been determined, although two-dimensional controls are considered to be superior and are generally used when this task must be accomplished by one man.

Controls can be designed so that their movement requires the use of different joints. Craik (1944) found that, when the amount of movement was expressed in degrees of rotation of the limb about its joint, the variable error decreased with increasing amounts

of rotation up to about 2 degrees. Woodworth (1899) called attention to Goldscheid-er's evidence that sensitivity to angular rotation of the long and short bones is such as to give comparable thresholds for different joints when accuracy is measured in units of absolute arc distance at the extremity of the limb. According to this principle the shoulder should be able to discriminate more joints

right movements, however, showed little difference in accuracy.

Corrigan and Brogden (1949) required subjects to move a stylus along a horizontal slot 35 centimeters wide at the relatively slow speed of 3 centimeters per second without touching the sides of the slot and varied the starting point systematically in order to determine the accuracy for different direc-

FIG. 27. Precision with which a stylus was moved along a straight horizontal path as a function of the direction of the movement with respect to the body. Data are for 48 subjects. A smaller score represents greater accuracy. (From Corrigan and Brogden, 1949.)

of angular movement than the other joints of the arm. From this it would seem that greater precision is attainable in a control properly designed for use by the entire arm than, let us say, in a control operated by the fingers alone. However, other considerations enter into such a practical question.

Accuracy of movements in relation to their origin, direction, and terminal point. When subjects moved a lightweight control along a track, movements away from the body were terminated more accurately than movements of equal extent toward the body (Brown, Knauft, and Rosenbaum, 1947). Upward movements tended to be too short in extent, whereas downward movements tended to be too long. Right-left and left-

tions of movement. Results from 48 subjects are represented graphically in Fig. 27. Movements directly away from the midline of the body are defined as being at 0 degrees (or 360 degrees). It will be seen from Fig. 27 that linear horizontal movements at 135 and at 315 degrees were made with greatest accuracy. If the marked sinusoidal relation between direction and accuracy of motion holds for other controller tasks, this finding has important implications for control design.

Accuracy in continuous-pursuit tasks, as a function of the location and orientation of the controls with respect to the body, has been studied by Grether (1947b). Fore-and-aft movements of a stick-type control and of a wheel gave a significantly better score

than did side-to-side or rotary movements of the same controls. The degree of arm flexion used in operating the controls, however, was found not to be a significant variable provided the operator could move the controls without physical restraint. Thus it appears that operators can be permitted to take up any comfortable position they like in using a hand control.

Vertical, horizontal, and oblique positions of a handwheel gave equivalent efficiency in another tracking task (Helson and Howe, 1942). Similarly, it was found that accuracy in applying force against isometric controls was equivalent for four directions of arm movement (Jenkins, 1947b).

The ability to terminate a free movement with precision in three-dimensional space without visual guidance is important in many machine operations, such as in reaching for a control or an object. Fitts (1947) and Fitts and Crannell (1950) studied the accuracy of such movements as a function of the location of the reached-for object. Data were collected for 24 different targets located perpendicular to a line extending outward from the nearest shoulder and 28 inches away from the shoulder reference point. The reaching motion was initiated with the hands in a position in front of the body and slightly below shoulder height, a common starting point for many reaching movements. Results for a group of 20 college men on the last 3 days of a 12-day training session are given in Table 10. As a general rule locali-

zation was more accurate to areas toward the front, below shoulder height, and near the origin of the reaching movement. Most areas revealed distinctive constant errors in localization, the most common error being that of reaching too low.

In subsequent experiments, when reaching movements were initiated with the hands at the sides rather than in front of the body, it was found that targets directly forward were still localized most accurately, but the relative accuracy of location discrimination for various areas was considerably modified. When targets were located only 21 inches from the shoulder points, instead of 28 inches, the absolute accuracy of location discrimination was found to increase, although not by an amount sufficient to indicate that accuracy at different distances can be resolved to a constant angular error at the shoulder. It appears, therefore, that point of origin, reaching distance, and terminal point all influence the accuracy with which a free movement can be terminated. A conclusion of practical importance is that controls ordinarily should be separated by at least 6 to 8 inches (three to four times the average error of localization) if a high degree of certainty is desired in 'reaching blind.'

Practical Problems in the Design of Controls

Many specific problems are encountered in the design of controls for various devices, and in the arrangement of controls for maximum convenience in sequential operations.

TABLE 10

AVERAGE ACCURACY OF 20 PRACTISED SUBJECTS IN REACHING TO DIFFERENT AREAS AROUND THE BODY WITHOUT THE AID OF VISION. ACCURACY IS EXPRESSED IN INCHES OF AVERAGE ERROR AT A DISTANCE OF 28 INCHES FROM THE SHOULDER POINT (FROM FITTS AND CRANNELL, 1950)

Location of Targets in an Up-and-Down Direction Relative to Shoulder Point	Location of Targets in a Left-Right Direction							
	Degrees to Left of Plane Cutting Left Shoulder Point				Degrees to Right of Plane Cutting Right Shoulder Point			
	135°	90°	45°	0°	0°	45°	90°	135°
Directly above the shoulder				1.9	2.0			
45° upward and outward	2.3	2.4	2.5	1.8	1.8	2.4	2.3	2.4
Level with the shoulder	2.5	2.3	2.1	1.2	1.1	2.2	2.2	2.4
45° downward and outward	2.0	2.3	2.0			1.8	2.4	2.2

No attempt will be made to deal systematically with all these questions. However, brief consideration is given to a few selected topics of practical importance in order to indicate how psychological data can be applied to practical problems.

Design of perceptual-motor tasks for efficient learning. The criterion of ease of learning is one of the most important for equipment design. According to existing facts and accepted theory, learning should progress most rapidly and reach the highest levels of efficiency when multiple feedback of information regarding the results of controller acts is provided, when discriminations are simple and interpretational processes are at their minimum, and when responses can be made directly to the stimulus position or magnitude, rather than to its integrals or derivatives. Learning should be most rapid also when the direction of movement, the mode of operation of controls, and the principles of instrument display agree with population stereotypes.

Arrangement of controls. The typewriter presents an example of a control arrangement problem. Although a standard typewriter keyboard has been in use for many years, the standard arrangement of the keys is poorly adapted to the nature of the typist's task. The work load on the different fingers varies greatly and is not related to differential finger strength or agility (Dvorak et al., 1936). Finding that 35 digraphs (two-letter combinations) account for half of all typing copy, Dvorak et al. devised an improved keyboard that permitted a maximum number of successive movements by fingers of the opposite hand or by nonadjacent fingers, and a maximum use of the "home row" of keys. This work provides an example of the use of "link values" in solving a specific design problem.

An excellent summary of principles of motion economy that can be applied in designing various controller tasks has been given by Hartson (1939) in a review of research dealing with skilled movements.

Nonlinear relations between controls and displays. In order to meet varied demands for speed and precision, adjustable or nonlinear gear ratios between controls and displays sometimes have been used. For example, low gear ratios have sometimes been provided at one end of a range of movements in order to assist the controller in executing small movements, rates, or forces, and high gear ratios have been provided at the other extreme in order to facilitate the application of large corrections. It has been shown (Vince, 1946) that, when an individual first encounters a control, he operates it as if he expects to find a linear relation between control motion and display motion. Although individuals can learn to operate nonlinear controls, considerable habit interference is experienced when it is necessary to shift rapidly between different controller tasks. Nonlinear controls should therefore be avoided whenever possible.

Tracking systems. When an individual moves a control device, such as a winding wheel, he may affect the position of the output member or the rate of its movement. In a position-control tracking system the operator must continue to move the control as long as the target moves; in a rate-control system, if he can adjust the control to a position that corresponds exactly to the target rate, he need do nothing more. Numerous other ways of utilizing human motor output are possible. In one system, known as "aided control," a given input produces both a change in output position and a change in output rate. If a watch had a single adjustment that would set the hands ahead when the watch had lost a few minutes and also cause it to run faster thereafter, the adjustment would make use of the "aiding" principle. The ratio of position to rate component in the output is known as the aided-control time constant, or aiding ratio. The optimum time constant of a system depends on the statistical distribution of rates it is called upon to follow, on the extent to which the operator can generate

derivative control, i.e. respond to the rate of change of the error, and on the operator's reaction time, i.e. how large an error he allows to accumulate before he makes a corrective response. The more the operator can himself detect and respond to target rate, and the shorter his reaction time, the smaller will be the optimum time constant or aiding ratio (see James, Nichols, and Phillips, 1947, for a discussion of aiding ratio).

