Trials to mastery, list 1 vs list 2	0.61	0.73	0.77

criterion of three consecutive perfect responses. Because the subjects learned one list per day for 6 consecutive days (two lists of each of three lengths), there were some disturbing practice effects affecting the coefficients, as pointed out by Melton (1936). In the absence of other coefficients obtained with more elegant controls, these are useful in giving some idea of what may be expected.

Studies that have attempted to deal with the common abilities in memory experiments by the methods of factor analysis have usually reported reliability coefficients (e.g. Garrett, 1928; Anastasi, 1930, 1932-33). Some representative ones from Garrett (1928) are given in Table 13.

Such reliabilities have no absolute meaning, because the tests have varied in length, in types of score, and so on. They show, however, that care is needed to ascertain that the situation used is sufficiently reliable for the purposes at hand because a range of

TABLE 13

RELIABILITY COEFFICIENTS FOR SOME MEMORY-LEARNING TASKS (AFTER GARRETT, 1928)

Paired associates (visual)	0.95
Digit-symbol substitution	0.95
Turkish-English vocabulary	0.91
Paired associates (auditory)	0.90
Code learning	0.85
Digit span (auditory)	0.80
Digit span (visual)	0.68
Logical memory	0.60

reliabilities may be found among tasks that appear to be equally serviceable.

LEARNING CURVES AS ANALYTIC DEVICES

Plotting the scores from learning experiments in the form of performance curves has proved serviceable since the earliest days of experimentation. Such curves are ordinarily plotted with the independent variable on the abscissa in units of repetitions, trials, or time; the ordinate shows the dependent variable of proficiency as measured by time, errors, amount, quality, rate, or other convenient scores.

Acceleration in Learning Curves

In the description of learning curves it has been customary to describe their course according to the rate of change in gains. Thus, if gains between later trials are greater than gains between earlier ones, the curve is said to be a curve of *increasing gains*. If gains grow less with practice, the curve is said to be one of *decreasing gains*. These terms are applied whether the units lead to a rising or falling curve, keeping the psychological meaning the same whether a "gain" is an increase or a decrease in score.* In the nature of the units there is a greater tend-

* The common designations of 'negative acceleration' for decreasing gains and of 'positive acceleration' for increasing gains are to be avoided because, as used in the description of learning curves, they sometimes depart from mathematical conventions.

ency for falling curves to show decreasing gains than for rising ones to depart in that direction from linearity, i.e. from a curve of uniform gains. This can be demonstrated easily by transmuting the scores from one kind of unit to scores in another kind of unit, as in Fig. 9. The two sets of curves, plotted from the same hypothetical data, dramatize the tendency for curves plotted in

learners. This is what the learning curve is intended to show.

The method runs into difficulties when learning is to a criterion of mastery, so that different subjects have had different numbers of trials. Either the average curve must be stopped when the most rapid learner reaches the criterion of mastery, or some arbitrary solution must be adopted. One

FIG. 9. Influence of type of score upon acceleration of learning curves. Curves A, B, and C represent scores plotted as amount per unit time, yielding rising curves that illustrate decreasing gains, uniform gains, and increasing gains, respectively. In curves A', B', and C' the same scores (hypothetical data) have been transmuted to time per unit amount, yielding falling curves. Now the data result in one curve that is linear and two that show decreasing gains. Curves A', B', and C', constructed from the same original scores as those of curves A, B, and C, illustrate the greater tendency toward decreasing gains in falling curves.

units such as time per unit to show decreasing gains. As an empirical finding a curve of decreasing gains is common also for data plotted in amount per unit time, but such curves reveal better than falling curves the inflection points in learning.

Combining Scores from Several Subjects

Trial-by-trial averages. The problem of combining scores from different learners into one curve has been solved in several ways. The simplest and often most satisfactory method is a trial-by-trial average for learners who have had the same number of trials. Then the mean and standard deviation of each point is contributed by the individual differences in trial-by-trial progress of the

possibility is to assume that the successful learners would have continued to score at criterial level had they been permitted to continue. This is a fallacious assumption, and in any case it restricts the variability of the later trials through the artificial maximum imposed upon those learners who have reached the criterion.

The Vincent method. Another solution, first proposed in crude form by Vincent (1912), has since been described by her name, although the details have been much modified. The problem of combining the results of subjects who have required different numbers of trials to mastery is solved by dividing the total course of learning into an equal number of fractions. The subjects'

scores are then averaged according to the achievements within each such fraction of progress to mastery. The fraction includes more trials for the slow learner than for the rapid one. In effect the method shrinks and stretches the learning curves of all subjects so that they begin and end at the same points. Hence all that the final curve can reveal is something of the *form* of the function between the start of learning and the criterion of mastery. This is a very limited amount of information, and Vincent curves have occasionally been used inappropriately on the assumption that they could be used for more general purposes.

Several revisions of the Vincent method have been proposed. These have been reviewed by Hilgard (1938), their assumptions compared, and a preferred method suggested. Because the Vincent method is so limited in its applications, the details of computation will not be given here. The characteristics of the preferred method are as follows: (1) the form of the curve is expressed in the most general units (per cent of total scores given in stated per cents of learning trials); (2) all subjects are weighted equally (each subject contributes 100 per cent of his scores in 100 per cent of his trials); (3) all the scores of all the subjects enter into the computations; and (4) a serious artifact at the criterion, pointed out by Melton (1936), is eliminated.*

Equations of the Learning Curve

When the results of learning are plotted in a form that shows some regularity of curvature, it is possible to fit a mathematical function to the points. Two approaches may be

* If the criterion is met in a single trial, scores on that trial are eliminated in the computations, thus getting rid of the end spurt caused by one trial that is artificially high. If the criterion requires two or more trials (whether or not consecutive), it is necessary to eliminate not only the criterial trials but also the trial just before the criterion. The trial just before such criterial trials is artificially low, and eliminating only the criterial trials would result in an end dip in the average Vincent curve instead of an end spurt.

followed in fitting a curve to data. One is to judge by inspection what function will fit, and then to proceed to try it out mathematically. This is a purely empirical method, resulting in a formula that gives a shorthand description of the curve. If a formula with a large number of parameters is chosen, it may be made to fit a variety of empirical results (Woodrow, 1942). The other approach requires that an inference be made about the form of the function according to some rational theory. Then this function is fitted to the data. In this case the constants are still determined empirically, but they then have rational meaning according to the theory by which the curve was selected.

Among the many attempts to fit curves to learning data, several have proposed functions that have two parameters, one representing the upper limit of learning, the other representing the rate at which this limit is approached. Woodrow (1940) compared two such formulas and found a high correlation between the constants obtained when both were used on learning data. The first formula was that proposed by Robertson (1915).

$$\log \frac{(y)}{(A - y)} = k(x - x_0)$$

The second formula was that proposed by Moore (1932).

$$\log y = a + bc^x$$

Hull (1943) has made extensive use of a somewhat simpler growth function, expressed in the form:

$$H = M(1 - e^{-kt})$$

where H = habit strength.

M = upper limit of habit strength.

t = trials.

k = constant expressing learning rate.