Stability. The problem of stability in control systems is largely that of minimizing lag (such as lag in instruments that provide visual feedback) and of adjusting the frequency characteristics of the mechanical part of the system to match the capabilities of the human operator over the expected ranges of input frequencies. Displays that combine data from several sources and show only the resultant, such as instruments that mix acceleration, rate, and position information, "aided-control" systems that utilize the position, rate, and acceleration characteristics of the controller's motor responses, and controls that provide direct (proprioceptive) feedback of information about the extent, rate, and accelerations of movements, offer promising means for increasing the inherent stability of man-machine systems. On the one side displays and proprioceptive feedback can be tailor-made to provide an input that is optimum for the operator. On the other side the control signals produced by man's muscular responses can be integrated, differentiated, or otherwise modified to produce an optimum input for the mechanical part of the system.

Time lag is closely related to instability. Lag at any point in a man-machine system increases the error in continuous control functions. For example, Warrick (1949) found that tracking accuracy decreased following the introduction of a transmission lag in the feedback of visual information, even when the lag was so slight that operators could not detect it. Considered in

terms of continuous control process, time lags and inaccuracies are synonymous.

Work and Motor Performance

ROBERT H. SEASHORE

Northwestern University

The term *motor* refers primarily to action, that is, to the activity of the nerves running from the central nervous system to the muscles and glands, and particularly to the activities of the muscles and glands themselves. Behavior normally includes sensory, affective, and intellectual processes, as well as the motor activities of muscles and glands.

The term *work* is here defined as any overt motor performance, regardless of its vocational or recreational significance. Even though work and play may be the extremes of a continuum the distinction between them rests primarily upon the motivation involved rather than upon a fundamental difference between their motor aspects.

Muscular actions may be studied biophysically in terms of the physical and chemical aspects of cells, organs, and their patterns of interaction. Such studies are a joint interest shared by psychology with physiology, biochemistry, and other biological sciences, and the actual experimental literature is found in the journals of these fields. The principal interest of most psychologists lies in the biosocial or behavioral level of description of muscular activities. This interest is also shared with other sciences and technologies, such as physical education, motion-and-time study, education, and business and industry.

CLASSIFICATION OF MUSCULAR ACTIVITIES

It is useful to distinguish between the *gross* motor coordinations of athletics and

certain outdoor vocations and the *finer* coordinations involved in other manual skills, because many of the experimental findings related to them differ in important ways. In fact, anyone faced with a problem of motor skill should begin by asking whether it involves predominantly gross or fine coordinations, because the answer to this question often determines what type of investigation or practical solution may be appropriate to the problem. For example, Cozens (1929) showed that there is a moderate intercorrelation between gross motor skills of athletic types, and McCloy (1935) and Wendler (1938) have further analyzed such correlations by the factorial method. The author's own data show no significant relation between gross and fine motor speed skills.

Fine motor coordinations are those in which the factor of strength is secondary to speed or precision, or both. The size of the movements is usually smaller, as in typing, and the activity is concentrated in the limbs or other small musculatures. The role of the trunk muscles is largely that of maintaining relatively stationary postures or of orienting the limbs toward the work area, which is usually a desk, a bench, or a machine.

Both gross and fine coordinations may be classified with respect to their relative emphasis on timing, spatial precision, and strength. Theoretically there could be almost any combination of these three factors, e.g. a relatively slow, nonprecise, but powerful activity, as in shoveling snow, or a very

fast but not particularly precise or powerful activity, such as operating a safety control lever on a machine. In some actions, such as talking, neither rate, precision, nor strength may be crucial, whereas in still others, such as a long shot in basketball, all three factors may need to be skillfully combined. From these examples it is apparent that these aspects of movements—size, timing, precision, and strength—are really continua. It is only at the extremes that we find distinctive differences.

Within each class of motor activity we may further distinguish two types of performance, namely: *single action* in which one coordinated response follows a given stimulus pattern, and *serial action* which may involve either a chain of more or less unitary responses or a continuous "pursuit" type of coordination. An example of single action is the classical reaction-time experiment in which the carefully instructed subject awaits the stimulus that releases the response. Actually, of course, the movement of the hand in depressing the key is only the most striking part of the response, and many other background activities, such as postural tension, are involved.

Typing is an example of the chain type of serial action. It can be analyzed into a series of relatively discrete strokes upon the various keys. Such chain reactions are known as serial-discriminative responses, and they make up a large proportion of all practical skills. Differing from serial-discriminative action is the continuous or pursuit type of adjustment involved in steering a car. Actions of the pursuit type are commonly involved in piloting, whether of automobiles, airplanes, or ships. Pursuit activities are also important in many operations such as cutting or sewing cloth, painting or carving art forms, and in many athletic activities such as open-field running in a football game.

Motor Aspects of Mechanical Abilities

In considering the nature of skills we must be critical of the widely used concept of "mechanical abilities." Normally such abili-

ties are quite highly specialized. In the building of a house there are involved at least half a dozen mechanical trades: cement finishers, carpenters, lathers, plasterers, plumbers, electricians, painters, etc. We rarely find one person competent in all these skills. Nor do we expect the members of the construction trades to be particularly expert in repairing automobiles. Our industrial civilization would quickly founder without the specialized mechanical abilities of its citizens.

No doubt a great deal of this specialization in abilities is a matter of different kinds and amounts of training in the separate fields. The question then remains, are certain people significantly better qualified than others to undertake training in any one of these specialized mechanical fields because of certain aptitudes for acquiring such skills rapidly and continuing on to higher levels of attainment? There is little evidence that any particular type of physique is essential to success in the acquisition of mechanical skills, nor is there any significant amount of evidence that scores on athletic performance, or on fine motor tests that emphasize speed or precision of hand movements, are related to such mechanical skills as operating or assembling or repairing machines. Nor is there any significant evidence that general intelligence is either positively or negatively correlated with performance on mechanical tasks. The only two measurements that have been shown to be related to the acquisition of skill on even a few mechanical operations are those of spatial visualization (Paterson et al., 1930) and the comprehension of mechanical tools, parts, and mechanisms (Bennett, in Buros, 1949). A later section will review the specific findings on the measurement of the mechanical abilities.

INTERRELATIONS AMONG ABILITIES

The history of differential psychology shows a rather steady progression in the classification of human abilities away from

very broad groupings of related performances. In the eighteenth century the German faculty psychologists classified human abilities under rather broad groupings such as the faculty of memory, the faculty of concentration or attention, will power, etc. These classifications had the merit of recognizing some specialization among human abilities, but the particular groupings described have since been broken down into more basic categories that are not at all closely correlated. Thus a person might be outstanding in ability to remember the names of other people, but only average, or inferior, in remembering the visual appearance of their faces or their figures. Similarly, memory span for consonants is not closely related to memory span for digits, and neither of them is closely related to other types of memory for verbal materials.

Perhaps the best summary of the actual interrelations of human abilities is given in Thorndike's sentence: "In general, desirable human characteristics are slightly, but positively, correlated." Thorndike's phrase, "in general," means that when we consider large enough groups of persons we find that desirable characteristics are slightly but positively correlated. The word "slightly" indicates that the typical coefficient of correlation between various human abilities is of the order of 0.15 to 0.25, and the phrase "but positively" indicates that good qualities tend to go together.

Thorndike's dictum leads us to expect that a prediction from one ability to another will be only slightly better than chance, a finding that has been demonstrated over and over again, ever since the first experiments of Cattell, around 1900, on the interrelations of sensory acuities, reaction time, and scholastic achievements of students at Columbia University. Failure to recognize the applicability of Thorndike's principle has resulted in much wasted effort in personnel-selection programs. Only with verbal abilities has there been any great success in the prediction of individual differences in rate

or extent of acquisition of complex practical skills.