The importance of such equations as analytic devices rests both in the form of the function and in the constants that they determine. If the curves are based on accept-

able rational inferences, the same constants ought to reappear in different situations. These constants not only define individual differences in learning but also make possible additional inferences about the zero point in learning and about the upper limit of learning. These inferences are very important when learning data are to be scaled, as in the attempt to answer questions about the change in variability with practice (e.g. Anastasi, 1934; Woodrow, 1937).

For a recent discussion of the problem of quantifying learning data, see Hull et al. (1947).

NEXT STEPS IN THE STUDY OF LEARNING

In order for the science of learning to advance, two developments must take place together. Methods must be made increasingly precise so that more verified, reproducible relations may be known. At the same time conceptual formulations must be made increasingly appropriate to the processes investigated. Improvement in experimental methods, without the exploring of new concepts, is something of a danger and might lead to sterility. There is no real antithesis between experiments that are inventive and novel and those that are well controlled and dependable in their findings. Novelty should not be introduced as a decoration or as a mere gesture of originality, for the only consequence then is lack of comparability between experiments. Sufficient novelty can be achieved by the study of new variables or the consequences of new formulations, without departing in the control experiments from situations that have been standardized by others.

The possibility of 'miniature systems' (Hull, 1935, 1937) is not to be overlooked as one device for giving concepts careful quantitative testing within restricted domains, without arrogant claims that these concepts will solve all the problems of learning. Such systems, if they appear in num-

ber, will give alternative concepts a chance to be refined before the stage is reached when transformation equations will combine the smaller systems into more comprehensive ones.

Finally, a word needs to be said for naturalistic studies, which continue to make fresh starts in the uncovering of problems that have been neglected in the laboratory. In the end, one service of the laboratory must be to answer in precise fashion the questions that are raised by nonpsychologists confronted with the understanding and control of learning in situations outside the laboratory.

Animal Studies of Learning

W. J. BROGDEN

University of Wisconsin

Although learning has been the concern of most psychological experiments with animal subjects, not all these experiments fall within the scope of this chapter. Even when learning has not been the subject of investigation, the problem has often required a specific training procedure. In other experiments a practice effect has had to be controlled or eliminated, because learning interfered with the phenomenon under investigation. Studies of this sort lie clearly outside our present concern.

Even within the field of learning itself we shall have to restrict our interests. A complete bibliography of animal studies of learning would be enormous. Consequently it is necessary to sort these studies into categories, in order to guide our selection. Rated according to the nature of their scientific contribution, animal studies of learning fall into four classes. They provide evidence to the effect that: (1) learning occurs in a given kind of organism under conditions only vaguely specified; (2) learning of a certain kind occurs to a greater or lesser extent in a given animal under given conditions than does learning in the same animal when one or more aspects of the conditions are changed; (3) learning of a given kind shows progressive variation in amount or in rate as a function of a change in a single variable; and (4) learning of a given kind shows progressive variation in amount or in rate as a function of the systematic variation of a set of variables. Experiments lead-

ing to conclusions 1 and 2 demonstrate merely that learning occurs, that it occurs under conditions that are specified vaguely, or that a particular variable influences the rate or the amount of learning. These may be important first steps in the advancement of a science, but it is only the experiments of categories 3 and 4 that approach the scientific ideal of precise quantitative relations between the phenomenon of learning and the factors governing it. Emphasis will therefore be given to these latter experiments. The present treatment of animal learning will examine the variables that influence the rate and the quantity of learning, and will forego an enumeration of the many different kinds of learning phenomena and the species in which they occur.

Even with this restriction, the facts of animal learning are difficult to organize. No matter what the efficiency of experimental design, the variation in conditions from one experiment to another is appalling. This is often true of experiments that purport to examine the effect of the same variables on the same phenomenon of learning. Even the same research worker may not maintain standard conditions in a series of experiments on similar problems. Lack of standardization makes most experiments wholly unique.

Despite these negative aspects, however, there is much to be said on the positive side. Our fund of knowledge about animal learning is great, and the ingenuity and

skill of numerous workers have produced impressive results. It is possible to marshal these results in a number of ways, each of which has its special advantage. The preference of the writer is to classify the phenomena of animal learning under three categories, acquisition, transfer, and retention, and to show how they occur in three classes of animal learning—conditioning, discrimination learning, and serial learning. This approach requires the development first of adequate definitions.

Acquisition is the primary phenomenon of learning. Its definition provides the basis for defining transfer and retention, for establishing the categories of conditioning, discrimination learning, and serial learning, and for distinguishing learning from other psychological phenomena. Acquisition is a change in performance by an organism. Its course is limited by the arbitrary initiation and termination of measurement, and it comes about through the repetitive or continuous presentation of controlled conditions. The factor of change distinguishes acquisition from psychological phenomena that are relatively static. The direction of change in performance separates acquisition from other dynamic phenomena like inhibition and fatigue. These characteristics may be integrated in the following definition: *acquisition is a progressive incremental change in the proficiency of performance by an organism; the direction, rate, and extent of change in the proficiency of performance are functions of the repetitive or continuous presentation of the conditions under which measurement of the change in performance is made.*

Transfer is the effect of a previous acquisition upon its subsequent proficiency under altered conditions, or upon the proficiency of the subsequent acquisition of some other performance. The measurement of transfer requires that there be a difference in performance under at least two training conditions. The two conditions may be met either by: (1) the acquisition of a given per-

formance and its reacquisition under an altered training procedure, or (2) the acquisition of two different performances, one after the other. These methods require the use of control groups that are given only the second training procedure of the sequence. A further step in precision can often be obtained by making initial tests of the performance under the second set of training conditions, prior to occurrence of the first set.

Transfer is thus always a difference in performance. Although it may be positive or negative, it must be demonstrated to have occurred as a result of differences between at least two training conditions. Transfer cannot be determined precisely by the difference in performance between the two training conditions. The base line of performance from which transfer is measured must come from the control procedures mentioned above. We arrive, then, at the following definition: *transfer is a change in the proficiency of a performance that is demonstrated, by appropriate control procedures, to be a function of a change in the conditions under which it was originally acquired or in the conditions under which a similar performance was previously acquired.*

Retention is the persistence of an acquired performance after a lapse of time during which the performance has not taken place. Theoretically, retention is involved in both acquisition and transfer. There could be no acquisition of a performance if there were no persistence of increments from trial to trial. Nor could there be transfer if the change involved in the acquisition of a performance did not remain to influence the subsequent acquisition of another performance. However, as with transfer, the definition of retention must be made relative to the definition of acquisition and in terms of the experimental procedures used to study retention. In animal studies, retention may be measured as the saving in the cost of reacquiring a performance after a lapse of time from the cost of the original

acquisition. Or it may be measured by the proficiency of a performance in a short series of trials relative to that for an equal series of trials made earlier in the terminal stage of an original acquisition. The variables that operate within the lapse of time may either be controlled by the experimenter or they may be left to chance. In any case the lapse of time involved is relatively greater than the intervals between the trials that led to the acquisition. The following, then, is our definition: *retention is the difference in proficiency of a performance during reacquisition or retest from that during acquisition; the subsequent measure is made after a lapse of time (1) ordinarily greater than the intervals between trials during acquisition, (2) in which the performance does not occur, and (3) during which variables that are a function of it may be controlled.*

Every special kind of learning represents a subclass of acquisition. The definitions of conditioning, discrimination learning, and serial learning first must fall within our definition of acquisition, and second must be such that each is differentiated from the other two. Measurement of any performance defines its beginning and its end. The beginning and end of the performance determine its duration in time and its location and extent in space. Thus performances may be relatively long or short in time and of relatively large or small extent in space. The acquisition of performances of relatively short duration is characteristic of conditioning. The acquisition of performances of relatively long duration, where subunits of performance may be measured, is characteristic of serial learning. Either kind of performance may be involved in discrimination learning.