INTERRELATIONS AMONG FINE MOTOR SKILLS

In order to answer the question "What are the various kinds of motor skills, and how are they interrelated?" it is first necessary to define the four basic terms, skills, abilities, aptitudes, and capacities.

1. *Skill*. A person's effectiveness in terms of end results, e.g. speed, precision, strength, a qualitative characteristic (such as rhythm), or a combination thereof. The degree of skill is dependent upon the particular work method employed. Furthermore, of two persons attaining the same end results, the one that does so at a lower energy cost is said to be the more skillful.

2. *Ability*. What one is *able* to do in a given performance at a given time. Synonymous with present skills, but often misused in the sense of ultimate capacity.

3. *Aptitude*. An individual's probable rate, or possible ease, of learning a skill. It is to be noted that: (a) Aptitudes are ordinarily quite stable but may change as a result of training. (b) Rapidity of learning is positively correlated with high ultimate capacity. (c) High aptitude leads to ease in terms of low energy cost per unit of output. (d) Interest and satisfaction in the exercise of potential ability are easily developed. (e) Aptitudes are relatively specific, or, at most, are related only within small groups.

4. *Capacity*. A person's maximal *potential* effectiveness in terms of end results (i.e. speed, precision, strength, qualitative characteristic, or a combination thereof) that may be achieved by using a given work method after optimal training. Capacity further connotes that: (a) The functional limit is based on anatomical and physiological constants of separate organs involved in the given work method and on their integration through neural and humoral systems. (b) Conversely, change to a work

method involving a different set or organs would result in a different capacity. (c) A change in work methods alone, utilizing the same organs, could still change the capacity. (d) The capacity is relatively stable for each work method, owing to the stability of the anatomical and physiological characteristics involved. (e) Although there are minor variations due to age, health, and motivation, the individual tends to retain his relative ranking among others subjected to the same working conditions. (f) Optimal training includes both direct and transferred training under expert supervision. (g) Adequate tools, materials, and working conditions are assumed. (h) Since capacity refers to a *potential* limit, it can only be *inferred*. This limit can be estimated only by extrapolation of an individual's learning curve for a particular skill, on the assumption that his curve will develop in about the same way as those of other learners. These learning curves are probably asymptotic to a hypothetical ultimate level. And (i) initial *rate* of progress is thereby assumed to be significantly and positively correlated with ultimate capacity.

Capacity, then, is not a very useful concept, since a person's capacity in a given skill can only be *inferred*, and it is not defined so that it can be readily observed. In most cases the concept of aptitude is more useful.

From these definitions we see that the term "ability" is practically synonymous with level of skill, so that they may often be used interchangeably. The term "aptitude" refers to any structural or functional asset that gives a man a head start in the acquisition of a given skill, and, conversely, a low degree of aptitude may be thought of as a handicap. The term "capacity" involves so many assumptions that, aside from theoretical analyses, it is more likely to be confusing than helpful. At best, it represents a hypothetical concept that can rarely be demonstrated experimentally.

It may be appropriate to point out the fallacies commonly involved in the psycho-

logical use of the term "capacity." The term has its analogue in the physical sciences where the structure of a machine determines its maximum effectiveness. Thus a windmill pump will raise an amount of water per minute that is strictly determined by the velocity of the wind, and its capacity is readily defined. But the analogy between the human organism and a simple mechanical system overlooks the complexity and adaptability of the human machine. Our sense organs, our nervous systems, and our muscles and glands *can be used in a great variety of ways*. Furthermore these various modes of using our biological equipment result in different levels of efficiency in terms of end results. Another name for these different ways of using our physical structures is *work methods*.

It follows from the great variety of these work methods and their various efficiencies that measurements of any single aspect of structure are not very helpful in predicting the amount or quality of the work done. The greater importance of work methods, as compared to structural characteristics, is indicated by the following sets of experiments, in each of which one of the possible factors underlying individual differences is varied while the remaining factors are held constant. The reasoning is that, if variation in a given factor produces no significant change in the relative end result, then this factor does not account for individual differences in motor skills. If, on the other hand, varying a factor produces noticeable changes in an individual's performance, the factor is important in determining individual differences.

Effects of sense modality on motor skills. In this type of experiment (Seashore, Buxton, and McCollom, 1940) the individual performs the same general type of task with the same musculature but changes from one sense modality, e.g. vision, to another, e.g. audition. For example, in a simple reaction-time experiment the movement and the musculature are held constant, while the first

set of trials employs a visual stimulus and the second an auditory stimulus. It is known that the split-half reliability for reactions to either visual or auditory stimuli is of the order of 0.80. Hence if the intercorrelation between visual and auditory reactions is found to be about 0.45, as is actually the case, we have evidence for the *moderate importance of the particular sense organ employed*. Since this is actually known to be a fairly representative finding for other serial motor skills, such as serial reaction times, we conclude that in general the particular sense employed in a motor skill is a moderately important variable underlying individual differences.

Effects of musculature. If, in the reaction-time experiment, we hold constant the particular movement performed and the sense employed, we may then determine the importance of the particular musculature involved. If, for example, we change from the right to the left hand we find that the intercorrelation is almost as high, $r = 0.80$ approximately, as the reliability of either the right or the left hand by itself. Since the individuals retain approximately the same relative rank with either hand, and for that matter also with either foot or with other musculatures such as the jaw, the elbow, the shoulder, or the neck (Seashore and Seashore, 1941; Reymert, 1923), we conclude that the particular musculature is not a major factor underlying individual differences in motor skills. This conclusion is further supported by the fact that similar results are found on serial reaction times (Campbell), tapping rates (Seashore, Buxton, and McCollom, 1940), and motor rhythmic coordinations (Seashore, 1940). Actually the intercorrelation between the two hands is slightly higher than between one hand and one foot, or between other dissimilar musculatures, but the difference is not great. Some experimenters (e.g. Campbell), noting this high intercorrelation between different musculatures, have con-

cluded that there is a general motor ability. But this does not follow, for it has been shown that a change in the pattern of movements makes a great deal of difference.

Effects of patterns of movement. If we again study the visual reaction time of the right hand, but vary the extent of the movement from 1 millimeter to approximately 150 millimeters we find that the correlation between the two performances is approximately 0.45. In other words, a mere change in the extent of the movement causes a moderate shift in the relative ranking of individuals from one performance to the other. Furthermore if we change the pattern of the movement we are likely to find an even lower intercorrelation between the two performances: usually about $r = 0.15$, a very slight relation. Another example is the comparison between visual reaction time with the right hand and maximal tapping rate with the same hand and the same key. Seashore, Buxton, and McCollom (1940) found that even these apparently similar performances are unrelated. They also found similar low intercorrelations between most other fine motor skills in which speed was emphasized.

In summary we may say that among the factors underlying individual differences in fine motor skills the sense employed is of moderate significance, the musculature employed is of very slight significance, and the pattern of movements involved is likely to be the most important factor.

GENERAL, GROUP, AND SPECIFIC FACTORS

If there were at least moderate intercorrelations among measurements of all human abilities, we should say that there was probably one *general* ability. But since many human abilities are not significantly correlated with other abilities, the term "general ability" is not a useful one in actual practice.

Group Factors

It is still possible, however, that certain *groups* of abilities may be moderately inter-correlated, and if so we should be justified in using the name "group factors" to indicate that individuals tend to rank consistently high or low within a particular range of performances. Sometimes these group factors may be extremely narrow. Thus in a battery of tapping tests (Seashore, Buxton, and McCollom, 1940) one subgroup of related tests showed a common characteristic based on simple oscillation in one plane, either up and down, or sideways. The remaining tapping tests were inter-correlated among themselves and their common characteristic was movement through at least two dimensions, e.g. tapping alternately on two squares 6 inches apart or on three squares arranged in a triangle. This subgroup of multidimensional tests constituted a second narrow group factor. Contrary to the expectations of nearly everyone, the two subgroups showed only slight inter-correlations.