The acquisition of a performance occurs in a set of environmental conditions that are presented to the organism continuously or repetitively. Some one or more aspects of the environment that are controlled by the experimenter are called the stimulus. When the stimulus is manipulated as a discrete

and unitary event in space and is of relatively short duration, the performance involved is ordinarily of short duration. This situation is characteristic of conditioning. Where the stimulus is of relatively long duration and is patterned in space and time, the performance is ordinarily one of long duration and capable of division into subunits. These circumstances are characteristic of serial learning. Discrimination learning requires that there be at least two different stimulus situations to which the organism is required to make different responses. The experimenter may manipulate the stimuli so that they occur simultaneously or in temporal succession.

CONDITIONING

The classification system of Hilgard and Marquis (1940) will be followed in discussing the procedures for acquisition of CR's.* The primary distinction is between the classical and the instrumental training procedures, with a subclassification for the training procedures of instrumental reward, instrumental escape, instrumental avoidance, and secondary reward.† The classical train-

* Abbreviations: US = unconditioned stimulus; UR = unconditioned response; CS = conditioned stimulus; CR = conditioned response; RS = reinforcing stimulus.

† The distinction of four varieties of instrumental training is open to question. Instrumental reward and secondary reward training may be reduced to a single variety. Once training has been given the animal to establish the token-reward habit, the training for acquisition of the CR is the same. The preliminary training on the token habit is itself instrumental reward training: the experimenter selects an RS that has been shown to be effective as an RS by other observations. The effectiveness of this stimulus is probably the result of previous training. Instrumental avoidance and instrumental escape training may be reduced to a single variety by the introduction of a CS to the escape training procedure. If a CS is introduced into reward training, as was done by Skinner (1935) to establish what he called a pseudotype CR, all varieties of instrumental CR become comparable. Although a distinction is made between instrumental CR's established with noxious and reward-type US's or RS's, this is not done for classical training. In fact, that a given instrumental CR may be

ing procedure is that originally used by Pavlov (1927, 1928). A response already within the repertory of the animal is designated the UR, and the stimulus that elicits it is called the US. The UR is preferably a conveniently measurable response readily and consistently evoked by the US. Another stimulus that has been shown by test not to elicit the UR is called the CS. The CS and the US are presented repeatedly to the organism either simultaneously or with the CS preceding but overlapping the US in time. A response that is similar to the UR develops to the CS and is called the CR. The change in response to the CS from an initial zero magnitude of CR to some terminal magnitude constitutes an acquisition that is called conditioning.

Pavlov and his many collaborators worked with the dog. Ordinarily the UR was salivation; the US was food or weak acid; the CS was a stimulus for the auditory, tactile, or visual sense modalities; and the CR was salivation.

The procedures used in instrumental conditioning differ from the classical procedures in that there are two conditions of stimulus presentation: one prevails when a CR occurs, the other when a CR fails to occur. When the condition results in an increase of the CR, it is called reinforcement; when it results in no increase of CR, it is called nonreinforcement. These terms are also applied to the classical procedure: the US paired with the CS constitutes reinforcement; presentation of the CS alone is nonreinforcement. With instrumental training, reinforcement may occur in the absence of a US. The presence or absence of an RS provides the conditions for reinforcement and nonreinforcement in the training procedures.

readily maintained when a shift is made of the RS from shock to food has been shown by Brogden (1939a). The distinction of four varieties of instrumental training is based primarily upon the lack of control exercised by the experimenter over the conditions under which acquisition takes place and the time at which responses occur.

Reinforcement may be homogeneous or heterogeneous. Homogeneous reinforcement is typical of classical conditioning. It occurs when the US determines the nature of the response to be conditioned, and the presence or absence of the US provides the conditions for reinforcement or nonreinforcement. Heterogeneous reinforcement means that the response to be conditioned is not determined by the RS, but the presence or absence of the RS constitutes reinforcement or nonreinforcement.

Instrumental reward training has the following characteristics: (1) When the animal makes a response previously selected by the experimenter (the CR), an appropriate incentive such as food or water (the RS) is immediately presented. (2) If the animal is allowed to remain in the experimental situation, reinforcement takes place again when next the CR appears; if the animal has been removed, the experimenter returns it to the experimental situation so that a second CR may occur and be reinforced by the RS; in either case, the CR is the instrument that controls the occurrence of the RS. (3) Acquisition is measured in terms of time required for the CR to occur after the last CR, or after introduction to the experimental environment (latency), or in terms of frequency or rate of CR in a fixed unit of time. (4) These training conditions are continued until the individual animals have reached a critical performance, or until a predetermined number of trials is given or a predetermined amount of time has passed. (5) The experimenter does not exercise specific control over events similar to either a CS or a US. He merely sets the general experimental environment and introduces the animal to it.

The characteristics of instrumental escape training* parallel closely those for reward training, except that the conditions of rein-

* Although instrumental escape training has received relatively little study, it has been shown to provide an excellent means for the study of acquired drives (see Chapter 13).

forcement involve noxious stimulation by electric shock, water, or extreme deviations of environmental temperature from body temperature. (1) The animal is presented with a noxious stimulus that continues to operate until a performance already within the repertory of the animal (the CR) occurs. (2) Either the CR terminates the RS, or it is the means of escape to another locus. (3) The animal is returned to the noxious environment if the CR results in escape to another locus, or the RS is reinstated by the experimenter; the appropriate condition prevails until the CR occurs again. (4) Measurement of acquisition may be in terms of latency or amplitude or in terms of frequency or rate of CR. (5) Practice is handled in terms of trials or units of time and is terminated when a criterion is attained or a given amount of practice is completed. (6) There is no US or CS under the control of the experimenter, except in terms of the extent to which the RS may function originally as a US or come to function as a CS.

Instrumental avoidance training is very similar to classical training in which the US is a noxious stimulus such as electric shock. (1) There is a definite US under the control of the experimenter that evokes a UR. (2) The CS and US are presented initially under the same conditions as in classical training. (3) The CR selected by the experimenter is similar in character to the UR. (4) When the CR is evoked by the CS, the US is not applied—the CR is the instrument of shock avoidance. (5) The measurement of acquisition may be in terms of amplitude, latency, or frequency of response. (6) Practice is handled in trial units and is terminated when a criterion is reached or a given number of trials has occurred.

Secondary reward training is a special case of instrumental reward training.* Initial

* Studies of secondary reward training provide a measure of the effectiveness of an acquired drive. Since an extended discussion of such studies in relation to learnable drives is given

training must be given to establish the performance, e.g. the operation of a food vendor by the insertion of poker chips. When this performance has been acquired, instrumental reward training is applied, except that the stimulus object for the food-vending machine is used as the RS.

Acquisition of a Conditioned Response

The UR. Many responses have served as the UR in experiments on conditioning. Lists of responses that have been conditioned are presented by Hull (1934) and by Hilgard and Marquis (1940).

The UR is rarely the independent variable in an experiment on the acquisition of a CR. In most situations it is not possible to vary the UR without varying its US. However, when the US is electric shock, the locus of application may be varied without other appreciable change in the UR. With dogs, cats, and rats investigators have reported on the acquisition of flexion responses of one or the other of the four limbs, but few have compared acquisition as a function of the responding members. Brogden (1940b) was unable to demonstrate a difference in the rate of acquisition of an instrumental avoidance response in dogs for the right and left forelimbs.

The acquisition of a CR may involve at least two stages: a first step that requires development of the UR to the US alone (or response to the RS alone); and a second stage, dependent upon completion of the first, during which the CS begins to evoke the CR (or during which the RS may be applied effectively). Both Skinner (1938, p. 66) and Girden (1938) cite evidence for two stages in the acquisition of a CR.

The definition of the UR also influences the measurement of acquisition. A US may evoke many changes in the effector system of an organism, of which usually only one is measured quantitatively as the UR. Re-

in Chapter 13 the present chapter will give only limited treatment to experiments on secondary reward training.

striction in measuring the UR usually imposes the same restriction on measurement of the CR. Research workers have been acutely aware of this, and it has been customary for them to comment on aspects of performance during acquisition that have not been subjected to measurement. An extensive description of these performances in

urination, and defecation. The measurement of any one of these aspects would provide data on the acquisition of a CR. The four curves of Fig. 1 are evidence that the results of an experiment on acquisition are in part a function of the response component to the US that has been selected for measurement as the UR and CR. This consid-

FIG. 1. Relative frequency curves of leg flexion made to the CS when the right rear foot of a dog receives the shock US during instrumental avoidance training. The break in the curves indicates a time interval of 2 to 4 months. The curves for test periods 1 to 10 are based on data for 6 dogs; test periods 11 to 20 are based on data for 5 dogs. (Wolf and Kellogg, 1940.)

the salivary conditioning of dogs has been given by Zener (1937). Moore and Marcuse (1945) have dealt with salivary, motor, and cardiac indices of conditioning in sows.

Kellogg and Wolf (1940) and Wolf and Kellogg (1940) gave this problem particular attention in the acquisition of instrumental avoidance CR's in dogs. During training for acquisition, measurements were made of the responses of each of the four limbs and of respiration to both the bell CS and the electric shock US. The shock was applied to the right rear foot, and a flexion to the bell that raised this foot $2\frac{1}{2}$ inches resulted in shock avoidance. Figure 1 presents the composite relative frequency curves for CR's of each of the four feet. A still more complete picture of acquisition would include the changes in respiration made to the bell and such components of reaction as vocalization,

urination, and defecation. The measurement of any one of these aspects would provide data on the acquisition of a CR. The four curves of Fig. 1 are evidence that the results of an experiment on acquisition are in part a function of the response component to the US that has been selected for measurement as the UR and CR. This consid-

eration is pertinent to all studies of animal learning.

The US and RS. The US is not completely independent of the UR, but it is more readily subject to manipulation than the UR. Although a change in the US will usually produce a change in the UR, the manipulation of certain aspects of the US affects acquisition. For example, many experimenters have stated that there is an optimal intensity of the shock US. Dunlap, Gentry, and Zeigler (1931) studied the relation of intensity of electric shock to the acquisition of an instrumental escape response in rats. All animals were given training of 10 trials daily until they attained the criterion of 8 CR's for one test period. The intensity of the shock was 0.044, 0.088, and 0.176 milliamperes, respectively, for each of three groups of 20 animals each. The 0.044 level

was apparently close to the threshold, since only 9 of the 20 animals reached the criterion. The mean number of test periods required for the group to reach the criterion was 11.3 for the 0.088 value, and 13.5 for the 0.176 value. These results support the generalization given above and are also in agreement with the effect of shock on human learning.

FIG. 2. Acquisition as a function of magnitude of reinforcing food stimulus. Each point on the curve represents the performance of a different group of animals and is the average of the individual mean performances for the terminal stage of acquisition of an instrumental reward running response. The RS unit is a 0.02-gram piece of Purina dog chow presented to a rat deprived of food for 22 hours. (Crespi, 1942.)

When food is the RS, its quantity might be expected to affect the rate of acquisition of a CR. Indeed, Crespi (1942) has shown that the acquisition of an instrumental reward CR by the rat is positively related to the magnitude of the food RS (see Fig. 2). In terms of the average maintenance diet of 7.5 grams, the range of 1 to 64 incentive units (0.02 to 1.28 grams) is considerable. Similar studies have used a smaller number of values of the RS and a more restricted range, but the results have agreed with those obtained by Crespi.

It is possible to vary the frequency with which the US or RS is presented within a given training procedure. Pavlov (1927, p. 384) reported that with a single animal the first salivary CR appeared on the twentieth trial when the US followed the CS on every other trial (50-per-cent reinforcement). This

result does not differ from that obtained with 100-per-cent reinforcement, when the first CR also occurs by approximately the twentieth trial. No statements are made by Pavlov about the further course of acquisition under these two conditions of reinforcement.

Similar experiments have been carried out by Skinner (1938, pp. 116ff.) on an instrumental reward CR in rats. In each animal the response was first conditioned and then extinguished. Thereafter for different groups of animals the food RS was presented at intervals of 3, 6, 9, and 12 minutes. Rate of acquisition was found to be inversely related to the interval between reinforcements up to 9 minutes. The results for the 9-minute interval are little different from those for the 12-minute interval. Similar results are obtained when these conditions prevail for a single experimental session (1 hour) and for a series of experimental sessions (25 1-hour sessions). In two almost identical experiments with rats, Finger (1942*a, b*) found, with an instrumental reward CR (running), that acquisition was significantly greater for 100-per-cent reinforcement by the food than for 50-per-cent random reinforcement, and that extent of acquisition for the 50-per-cent reinforcement group was equivalent to that for a group of animals that was given 100-per-cent reinforcement, but only half the number of practice trials.

The CR. The CR is the dependent variable in studies of acquisition; however, the results are in part a function of its definition and measurement. Just as with the UR, the definition of the CR is arbitrary, and only certain aspects of the animal's performance to the CS are measured. There is also another factor that influences the measurement of acquisition. Data on acquisition of a CR may be in terms of frequency, latency, or amplitude. It is rare that all three measures are recorded and reported. When they are reported, the three measures are found to intercorrelate differently with one another

and to vary in their reliability. The problem of standardization is perhaps more critical for the dependent variable in studies of animal learning than for any other aspect.

The CS. Many different CS's have been used in studies of conditioning. The limits appear to be determined by the sensitivity of the animal's receptor equipment and by the organism's previous training.