Two series of large-scale studies on the interrelations of aptitudes for fine motor skills have brought to light a number of relatively narrow group factors. The nature of these factors may be identified in the light of the various tests that show significantly high factor loadings on each factor, and, conversely, their scope may be delimited by the apparently similar tests that fail to show significant loadings on the factors. In the first series, twenty-one instrumental motor tests were employed by Seashore, Buxton, and McCollom in order to determine their interrelations.

Table 1 shows that six factors were necessary to account for the zero-order table of correlations. For convenience, loadings of 0.40 or higher were arbitrarily considered as being of probable significance and are printed in boldface. Some of the loadings are starred to indicate that in this prelim-

inary survey they disagree somewhat with our qualitative identifications.

From previous studies we should expect that a group factor among motor tests would appear in performances involving a *similar* pattern of action, and that loadings would vary only slightly, according to the particular sense field or musculature employed. Thus we find that factor I has its most significant loadings in the four simple reaction times (tests 1-4), whether the stimulus was visual or auditory, and for both a simple 1-millimeter press reaction of the finger and hand, or a much longer (6-inch) jump-and-press reaction of the hand and forearm. It is tentatively designated "speed of single reaction." The only other significant loadings in this column are for test 7, which behaves anomalously in relation to several other axes, and the speed drill (test 15), which is a test of ability to move the hand continuously in a circle and, therefore, does not seem to resemble the simple reaction-time tests. Only a retest can check the significance of this latter relation. Each of the factors shows one or more such anomalies, which may possibly be due to statistical fluctuations from the relatively small sample of 50 cases. In a number of these instances the loadings are definitely known not to be representative of the correlational findings from previous experiments with the same tests, a matter that calls for further study.

In factor II the significant loadings fall on five tests: tests 5 and 6, tapping a telegraph key vertically (the same test was given 2 weeks in succession, which accounts for two entries in the factor table); test 7, tapping a telegraph key horizontally; test 11, the two-finger oscillometer; and test 12, the arm and hand oscillometer. All involve short oscillating movements in one plane only. Test 8, one-plate stylus tapping, fails to receive as high loadings as would be expected from our tentative identification of this factor, which is: "finger, hand, and forearm speed in restricted oscillatory move-

I = speed of single reaction; II = finger-hand speed in restricted oscillatory movements; III = forearm and hand speed in oscillatory movements of moderate extent; IV = steadiness; V = manipulation of spatial relations; VI = unidentifiable or residual factors.

* The reliability coefficients, or correlation between the last two cycles of each test, are uncorrected for length.

† The values in h^2 and h^2 assumed are taken from the orthogonal solution.

‡ Loadings seemingly inconsistent with identifications.

ment." Note that the repetitive action tests that call for wider movement in two planes do not have high loadings in this factor.

Factor III shows relatively significant loadings on all three stylus-tapping tests (tests 8, 9, and 10), with the two- and three-plate stylus-tapping tests receiving definitely heavier loadings. The spool-peg transfer test (test 13), designed to involve the same distance and accuracy of movement as the two- and three-plate tests, also receives a significant weight. The ability called for seems to be "forearm and hand speed in oscillatory movements of moderate extent." These movements are nearly all in two planes, in contrast with the single plane for factor II. Two anomalous loadings are found, a moderately large one for the auditory jump reaction time (test 3) and a higher one for serial discriminative action of the four fingers (test 16).

Factor IV is best identified from the two high loadings on the standing and sitting postural sway tests (tests 18 and 19) and, on the basis of previous experiments by Seashore and Adams (1933), Buxton and Humphreys (1935), and Buxton (1938), these tests seem to be sampling a group factor having to do with steadiness or precision. It may also be related to a relaxed condition in taking the tests. The weighting of the pursuit test (test 17) seems to be logically acceptable, but it is negated by the correlational results of two previous studies. Test 7, horizontal telegraph-key tapping, is again an anomaly.

In factor V the weightings of the Minnesota spatial-relations form-board and assembly tests, together with the loading of the pursuit rotor (tests 20, 21, and 17, respectively), suggest that this factor should be designated "skill in manipulating spatial re-

lations." This rather complex identification seems necessary because of the possibility that future experiments will show this to be largely a space-perception factor. The two negative loadings, of the vertical and horizontal telegraph-key tapping tests (tests 5 and 7), probably have to be explained again in terms of error, since no other tapping tests receive significant weights.

Factor VI seems to be a residual for this battery of tests.

The discussions contained in the papers of this series have shown that a modification of the type of interpretation given to motor factors by Buxton may be necessary. The shift probably should be from an anatomical to a functional emphasis in the identification of factors.

Specific Factors

An example of the relatively high degree of specificity to be found among many fine motor skills is afforded by the study of motor rhythm by Seashore and others.

Motor rhythm. In a previously unpublished study, Seashore found that scores on a motor-rhythm test did not correlate significantly with scores on the same apparatus when two other rhythm patterns were used as stimuli. Seashore's original study (1926) showed that motor rhythm correlated with a test for the discrimination of sensory rhythm patterns. This seems to conflict with the findings of low correlations between patterns of the same type of motor-coordination test.

Two minor studies on the relation of the Seashore motor-rhythm test to dancing ability may be mentioned as indicative of the limits of the hypothetical group factor of motor rhythm. The first, performed by the writer's students at the University of Oregon, involved the selection, by a group of fraternity students, of 50 girls who were judged distinctly superior in social dancing ability. The girls were then given C. E. Seashore's phonographic test of sensory rhythm and R. H. Seashore's test of motor

rhythm. In comparison with the norms for these tests, the average of the superior dancing group fell at the 65th percentile on the sensory-rhythm test, and at the 35th percentile on the motor-rhythm test. There is some question whether the norms used for the former test do not give results that are consistently too high. Although this result is clearly contrary to expectations based on the hypothesis of a group factor in motor rhythm, there may be several sources of error. In the first place, the men's criteria of selection may have been unduly influenced by such factors as beauty, conversational ability, and dress, and, as the girls pointed out, a girl follows her partner, not the music (!) in social dancing.

The girl selected as the outstanding dancer (both social and interpretive types) also made the best score ever reported on the motor-rhythm test.

The second study, by Childers (1937), attempted to avoid the errors of selection involved in the judgment of social dancing by studying individual tap dancing. The children studied, members of her private dancing class, were tested for the number of trials required to learn each of a series of tap routines of gradually increasing difficulty. This gave a fairly accurate estimate of their attained proficiency. No significant relation appeared between the sensory- or motor-rhythm tests and the dancing proficiency ratings.

Steadiness

An example of a somewhat broader group factor is one that was originally labeled "steadiness" by the writer and others. According to the hypothesis of a group factor for steadiness, those coordinations that emphasize accuracy (precision or steadiness), while minimizing speed and strength, should cluster together. Steadiness tests, in wide variety, should intercorrelate moderately or highly, and correlate only slightly with speed and strength tests. Actually, Spaeth and Dunham (1921) reported

$r = +0.61 \pm 0.11$ between Dunlap's test for precision in thrusting a stylus at a graded series of holes and rifle target shooting for 73 army men ranging from poor to expert marksmen. Extending this study, Seashore and Adams (1933) found that in terms of a multiple score for five steadiness tests (postural sway with eyes closed, rifle muzzle sway when sighting, hand tremor, stylus thrusting at holes, and stylus held stationary in holes) a university rifle team of 6 men was superior to all but one of the 50 unselected fellow students enrolled in R.O.T.C. They also found that in spite of several rather low test reliabilities all test inter-correlations were $+0.45$ or higher. The same trends were verified in a subsequent study of Humphreys, Buxton, and Taylor (1936) in the same laboratory.