Investigations of the effect of the CS upon rate or quantity of acquisition might take place for many stimulus dimensions. The sense modality of the stimulus is one such dimension. A CR in some form or other has been established in some species of animal to every sense modality possessed by the human being, but the visual and auditory modalities have been used most frequently. Experimenters have often noted that acquisition is slower to a visual CS than to an auditory CS, but differences in other conditions might have been responsible for the difference in acquisition. In any case it would be necessary to equate the intensity of the visual and auditory stimuli before any difference in acquisition could be attributed to the difference in sense modality.

Within a given sense modality, it should be possible to determine the effect of the magnitude of the CS in terms of intensity, duration, and other characteristics. Intensities of CS have most often been described as being within a middle range. Pavlov (1927, pp. 383ff; 1928, pp. 89, 91) reported that for some stimuli acquisition is slowed when the CS is weak, but that for others no effect of intensity occurs. The frequent use of conditioning techniques for obtaining absolute thresholds demonstrates that, once a CR has been acquired, it may be evoked by stimuli of minimal intensity.

The factor of duration of CS is relative to the duration of the US and to the latency and duration of the UR and the expected CR. The duration of the CS is customarily greater than the latency of the CR. It may be greater or less than the duration of the

US. Duration of the CS does affect acquisition, but it is not independent of the interval of time between termination of the CS and onset of the US. In general, a CS of relatively long duration results in slow acquisition.

Pavlov (1928, p. 91) reported that the combination of two or more stimuli representing different sense modalities produces a salivary CR of greater magnitude than will occur to either stimulus alone. What effect these stimulus conditions have on acquisition is not known. Other characteristics of stimuli that have served as the CS in conditioning studies, such as form, size, and frequency, have not been subjected to investigation in relation to acquisition.

Time relations of US and CS. Pavlov (1927, 1928) demonstrated that both acquisition and the characteristics of the salivary CR in dogs are affected by the relative duration of the CS and US, the degree of overlap and separation of the two, and their temporal order. He gave a classification of CR's in terms of these variables, which in general has been shown to hold for other animals and other CR's. Other investigators have presented results for other time variables. The following classification is both a modification and an extension of Pavlov's original classification of CR's in terms of procedures with temporal variables.

1. The simultaneous CR. The CS is either coextensive in time with the US, or it starts from a fraction of a second to several seconds before the US, and overlaps with it. If the US and CS are coextensive, test trials of the CS alone offer the only opportunity for measuring the CR. If the onset of the CS occurs before the onset of the US, the CR may be measured on each trial. This interval is customarily proportional to the latency of the CR. For the salivary response in dogs it varies from 5 to 30 seconds. For striate muscle responses a shorter time interval is used, from $\frac{1}{4}$ second to several seconds.

2. The delayed CR.* The CS has a greater duration than it has for the simultaneous CR. This name was given by Pavlov because here the latency of the CR is longer than the latency of CR's in the simultaneous category. The duration of the CS is therefore greater than the upper limit for duration of CS with the simultaneous CR.

3. The trace CR. The CS is presented and terminated, and there is a lapse of time before the onset of the US. With salivary conditioning of dogs, the interval of time may vary between a few seconds and several minutes. The terms short trace and long trace are applied, respectively.

4. The temporal CR. The US is presented alone at a constant rate, and the time interval between presentations of the US functions as a CS.

5. The backward CR. The onset of the CS occurs after termination of the US and after the occurrence of the UR.

6. The pseudo CR. The US is presented alone in a series of massed trials, and then, after a short interval of time, the CS is presented in a series of massed trials.

With other conditions equal, the simultaneous CR is acquired at a more rapid rate than CR's involving other time relations. Curves of acquisition for simultaneous CR's established by classical training, and by instrumental reward, avoidance, and secondary reward training are shown in Figs. 1, 3, 4, 5, 6, and 8.† Comparable curves of acquisition for other temporal relations are not available

* Pavlov refers to short-delayed and long-delayed CR's but does not distinguish between these two categories in terms of the duration of the CS (1927, p. 90).

† Acquisition curves of different forms have been obtained in conditioning studies. Since many variables have been found to influence the extent or rate of acquisition, the form of the acquisition curve is also probably influenced by these same variables. It is doubtful whether there is a form of curve common to the acquisition of all CR's. Although there has been considerable study of the form of curves of acquisition and extinction of CR's (for examples, see Hull, 1943, and Skinner, 1938), this topic will not be treated in the present chapter.

for all types of training. Pavlov's results are not presented in such form that curves of acquisition, rate of acquisition, or terminal quantity of acquisition may be obtained. However, Pavlov reports that the simultaneous CR is acquired more readily than CR's involving other time relations. The CR then is of relatively short latency and begins to occur early in the training, usually by the

FIG. 3. Curve of acquisition for a classical salivary CR in dogs. Each point represents an equally weighted Vincent fraction for magnitude of salivary CR by 4 dogs given classical training. The Vincent curve data were derived by Hull (1934) from unpublished data provided by Kleitman and Crisler (1927).

twentieth trial (1927, p. 385). As training continues, the frequency and amplitude of CR increase and the latency decreases. Finally a relatively stable CR is established. Pavlov reported no studies of the effect of duration of the CS within the 0- to 30-second range. A 30-second CS is the most frequent duration of CS reported in his books, and, when greater intervals of CS occur in tables, the CR's are labeled delayed CR's. Finch (1938) reported that there is no difference in the reliability of the magnitude of the salivary CR between a CS of 30 seconds' duration and one of 10 seconds' duration. He suggested therefore that the latter duration of CS be used, since more trials may be given per test period and any possibility of the development of a delayed CR is eliminated. Although this is not direct evidence that the duration of the CS affects acquisition of the salivary CR, it does sup-

port the inference drawn from Pavlov's writings that acquisition of the salivary CR is not markedly affected by variation in the duration of the CS from a few to 30 seconds.

may be carried out in either of two ways. The duration of the CS is gradually increased at successive test periods (in steps of the order of 5 seconds). The CR is thereby

FIG. 4. Curve of acquisition for an instrumental reward CR in rats. Each point is the median latency of an instrumental reward CR for 59 rats and was obtained by the justly weighted Vincent technique. Latency of CR was measured from the time of raising a shutter (CS) that exposed a lever to the time at which the rat pressed the lever (CR). The lever was made inaccessible to the animal immediately after the CR. Each CR was instrumental in producing a pellet of food (RS). One trial was given each day to each animal when the animal had been deprived of food for 22 hours. The equation is for the fitted function represented by the smooth curve. (Felsing, Gladstone, Yamaguchi, and Hull, 1947.)

The delayed salivary CR results with extension in time of the CS beyond the 5 to 30 seconds' range. Pavlov indicated that CR's to stimuli lasting longer than 30 seconds are extremely difficult to establish, unless prior training on a simultaneous CR has been given. Training for the delayed CR

maintained, but its latency shows a progressive increase with increase in the duration of the CS. The second technique is to increase the duration of the CS to that desired in a single step. The CR then disappears, but as training continues it reappears—with a long latency. With further training,

latency diminishes, magnitude increases, and a stable delayed CR is formed. The latency of a delayed CR is proportional to the duration of the CS. The rate of acquisition of a delayed CR by either of the two techniques described above varies considerably from animal to animal. In some dogs the delayed salivary CR may be produced after only a day's training; in others, more than a month's training may be required.