The writer's earlier findings (1926) of an r of $+0.30 \pm 0.09$ between precision of thrust and steadiness in tracing a narrow V-slot may or may not be an exception to the above trend, depending upon the representativeness of the coefficient. In view of the encouraging findings on steadiness, which are also corroborated by a moderate correlation between various types of postural sway in later studies by H. G. Seashore

and Koch (1938) and Seashore, Buxton, and McCollom (1940), the writer has been extending and improving a battery of such tests in order to determine more accurately the range in kinds of tests, the closeness of the relation, and the significance of this factor.

In a minor experiment employing a photoelectric device for measuring steadiness of arm and hand, Katz (1935) studied a group of 25 boys in an institution for juvenile delinquency. These 25 boys were picked for "emotional instability," as evidenced by temper tantrums, and other emotional maladjustments. In comparison with 25 other less emotional boys paired for age and IQ there was no significant difference on the steadiness test. Both emotional and muscular stability have been referred to a *neural* basis, but, whatever the merits of this theory, these results indicate that they obviously do not depend on the same factors.

Subsequently this study was expanded by Seashore, Dudek, and Holtzman to test the possibility of finding more than one group factor in the general range of tests that emphasize equilibrium, precision, or steadiness in posture or in relatively slow move-

TABLE 2

FACTORIAL ANALYSIS OF ARM-HAND PRECISION TESTS (FROM SEASHORE, DUDEK, AND HOLTZMAN)

Test	Description	Trials
1. } 2. } Ataxiometer	Measure of arm-hand sway. Horizontal and vertical components measured separately.	5 trials of 15 seconds each in each cycle.
3. Target register	<i>S</i> aimed a beam of light at a stationary target.	5 trials of 15 seconds each in each cycle.
4. Straight trace	<i>S</i> traced, with a stylus, a straight horizontal path toward himself.	5 trials of 10 seconds each in each cycle.
5. Curved trace	With a stylus <i>S</i> traced an irregular horizontal path from left to right.	10 trials of 15 seconds each in each cycle.
6. Sine trace	<i>S</i> moved a ring stylus along a rod that was bent vertically in the form of a sine curve.	5 trials of 30 seconds each in each cycle.
7. Three-dimensional trace	<i>S</i> moved a ring stylus along a rod that was bent irregularly in three dimensions.	5 trials of 40 seconds each in each cycle.
8. Thrusting steadiness	<i>S</i> thrust a stylus into a hole at a rate of one thrust every 2 seconds. Holes of three different diameters were used.	5 trials of 10 thrusts each in each size hole.

Factor names: I = Steadiness in two- or three-dimensional space.

II = Steadiness of movement in a restricted plane.

III = Involuntary movement of the arm and hand.

Estimated correlations between factors: $r_{I II} = 0.47$

$r_{I III} = 0.00$

$r_{II III} = 0.24$

ments. The description of seven of these tests together with the intercorrelations, reliabilities, and factor loadings from Holtzman's experiment on 39 subjects and Dudek and Seashore's experiment on 100 men are given in Tables 2, 3, and 4.

This series of studies includes a further analysis of relatively pure tests representing each of the three factors listed in Table 4 in relation to measures of static equilibrium or postural sway (with and without visual cues), and a measure of dynamic equilibrium (a balancing chair simulating the movements of a Link trainer), a measure that does not involve bodily equilibrium but does involve the similar complex coordinations of a miniature airplane tridimensional pursuit test. Eventually there should be made available a battery of tests for primary motor abilities comparable to the primary mental abilities described by Thurstone and later extended by the AAF aircrew selection studies. The first unit of a portable battery of such tests of precision and steadiness is now nearing completion.

STUDIES IN VALIDITY

A possible hypothesis about the acquisition of complex motor skills is to assume that each person has had ample opportunity to practice many simple common skills and that if a person tended to do well on the earlier samples of this experience he would thereby be encouraged to try more skills and to perfect the skills in which he enjoys superiority. To test this hypothesis, Seashore, Jerome, and Harney, in an unpublished study, worked out a list of approximately twenty common manual skills, such as (1) bolting two boards together with a spring and washers for proper spacing, (2) making simple free-hand drawings of objects such as the covering plate of an ordinary electric switch, or of a three-dimensional object such as the paper carton for a bottle of ink, (3) hand-writing (scored by the Ayres and Thorndike

scales), (4) pinning two squares of cloth together with two safety pins on each side, (5) sharpening a pencil, (6) assembling a simple object with a screw driver, etc.

If there were any validity to such concepts as "manual dexterity," "being clever with one's hands," etc., it would be expected that persons who were skillful on one group of these skills would tend to be proportionately skillful on a second group. Very briefly, they weren't. One battery of ten common skills showed no significant correlation with another ten skills. Thus we have another line of evidence corroborating the previous findings on the specificity of fine motor skills. Neither on simple artificial laboratory tests where there has been no opportunity for previous practice nor on this sample of widely practiced manual skills is there any evidence for a general factor in manual coordinations. The subjects for the experiment on common motor skills were first-year high-school boys enrolled in a non-vocational shop course required of all students.

In a related experiment on the same group of subjects Harney also studied the possibility of predicting grades in the five subdivisions of this course in shopwork from a battery of tests of several fine motor skills. The five branches of the shop course included mechanical drawing, carpentry, metal work, auto mechanics, and electrical assembly and repair. Scores on the fine motor tests and on the common manual skills battery were not related significantly to a series of project scores in any of the five subdivisions of the shop course. Neither were scores on any of Holzinger's primary mental abilities tests related to success in any of the five shop scores. It is further interesting to note that the grades on the five divisions of shop work were not significantly related among themselves, except that drawing was slightly related to several. Here we have a third line of evidence against any general factor underlying motor abilities.

''MECHANICAL ABILITIES''

Closely related to such concepts as manual dexterity, being clever with one's hands, etc., is the concept of mechanical abilities. Two critical experiments may be reported here. In the first, Hazelhurst (1940) tested several hundred men who had completed a year's correspondence course on air-conditioning and refrigeration work and were undergoing a month's shop training on actual assembly and repair. Hazelhurst employed approximately fifty paper-and-pencil group tests, including a considerable number of tests that he designed and constructed himself on the basis of his own training in electrical engineering and psychology. Five criteria of success in the shop work were also obtained, and all the tests and criteria were submitted to a factorial analysis. The battery of fifty tests was analyzed to nine relatively narrow group factors of mechanical abilities; and the five success criteria were found to cluster in two groups. However, no single test nor any of the nine group factors was related to any of the success criteria. The result of this ambitious experiment should make us skeptical of any concept of a single mechanical ability or even of a series of mechanical abilities.

A parallel study by Guylee (1940) of the use of mechanical assembly tests on these same trainees showed similar negative findings. Unfortunately these careful studies have not previously been published, and personnel workers have in many instances continued to make erroneous assumptions about the nature and origin of abilities underlying the acquisition of mechanical skills.

So far as is known to the writer, there are no cases in which so-called mechanical-abilities tests have been clearly shown to be predictive of success in the acquisition of more complex mechanical skills. Isolated instances of a significant correlation need to be verified, for all such studies are subject to chance variations. This is particularly important because of the tendency of in-

vestigators to consider negative findings as due to inadequacies of experimental method or as scientifically uninteresting. Even a survey of published evidences might be misleading, since there is a tendency to report only positive findings.

Prediction of success in typing. In another study Walker and Adams (1934) attempted to predict individual differences in rate of learning to typewrite among sophomore students in a commercial high school. They used the six tests of Seashore's Stanford Motor Skills Unit (1928a) (rate of tapping a telegraph key, four-finger serial visual discrimination, auditory motor rhythm, rotary wrist movement in turning a hand drill, bimanual spool packing, and eye-hand rotary pursuit). The scores were not significantly correlated with scores on speed of typing at the end of the year's training, even though each of the six motor tests had sufficient reliability to rule out this factor as a possible source of error. Incidentally, the scores for the first fifty subjects on one test, rate of tapping, were significantly correlated with the corrected number of strokes. Suspecting that the very high error penalty represented a heavy chance loading of the score, the entire experiment was repeated a second year on another group of fifty subjects and no correlation was found with either the weighted or unweighted typing scores.

A review of the literature on the prediction of success in typing brought to light one study by Book (1924) in which it was shown that there are some differences between the average tapping rate of unselected university typing students, amateur champion typists, and world's champion typists. However, the size of the differences was slight in comparison with the known range of tapping rates and all three groups were near the average tapping rate for all adults.

An earlier study by Seashore (1930) on fifty male Stanford students had shown that

ratings of the total amount of previous training in manual skills, such as typing and instrumental music, were not related to any of eight tests of fine motor skills, which included two other measures of eye-hand pursuit coordinations and a measure of postural sway, in addition to the types of tests included in the Stanford Motor Skills Unit. This seems to indicate again the specificity of fine motor skills, since there was apparently no cumulative transfer of training from typing and instrumental music to any of the tests of fine motor skills. Such a finding, of course, is definitely in keeping with the hypothesis that individual differences in fine motor skills are determined largely by "hitting upon" favorable work methods, which are largely specific to a particular type of operation or, at most, a relatively narrow group of operations.

Prediction of success in operating winding machines. Using the same Stanford Motor Skills Unit employed by Walker and Adams, another investigator, S. H. Seashore (1932), tested sixty apprentices of a knitting mill for any possible relation between these motor test scores and success in operating winding machines. On these machines the workers had to watch for any breakage of the wool thread, and after tying the broken ends with a weaver's knot they would loop the thread over several hooks and start the machine again. As soon as a person became reasonably proficient in operating one machine, he was given an opportunity to supervise a number of machines simultaneously, and success was measured objectively by weighing the amount of yarn wound by each worker during the first and second halves of the third month of work. Even though the range of abilities was great and the reliability of the criterion was high enough to exclude any major error from this source, there was no correlation between the criterion and any of the six motor test scores or a combined standard score from the battery of six tests.

Individual Differences as Stages of Learning

One of the peculiarities in the development of a new science seems to be the extent to which special fields are studied in isolation from related fields. This is illustrated in the field of motor skills, where an analysis of the factors underlying success has proceeded for years with very little consideration of theories about the nature of learning. It is apparent, however, that the work-methods hypothesis for the origin of individual differences in motor skills is also a hypothesis to describe the way in which successive steps in learning achieve quantitative progress in terms of end results, such as amount, rate, or accuracy of work performed.

The work-methods hypothesis states that individual differences in *any* human ability (not just motor skills) are attributable to three groups of factors: (1) the physical constants of the various organs (especially sense organs, nervous system, and musculatures) employed, (2) the general qualitative pattern of component actions involved, and (3) the refinement of these component actions with respect to both strength and timing so as to produce an optimal pattern of action. Thus it is conceivable, though rarely demonstrated, that lack of sensory acuity or reflex motor speed might handicap a person in attaining a high degree of skill in a complex motor coordination. Actually, however, the empirical evidence seems to be that skilled workers in fine manual skills rarely need to press themselves to their physiological limits and that, instead, they attain their superior results by hitting upon qualitative patterns of action, or work methods, that make the work easier. Even a person with low physiological limits can surpass one with higher physiological limits if the latter is not using an equally effective work method. A part of the process of trial-and-error practice is simply experimenting with various work methods. The sudden progress associated with insight learning is

probably to be attributed very largely to the perceiving of new qualitative patterns of action. On the other hand, the relatively steady progress frequently observed in learning of all types is usually attributable to refinements within a pattern.

A hypothetical example of progress in learning to unlock the front door of a new home may illustrate the principle. The new owner will probably come up to the door, fumble in his pocket for the keys, try several keys in the hole of the lock, one of them perhaps upside down, then try both directions of turning the lock, and finally turn the door knob and push. Progress usually involves the dropping out of useless movements, such as selecting the wrong key or the wrong position or the wrong direction of turning. The remaining essential movements are made to *overlap in time*, so that on later trials as the person comes up the steps he reaches in his pocket for the key, selects the proper key *en route*, orients the key to the right position as he crosses the porch, starts turning the key immediately upon recognizing tactually the proper depth of insertion in the lock, and simultaneously twists the door knob in the proper direction. In the final stage, the component movements are essentially the same in kind as in the earlier stages, but time is saved by starting each successive step so that it is ready as soon as the preceding step is finished.

Most motor skills are developed largely by trial and error without much benefit of formal coaching or the use of scientific devices, such as slow-motion pictures, that would help the individual to understand just what he is doing in the performance, what faults need to be dropped, and where his timing could be improved. As a result, it appears that most favorable work methods are "hit upon" rather than carefully thought out or even recognized afterward. It has long been observed that a person who is himself highly skilled is not necessarily very effective in either analyzing his own performance verbally or teaching it to another

person. "All-American" athletes may be quite unsuccessful as athletic coaches.

In the common absence of an analytical understanding of the methods used by a performer, it is not surprising that the quantitative individual differences observed in any particular skill are frequently quite stable. Improvement in any of these habits may easily be a matter of chance, in which a person accidentally achieves a particular improvement several times before he recognizes the nature of the change and thereby becomes better able to control it. To a certain extent the mere association in time of successive component actions tends to produce an overlapping in the timing of successive movements through the process of conditioning, in which insight may or may not be involved. Unfortunately, however, there is no automatic process by which errors are eliminated, particularly if they are only useless and not actually impediments in the performance.

Dependence of Motor Activities on Nonmotor Factors

Both observation and experiment indicate that success in complex motor activities may depend upon sensory, affective, and intellectual as well as motor factors. Thus the reports of the Army Air Forces Aviation Psychology Program (Guilford and Lacey, Eds., 1947) analyze the factorial makeup of 65 psychological tests developed to predict success in the training program for pilots, navigators, and bombardiers during World War II. Of these tests approximately 60 were objective "paper-and-pencil" tests covering every aspect believed to be significant in the learning of aircrew skills, and about 5 were individual psychomotor tests employing physical instruments. The multiple correlation between the most significant paper-and-pencil tests and a training criterion was approximately 0.50; the addition of 6 psychomotor apparatus tests raised the multiple correlation coefficient of validity to 0.70.

Among the psychological factors that were significantly related to the training criterion were those tentatively designated by the names carefulness, integration (three factors), judgment, kinesthetic (nature unknown), length estimation, memory (three factors), mathematical background, mechanical experience (interest and training), mechanical experience, perceptual speed, pilot interest, planning, reasoning (three factors), spatial relations (three factors), social science background, verbal, and visualization. Obviously, if the multiple correlation between the criterion and this group of nonmotor factors is only 0.50 it is unlikely that more than a few would be very predictive by themselves. Most of them have such slight validity that it could be detected only by using hundreds of cases in the test samples.

Of the three psychomotor factors studied, the one designated psychomotor coordination 1 seems to be somewhat similar to what we have previously designated as a pursuit or continuous coordination factor. Psychomotor precision, the second factor, was represented by only two tests, discrimination reaction time on a complex spatial pattern, and finger dexterity in turning over pegs. This factor does not appear to be very well named, since both tasks are primarily measures of speed, but at any rate it apparently does not refer to the types of factors that Seashore, Dudek, and Holtzman reported for tests involving precision in aiming or in slow movements. The third factor, psychomotor speed, likewise appears to be given much too broad a name since it is represented primarily by two paper-and-pencil tests of log book accuracy and marking accuracy, whereas the literature indicates that there is a considerable number of unrelated psychomotor factors that emphasize speed in fine motor skills.

In spite of this minor difficulty in the naming of factors, the AAF Aviation Psychology Program represents one of the largest and most successful programs of vo-

catational selection ever attempted. It made possible great savings in time, machines, and man power during the war. The cost of training a pilot was an estimated \$25,000 per man, but the administration of a battery of individual psychomotor tests cost only about \$5.00 per man. It paid to eliminate the potential failure.

The AAF program also included tests of mechanical abilities for the selection of ground crews engaged in servicing planes, but the outcome here was not nearly so clear as in the work on aircrew selection.