Studies of the effect of duration of CS upon motor conditioning cover conditions that might be expected to distinguish simultaneous, delayed, and trace CR's. Kappauf and Schlosberg (1937) conditioned limb flexion in rats to durations of CS of $\frac{1}{3}$, $\frac{2}{3}$, 1, 2, 4, and 7 seconds. No evidence of the development of delayed CR's was obtained. The latency of CR was brief for all animals, no matter what the duration of the CS. There was a greater frequency of CR for animals in the group with a CS of $\frac{2}{3}$ second, but individual differences were large.

Warner (1932) gave avoidance training to rats in which the CS was a buzzer of 1-second duration and the CR involved jumping into another compartment of the apparatus. Different groups of animals were trained with intervals of 1, 10, 20, and 30 seconds between the termination of the CS and the onset of the US. Although the longer time intervals provided an opportunity for trace conditioning, no such CR's were developed; when CR's occurred, they were made to the CS and not during the interval between termination of the CS and onset of the US. All 5 animals in the 1-second delay group met the criterion of conditioning (6 consecutive CR's within one 50-trial test period). The criterion was met within 20 test periods by 4 of 5 animals in the 10-second delay group, by 6 of 10 in the 20-second delay group, and by none of the 10 animals in the 30-second delay group. For the animals that reached the conditioning criterion there was a progressive increase in the number of test periods required to reach the criterion as the delay interval was increased.

Mowrer and Lamoreaux (1942) studied the effect of duration of the CS on acquisition of instrumental avoidance by rats. For one group of animals the buzzer CS was 1 second in duration and the shock US occurred 6 seconds after the onset of the CS. For a second group the US was given 6 seconds after the onset of the CS, but the duration of the CS was determined by the latency of the CR; that is to say, the duration of the CS was made equal to the latency of the CR by having the CR terminate the CS. The relation between onset of CS and US for the animals of a third group was the same as that for the other two groups, but the duration of the CS was held constant at 5 seconds. Acquisition occurred more rapidly and to a greater extent for the group in which the CR terminated the CS than for either group with a fixed duration CS. There was no difference in acquisition between the 1-second and 5-second CS groups. Throughout training, average latency of CR was of the same order for the groups with fixed duration CS but was less for the animals that received the variable duration, i.e. response-terminated CS. The results for the 1-second group might be considered representative of that obtained by training for trace conditioning, since the CR's occurred after termination of the CS. Thus there is no difference in the acquisition or characteristics of this trace CR and the simultaneous (or delayed?) CR of the 5-second CS group. However, the most important outcome of this experiment is the identification of an independent variable—termination of the CS by occurrence of the CR—that contributes to efficiency of acquisition.

Pavlov says little about the characteristics of trace salivary CR's. If only the interval between the onset of the CS and the onset of the US is considered, there is no difference between the conditions for the delayed and the trace CR. Presumably the characteristics and mode of acquisition of delayed and trace CR's are similar if the time interval between onset of CS and onset of US is the

same. Certainly there is no evidence that the duration of the CS affects either the acquisition or the characteristics of CR's independently of the interval between onset of CS and onset of US. Although for motor CR's there is evidence that acquisition is inversely related to the magnitude of the interval between onset of CS and of US, there is no evidence for either trace or delayed CR's in terms of latency or amplitude of CR.

Strictly speaking, with the usual conditions of instrumental reward training, it is not possible to generate either delayed or trace CR's. Because there is no CS under the control of the experimenter, more than one CR may occur before the delay period is completed and the RS presented. Skinner (1938, pp. 72ff.) states that an instrumental reward CR may be established with delays of RS up to 8 seconds, but his results are complicated by the occurrence of CR's during the delay period. Perin (1943*a*) eliminated this difficulty by removing the bar once it had been pressed by the rat. This puts the CS under the control of the experimenter, who can then control the presentation of trials and the occurrence of responses. The latency of the CR (interval of time between opening the door into the experimental compartment and pressing the bar) can then be investigated as a function of delay of reinforcement (interval between bar pressing and the presentation of food RS). Five groups of animals were trained with delays of 0, 2, 5, 10, and 30 seconds. The 30-second group failed to acquire the bar-pressing response within 50 practice trials. The acquisition curves for the other groups were similar to one another. Each approached a relatively stable latency by about the twenty-fifth practice trial, and terminal latency was positively related to the delay interval. Group mean latencies for the last 5 of the 50 training trials were 2.14, 4.20, 5.46, and 12.73 seconds for delays of 0, 2, 5, and 10 seconds, respectively. Differences between successive means are reliable

by the *t* test at better than the 5-per-cent level of confidence. Figure 5 shows the relation between the delay interval and the measure of terminal acquisition. Perin's results demonstrate clearly that delayed instrumental reward CR's may be acquired by rats and that latency of CR at a terminal stage of acquisition increases with the interval of delay in reinforcement. The maximum delay at which acquisition may take

FIG. 5. Acquisition of an instrumental reward CR as a function of the period of delay in reinforcement. Each point represents the reciprocal of the latency asymptote of a function fitted to the acquisition data for a group of 25 rats given instrumental reward training of 50 trials, with a delay in reinforcement equal to that shown on the abscissa. The equation of the fitted curve is $1/L = 0.22 \cdot 10^{-215 T'} - 0.0188 T' + 0.320$. (Perin, 1943*a*.)

place is between 10 and 30 seconds. From theoretical curves, Perin sets these limits at 14 and 21 seconds.

The temporal CR has been little studied as such. Intervals as great as 30 minutes have been used successfully in establishing salivary CR's in dogs. Temporal motor CR's are apparently also acquired with ease. In most conditioning procedures, it is customary to vary the interval between trials at random during training in order to avoid the formation of a temporal CR.

Pavlov (1927, p. 27) stated very positively that backward conditioning is not possible. Later work apparently resulted in the statement that a backward CR could be formed but that such a CR is very unstable (1927, p. 381). Additional evidence that backward

conditioning may take place has been obtained in experiments on human beings.

Pseudoconditioning has been obtained in many different animals. In general, a US of relatively high intensity appears to be a necessary condition. The pseudo CR is not so well established nor so stable as a similar CR based upon equivalent training by simultaneous forward conditioning procedures (Harris, 1943). Wickens and Wickens (1942) reported that the amount of pseudoconditioning depends on the similarity between the US and CS. In this study, rats given training with an electric shock US that increased gradually in intensity gave a greater frequency of CR when the CS was a light that increased gradually in intensity than when the onset of the light CS was abrupt. The reverse training procedure, trials with abrupt shock followed by abrupt or gradual light, gave results similar to those obtained with gradual shock followed by gradual and abrupt light. With monkeys Grether (1937) found no difference in the acquisition of a CR produced by backward and by pseudoconditioning procedures. Pseudoconditioning should probably be treated as a variant of backward conditioning. However, both varieties of training involve time relations of the US and CS that are inefficient for the acquisition of a CR.

Training procedure. The relative efficiency of classical training and of instrumental avoidance training for the acquisition of a CR has been studied by several investigators. In all these studies the US for both training procedures has been electric shock. Experiments by Schlosberg (1934, 1936) and Munn (1939) with rats, and by Brogden (1939c) and Whatmore, Morgan, and Kleitman (1946) with dogs, have failed to demonstrate any difference in rate or quantity of acquisition for the two procedures. On the other hand, instrumental avoidance training has been shown to be a more efficient condition for acquisition of a CR than classical training for running responses of guinea pigs by Brogden, Lipman, and Culler (1938) and

Sheffield (1948), and running responses of rats by Hunter (1935). No one reports the superiority of classical training over instrumental avoidance training. It may be assumed that instrumental avoidance training is superior to classical training, and that in experiments that have failed to demonstrate a difference other variables reduce the efficiency of instrumental avoidance training.*

FIG. 6. Acquisition curves of a string-pulling CR in cats for instrumental reward and secondary reward training. The broken line is for instrumental reward training of one animal (string pulling produced food), and the solid line is for secondary reward training of another animal (string pulling netted a token exchangeable for food). Each point is the mean latency of CR for a block of 5 trials. Acquisition curves for some of the other animals start with shorter latency and show less change than do these sample curves. (Smith, 1939.)

It is also possible to compare the relative efficiency of instrumental reward and secondary reward training upon the acquisition of a CR. An experiment by Smith (1939) on the acquisition of a string-pulling response in cats, with instrumental reward and secondary reward training, resulted in no difference for the two procedures, provided the training trials required to establish the effectiveness of the token as a reward were ignored (see Fig. 6). It is reasonable to ignore the time required to establish the token habit. If a difference were to be found in the acquisition of a CR by instrumental

* Studies of this kind are similar to those on the frequency of application of the US or RS. Both bear on the reinforcement-nonreinforcement controversy in learning theory.

reward and secondary reward training, the lesser acquisition might be expected to occur with the latter procedure. The difference would be less a function of training than of the effectiveness of the RS. Mote and Finger (1942) report such a difference in acquisition when the RS for a running response in rats was merely the goal box in which the animals had been fed prior to training.

What Pavlov (1927, pp. 33ff.) called higher-order conditioning is an example of secondary reward involving the classical training procedure. The CR (e.g. salivation) established to a CS (e.g. bell) by classical training is called a first-order CR. When a neutral stimulus (e.g. light) is paired with the CS (bell) for a series of trials in which the US (food) is omitted, the salivary response that is evoked by the light alone is called a second-order CR. Third- and higher-order CR's would be established by pairing a neutral stimulus with the CS of the preceding order. The use of the CS in higher-order conditioning is similar to the use of the token RS in secondary reward training. By these procedures it has not been possible to produce more than a second-order salivary CR nor more than a third-order defense CR (electric shock as US for the first-order CR). The acquisition of higher-order CR's is difficult and requires much retraining at the first-order level. A higher-order CR is weaker than the CR of the next lower order.

A more efficient procedure for establishing higher-order CR's was developed by Finch and Culler (1934). The first-order flexion response was established by avoidance training. When a second-order CR had been established, its vigor was maintained by shocking the animal's thorax whenever the flexion CR failed to occur to the second-order CS. Conditioning was carried out to the fifth order by this procedure. Brogden (1939*d*) started first-order conditioning as did Finch and Culler, but for the higher orders he adapted their technique of reinforcement to food. A still more efficient pro-

cedure of higher-order conditioning was discovered by Eccher and Culler (1941). When a first-order CR had been established in cats by instrumental avoidance training, the second-order CS was followed by the first-order CS only when there was no CR to the second-order CS. Under these conditions it was never necessary to return to first-order training in order to set up the second-order CR. A third-order CR was readily established by the same procedure.

A CR was established by Miller and Konorski (1928*a*) through a variation on classical and instrumental reward training. Following presentation of the CS, the forelimb of a dog was lifted passively by means of a mechanical system. Although no CR's occurred to the CS during this procedure, conditioning took place readily when a food RS was presented on each trial after passive flexion and after each CR made to the CS. Woodbury (1942) was not able to repeat this experiment, but Wing (1947) has confirmed the results obtained by Miller and Konorski. Loucks (1935) obtained similar results by a somewhat different procedure. No CR was obtained to a CS when the UR was evoked by faradic stimulation of the motor cortex of a dog. When a food RS was presented following both the UR and any occurrence of a CR to the CS, conditioning was established readily. Loucks and Gantt (1938) obtained similar results with faradic stimulation of the motor root of the spinal column.

It is frequently impossible to compare experiments based on classical and instrumental training procedures because of differences in more than a single variable. Because of the lack of control by the experimenter of a CS and a US, the classical procedure may not be compared with varieties of instrumental training other than avoidance. This also prevents comparison of avoidance training with other varieties of instrumental training.

Distribution of practice. Some degree of distributed practice is generally more efficient

for the acquisition of a CR than the massing of training trials. Practice is ordinarily distributed over a number of test periods and also within the test period. Although in some studies the training trials have all been given within a single session, the intervals between trials have been distinctly larger than the durations of the CR and the UR.

five groups of 12 rats each, the intervals between trials being 0.5, 1, 2, 3, and 5 minutes. Only 8 trials were given, and the amount of the food RS was increased progressively with the interval between trials, the amounts being 0.06, 0.18, 0.56, 0.98, and 1.32 grams. Although the absolute amount of food RS varied directly with the interval

FIG. 7. The effect of distribution of practice upon the acquisition of an instrumental reward CR. Each point connected by solid lines is for the same group of 8 rats. Each trial was reinforced by a single pellet of food. The broken line represents data for five groups of 12 animals each, with amount of food reinforcement increasing proportionally to the size of the interval between trials, but with rate of eating held approximately constant. The two solid lines thus represent the relation of distribution of practice to acquisition when food reinforcement is held constant. The broken line shows the relation of distribution of practice to acquisition when rate of eating is held constant but magnitude of the reinforcing stimulus is not. The difference between the solid curve (eighth trial) and the broken curve is due to the two conditions of reinforcement. (Gagné, 1941a.)

Although the distribution of practice may vary over a wide range, for a given CR under a given set of conditions there is a distribution for which acquisition is optimal. Several studies have compared two conditions of distributed practice and found one of them to be the more efficient. This comparison was extended to more than two conditions by Gagné (1941a). Two experiments make up this study. In the first experiment, 15 trials of reward training were given rats during a single session. The intervals between trials were 0.5, 1, 2, 3, 5, and 10 minutes for the six groups. The CR was traversal of a 3-foot runway, and the RS was a pellet of dog food that weighed 0.06 gram. Acquisition was measured in terms of running time and of latency. In the second experiment, similar training was given

between trials, the rate of eating approximated a constant value.