Although there are relatively few published instances of the successful employment of psychomotor tests for the selection of persons to be trained in fine motor skills, this is only one use of motor tests. Actually, negative results from selection experiments may be of value if the experimenter is alert to the possibility of alternative explanations for the observed individual differences in the attainment of complex skills. Negative results on selection programs tell us that we need no longer concern ourselves about the factors tested. Instead we should turn our attention to other sources of the individual differences, for example, differences in motivation, training, health, the use of specialized tools or equipment, or simply more efficient work methods.

MOTION-AND-TIME STUDY

One of the anomalies in the development of our knowledge of psychomotor skills is the way in which the motion-and-time study methods of engineering have been neglected by psychologists and, conversely, the way in which various psychological factors in work output have been overlooked by industrial engineers. The divorcement of these two approaches is particularly striking in view of the fact that in the 1920's the work of motion-study engineers, such as Gilbreth, was quite widely known in psychology.

The basic idea of motion-and-time study is that work methods form the basis for

individual differences in skills and also for differing degrees of effectiveness at successive stages of training. Differences in work methods may best be analyzed by slow-motion photography, both for finding the errors of less skilled workers and for teaching to new workers the superior methods of the most highly skilled workers. In addition to this relatively simple analysis of the specific tricks of the trade on each job, there are certain general principles and procedures that apply to all jobs. Thus any type of manual skill may be analyzed into a series of about sixteen types of actions, called "therbligs," after the approximately reverse spelling of their developer, Gilbreth (1919). The names of these units are as follows:

1. Search
2. Find
3. Select
4. Grasp
5. Position
6. Assemble
7. Use
8. Disassemble, or take apart
9. Inspect
10. Transport, loaded
11. Pre-position, for next operation
12. Release load
13. Transport, empty
14. Wait (unavoidable delay)
15. Wait (avoidable delay)
16. Rest (for overcoming fatigue)

It is further known that a working surface, such as a desk or bench, should be at a particular height for each worker, depending upon his height and whether he is sitting or standing or alternating between the two positions. The materials should be arranged in front of the worker so that he can reach each one easily with the proper hand and move it a minimal distance to the next step in the procedure. Lost motion is avoided by placing each material where it will be used. Other principles include the use of both hands simultaneously wherever possible, and the use of fixtures for the accurate placement of materials without care-

ful visual control of fine movements. Thus a person folding printed material for mailing in envelopes might find it a saving (1) to do all the folding first, then (2) to arrange all the envelopes with the flaps turned back in overlapping flat piles so that (3) he can pick up a folded letter and insert it into the adjacent envelope, (4) moisten all the gummed edges at one time, and (5) seal and *drop* (rather than place) each envelope in a hopper.

From the fact that the principal method is that of photography and the fact that one therblig, "inspect," is used to describe all activities of careful perception in placement of materials, it should be evident that motion-and-time analysis has not yet gone much beyond the study of fairly large manual skills. To supplement this method we need two parallel techniques: (1) the electro-physiological analysis of nerve and muscular activity, and (2) psychological introspection for the analysis of the sensory, affective, and intellectual aspects of the skill.

Whether or not psychologists have contributed materially to the development of motion-and-time study technique, it is apparent that they should be familiar with them in order to study psychomotor skills. The writer (1939) has in fact outlined an extension of the concept of work methods to include skill in sensory, affective, and intellectual processes. Wyatt (1945) has shown the significance of work methods in the improvement of pitch discrimination among persons who were markedly deficient in either hearing or producing fine pitch differences. The writer (1947) has outlined a classification of the principal work methods by which individuals ordinarily try to solve problems when frustrated in a conflict situation, and with Jenssen (1948) has outlined the way in which such a classification of habitual approaches to difficult problems might be made the basis for a classification of temperaments.

The basic hypothesis underlying all variations in human skills might be roughly

stated: It isn't so much what kind of an organism you inherited as what you do with it. Granted that there are fairly large hereditary structural differences *between species* and that some species seem quite unable to do things that others can do easily, this does not necessarily mean that the differences of inherited structures *within a species* are equally important. Some of the world's greatest accomplishments have been by persons seriously deficient in physical endowment, e.g. Helen Keller, Steinmetz, Robert Louis Stevenson. Even champion athletes in a specialized sport, e.g. track dashes, football line play, etc., show variations in both size and proportions of body build, although these variations are not so great as those between, say, football players and high jumpers.* Football and track coaching, in fact, provides one of the best opportunities for the profitable analysis of work methods by motion pictures. The athlete who performed poorly on Saturday may, with the same physique, health, etc., on Monday show a considerable improvement simply as a result of seeing a slow motion picture of the previous game.

FATIGUE AND ALLIED PHENOMENA

The importance of work methods is by no means limited to individual differences in aptitudes or to progress in learning. Regression of behavior under unfavorable working conditions is likewise related to

* Cureton (1947) presents extensive evidence for a relation between body build (somatotype) and success in various categories of athletic endeavor. On p. 108 he concludes: "It is true that heavy athletes are relatively more mesomorphic (solid, dense muscle); also that track athletes run to slim body build with considerable ectomorphy (frail, linear) but with well developed musculature. Swimmers are more frequently meso-endomorphic (muscular and fat). Very seldom do men or women low in mesomorphy succeed in athletics."

An appropriate somatotype would seem to be a necessary but not a sufficient condition for success in a given athletic skill. (Ed.)

changes in method as well as to changes in bodily conditions. The volume by Bartley and Chute (1947), which systematically reviews the literature on fatigue and impairment in man, finds it necessary to distinguish among (1) physiological impairment of tissues, (2) psychological aspects of fatigue, and (3) changes in the work output of the integrated organism.

Since all three factors are important aspects of human behavior, it is desirable to know how they are interrelated. In this summary we shall follow the general analysis of Bartley and Chute. First of all, it must be recognized that the term fatigue has been commonly used in two senses, (1) a broad concept having to do with many after-effects of work — physiological, psychological, and economic — and (2) a narrower concept having to do with some one of these aspects.

It is further apparent that the physical after-effects of work are often confused or at least intermixed with a variety of other phenomena, such as boredom and feelings of conflict, that may represent the effects of previous affective conditioning. So great is the confusion that an earlier systematic writer, Muscio (1920), proposed the abandonment of the term fatigue in favor of more specific concepts.

Bartley and Chute suggest the following distinctions in terminology:

Fatigue is regarded as an experiential pattern arising in a conflict situation in which the general alignment of the individual may be described as aversion. This particular pattern involves feelings of limpness and bodily discomfort which, besides being undesirable in themselves, are frequently taken as tokens of inadequacy for activity. The subjective constituents of this fatigue pattern are not to be taken as epiphenomena, or as symptoms of fatigue, but as fatigue itself. [Pp. 47-48.]

Impairment is a physiological change in tissue which reduces its ability to participate in the larger aspects of organic functioning. Impairment is identifiable only through the

methods of physiology and biochemistry. Reduction in the ability of the organism as a whole to perform is no criterion for the presence of impairment. [P. 48.]

Work output includes all overt activity that is measured either in the laboratory or in industry. [P. 49.]

Neither fatigue nor impairment can be measured by the work output of the *intact* organism. Activity may be used as a direct measure of impairment only when such systems as isolated nerve muscle preparations are used in ergographic studies.

These three factors, fatigue, impairment, and work output, are thus semi-independent variables. As mentioned previously, the experience of fatigue (tiredness, etc.) may arise either through impairment as an immediate after-effect of exercise or as a conditioned feeling of boredom, distraction, or other conflict. In some circumstances, as in a sporting event, physiological impairment may be associated with pleasant feelings or exhilaration, very different from the feelings of tiredness and distaste for an activity.

Fatigue in the sense of an experience of aversion to further work may arise from physiological impairment of tissues during exercise, or it may be largely a conditioned response, e.g. boredom. Likewise, work output may decrease as a result of either of these two factors, or for still other reasons. Conversely, under conditions of adequate motivation, physiological impairment of tissues may not result in either feelings of fatigue or reduced work output. Under even moderate motivation, a change in the work methods may by-pass the effects of impairment in certain organs by shifting the burden to other parts of the body.

Bartley and Chute point out that visual fatigue is not necessarily due to tissue impairment through long-continued use of the eyes, but may arise as a result of a conflict or early conditioning in an unpleasant experience. Carmichael and Dearborn (1947) similarly point out that their experiments involving hours of continuous reading did

not necessarily produce either the subjective effects of tiredness, discomfort, and aversion, or a decrement in work efficiency in the sense of decreased accuracy or comprehension.

Chronic fatigue is a definitely unpleasant experience that bears no consistent relation to expenditure of measureable energy. It seems to follow prolonged periods of unpleasant emotion, such as worry and uncertainty. Physical exertion may even obliterate the fatigue.

Factors compensating for fatigue and impairment in maintaining work output. One of the things that often astonishes both laymen and psychologists is the extent to which the human organism can continue to perform adequately under extremely unfavorable conditions. For example, Hovey (1928), in a study of the alleged unfavorable effects of having freshmen take intelligence tests during the excitement of the first week of college, retested some of these students under conditions of extreme distraction. Bells, buzzers, whistles, organ pipes, and a spotlight were among the distractors used. Other persons marched in step in the halls of the floor above. Shop machinery and pounding added to the noise and otherwise created disturbances without actually eliminating the possibility of continuing work in the large test room. No significant decrement in test scores was observed.

In the same laboratory the writer and his students measured the distracting effect of music from phonograph records of somewhat outdated popular songs upon the comprehension of semitechnical psychological literature. The control groups, who were initially equated with the experimental group for reading comprehension, showed no better scores under quiet conditions than did the experimental groups under conditions of musical distraction.

In Warren and Clark's study (1937) of the effects of going without sleep for 65 hours, the results likewise indicated that, although the subjects had to struggle to keep awake,

their work output on a variety of psychological tests showed little or no decrement. One explanation of this is suggested by a similar experiment of Laslett in which he had no difficulty securing volunteers for the experiment but had to prevail upon his friends to go through the control series of measurements with normal amounts of sleep allowed. Evidently the motivation of being in a difficult experiment is one of the factors that helps to compensate for any deleterious effects of sleep loss or other distracting factors.

Another fairly common finding is that measures of serial or continuous performances tend to show greater decrements in output than do tests that involve momentary single actions, with an opportunity to rest in between. Evidently a person can "pull up" momentarily even when he has undergone prolonged deprivation of sleep, but he has difficulty in maintaining this alertness, even for trials lasting only a few minutes, if the test calls for practically continuous performance.

Use of psychomotor tests to measure influences on behavior. An unpublished series of experiments by Ivy and Seashore and their collaborators illustrates the use of psychomotor tests to determine the possible advantages of analeptic drugs in overcoming the effects of prolonged military operations. Moderate doses of amphetamine sulphate (benzedrine), a similar German drug Pervitin, and caffeine all tended to be effective (in that order) in relieving symptoms of fatigue and impairment on a variety of psychomotor tests. These tests measured speed of simple discriminative reaction, arm-hand steadiness, aiming, postural steadiness, and a complex coordination of operating a miniature airplane to keep it pointed level and straight ahead while it was subjected to a series of irregular movements in three dimensions comparable to the effects of a heavy storm. The possibility of serious disadvantages or "side effects" of the drugs were first ruled out by miniature ex-

periments in laboratory rooms having artificially maintained temperature and humidity conditions comparable to desert and tropical jungle conditions, respectively. It was also shown that the drugs could be administered in moderate amounts to large groups of men under marching conditions in a temperate climate without undesirable side effects, and with a significant alleviation of various complaints common to this type of strenuous physical work. As might be expected, the administration of a neutral sugar pill or placebo produced many of the expected effects of the real drugs (through suggestion) even though all the dosages were disguised under the name of vitamins. The measures found to be most significantly affected were postural sway without vision (there was little effect with eyes open) and the airplane pursuit test. Later tests showed that similar effects were found on 24-hour truck-driving operations under black-out conditions in a moderately warm climate, and also on 20-mile night marches and 5-hour daytime tank operations under desert conditions. Commercial truck operations, up to 5 hours, did not show any significant effects, even though the drivers commented that they often had to struggle to keep alert and had various discomforts such as muscular cramps from working in one position for several hours at a time.

Psychomotor measures of efficiency under laboratory conditions of high altitude and low oxygen were found by Watson, Dunlap, and other investigators in World Wars I and II to be more sensitive indicators of impending dangerous losses in coordination than the introspective reports of difficulties as they were experienced. These and other instances indicate the possible usefulness of psychomotor tests for measuring the influence of many conditions believed to affect human behavior, e.g. the effects of age, the effects of motivation, the effects of stress, and the effects of various methods of training for motor skills.

OTHER FACTORS IN WORK OUTPUT

In our analysis of motor performances we have thus far stressed the factors inherent in the performer himself, his aptitudes and their bases in physical endowment, and the effectiveness of various work methods. It is obvious, of course, that other factors might also affect the effectiveness of the worker. Thus we have reason to believe that motivational factors, the interest of the person in his work, and group morale are relevant. Unusual neglect of, or special attention to, these factors might well alter the effectiveness of the worker, as was shown in the well-known Western Electric experiments (cf. Roethlisberger and Dickson, 1939). Physical working conditions such as temperature, ventilation, and lighting may likewise be important, as may also the design of desks, tables and benches, and specialized tools and machines.

It seems quite probable that one of the principal reasons for our relatively slight knowledge of motor abilities is the fact that industrial engineers have been so successful in designing machines to perform work that would otherwise call for high levels of dexterity. The manufacture of cigarettes, by a single machine that automatically rolls and packages the cigarettes, eliminates vast numbers of small movements of the human hand. At the other extreme, a machine stretching the entire length of a large factory can assemble heavy automobile chassis with the supervision of only five men on the whole assembly line. Even though the machine is very effective in practical operation, it is said that the designers regard the machine as a "technical failure" because it is not completely automatic!

Anyone who has carefully observed a mechanic in the process of repairing a modern automobile will realize the great importance of specialized tools and equipment in mechanical work. Of course, a knowledge of the tools and of mechanical processes

is equally important. Only rarely, however, as in the complex process of coordinating hand and foot movements in piloting an airplane, are the physical endowments of the person very crucial. A person who is physically handicapped may often overcome his deficiency by using a suitable work method. Thus it is possible for a deaf man to tune a piano by using a chromatic stroboscope, and a large part of scientific research relies upon methods of amplifying, translating, or measuring stimuli that could not be observed by the unaided human senses.

It is also worth emphasizing that, if a person is not physically fitted to operate a given instrument or machine, e.g. a piano, it is often feasible to adapt the machine to the operator. Thus John B. Watson long ago pointed out that if a boy, handicapped by stubby fingers, should want to become a professional pianist, it would be possible to build a special keyboard to fit the span of his hands. We have often failed to realize that the cost of such specialized equipment may be quite reasonable in comparison to the total cost of preparation for the career in which it would be used.

By the method of work simplification, i.e. breaking down complex processes into a series of separate and simpler steps, it is possible to transform enormous numbers of inexperienced men and women into effective workers in a complex industrial process. Simplification also has its disadvantages, however, for a person may lose interest in the work because he is unable to grasp the significance of his contribution to the end result. To overcome this difficulty many manufacturers are now going back to more complex assignments for each worker so that he can have a sense of accomplishing something by himself. Where this is not feasible, a desirable substitute may be to have special days when the workers and their families can go through the whole factory and see how their own efforts fit into the total process of manufacturing an article.

Whether any one of these alternative means for improving the effectiveness of workers should be introduced, instead of a program for the selection of trainees who are personally best qualified to do the difficult performance under the old conditions, is a matter of just how far each alternative has already been taken into account. Some factories, for example, may already have good physical working conditions, and so could expect little improvement by further attention to this aspect, but they may have poor morale that could benefit by remedial efforts. The applied psychologist will presumably begin his studies of motor performance by analyzing the adequacy of each aspect of the work, and he will frequently need to call in other specialists before deciding where to place his emphasis for the improvement of efficiency.