The results for these experiments are shown in Fig. 7. With the absolute amount of the RS held constant, the optimum intervals between trials were 0.5 and 1.0 minute; with the rate of eating held approximately constant, the optimum interval was 5.0 minutes. Whatever the effect of magnitude of the RS may be, the effect of distribution of practice does not seem to be independent of it. The effect of amount of practice is also related to the effects of magnitude of RS and distribution of practice. If number of practice trials is equated for the two experiments (see Fig 7), terminal acquisition does not differ for the short intertrial intervals, in spite of differences in magnitude of RS, but it does differ markedly for the longer

intervals. The curve for Crespi's data on the relation of acquisition to magnitude of the RS (see Fig. 2) suggests that the results of Gagné's second experiment are more a function of the magnitude of the RS than they are a function of the interval between trials.

Transfer of CR's

Many instances of transfer, both positive and negative, have been found in studies of conditioning. Transfer is usually positive when it is measured as the difference in performance under different conditions, each of which involves training for acquisition. Transfer is most often negative when it is measured as the difference between performance at a terminal stage of acquisition and a subsequent performance that results from alteration of some variable that was present during acquisition. In this latter case positive transfer may then be produced by the reversal of conditions or by the introduction of new or altered variables. Many phenomena of transfer were discovered in Pavlov's laboratory and were given special names. An attempt will be made to preserve these names and at the same time to classify the phenomena of transfer in terms of the variables that affect their occurrence.

Experimental extinction. The most striking phenomenon of negative transfer occurs when the US or the RS is deleted from the procedure used in acquisition. A progressive decrement then ensues, and finally a point is reached at which the CS fails to evoke the CR. This phenomenon was originally discovered and named experimental extinction by Pavlov (1927, 1928). It has been much studied for its own sake and for its importance in learning theory. Experimental extinction occurs for CR's acquired through all types of training. The CR usually drops to zero when the CS is presented repetitively with absence of the US or the RS. The zero level may be obtained in some cases only after long repetition, and in others there may be no evidence that ex-

inction will ever take place, even with endless repetition of the CS alone.

The fact that the US or the RS is required in order to set up and maintain a CR and that its absence results in experimental extinction has led to the inference that acquisition and experimental extinction are inversely related. In fact, resistance to extinction has frequently been used as a direct measure of the strength of an acquisition. Studies of extinction have also been undertaken to help determine the role of reinforcement in conditioning. Some have found measures of resistance to extinction to be directly related to measures of acquisition, but others have not. Even though the experimental results are in conflict and no generalizations may be arrived at safely, a few of the representative studies will be discussed here because of the theoretical importance of the problem.

Hunter (1935) reported that, for instrumental running CR's in rats, there is a negative correlation between the number of trials to reach the criterion of acquisition and the number of trials for extinction. Youtz (1938a) obtained a correlation (ρ) of -0.77 between the time required by rats to make 40 bar-pressing CR's and trials to an extinction criterion, when extinction occurred immediately after acquisition. In a second study (Youtz, 1938b), where there was a 24-hour interval between the last acquisition trial and the beginning of the extinction training, this same correlation turned out to be 0.69. However, in both these studies resistance to extinction was greater for animals given 40 acquisition trials than for animals given 10 acquisition trials. Ellson (1938) obtained a correlation (r) of -0.14 between the time required to make 30 instrumental reward CR's and the number of responses to the extinction criterion. Williams (1941) reported correlations (r) between measures of acquisition and resistance to extinction that are not significantly different from a zero correlation. Rohrer (1947) found correlations (ρ) of 0.70 and 0.46 between the

mean latency of an instrumental reward CR at the termination of acquisition training and the number of trials required to reach the extinction criterion for two groups of rats that were given similar training for acquisition but that were extinguished with massed and distributed practice, respectively. Brogden (1949) obtained a correlation (r)

and the period of food deprivation at the start of the experiment was 24 hours. The slope of the extinction curves appears to increase as the number of practice trials was increased, indicating a decrease in resistance to extinction with increase in training for acquisition. Mote and Finger (1943) gave groups of rats 4, 8, 16, and 32 acquisition

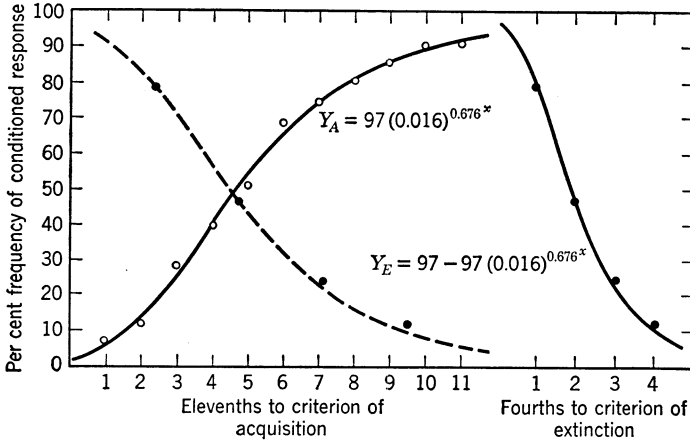

FIG. 8. Vincent curves of acquisition and extinction of an instrumental avoidance response in dogs. The open circles represent the mean per cent frequency of CR for a group of 30 dogs for the appropriate fraction of training at the rate of 20 trials per day to a conditioning criterion of 100 per cent. The mean number of test periods required for the group to reach the criterion was 11.37 ($\sigma_M = 0.41$). The filled circles represent mean per cent frequency of CR for the same animals during extinction training at the rate of 20 trials per day to the response criterion of 0 per cent. The mean number of test periods to the extinction criterion was 4.30 ($\sigma_M = 0.79$). The solid lines represent the equations shown on the graph for acquisition and extinction. The equation $Y = vgL^x$ was fitted to the empirical data by Dr. Don Lewis. The broken-line extinction curve is drawn on the same extent of abscissa as that for the curve of acquisition in order to show the inverse relation between the two curves. (Brogden, 1949.)

not significantly different from zero between the number of trials to the criterion of acquisition and the number of trials to the criterion of extinction for an instrumental avoidance CR in dogs. However, in this same study, the form of the Vincent curve for acquisition showed an almost perfect inverse relation to that of the Vincent curve for extinction (see Fig. 8).

Mote (1944) found no difference in the extinction scores for groups of rats that had been given 3, 6, 12, 18, and 24 practice trials for acquisition of an instrumental reward CR (running). Acquisition and extinction were carried out in a single experimental session,

trials and measured resistance to extinction 24 hours later.* There were no reliable differences in extinction among the four groups of animals.

* The interval of time between the acquisition of a CR and the measurement of extinction may be a critical factor since it is the variable manipulated in retention studies. However, the high degree of retention of CR's after long periods of no practice makes this seem unlikely (see section on retention of CR's). Studies of resistance to extinction after relatively long periods of time offer little help in resolving the differences obtained in resistance to extinction between a brief interval and a 24-hour interval. Youtz (1938b) reported greater resistance to extinction of an instrumental reward CR in rats after 15 days than after 1 day. The difference in favor of the

In a study where there was no interval between acquisition and extinction, Finger (1942*a*) found resistance to extinction to be greater for 8 acquisition trials than for 16. In a second experiment, with a 24-hour interval between acquisition and extinction (1942*b*), he found no difference between the extinction following 8 and following 16 acquisition trials. Lawrence and Miller (1947) repeated Finger's first experiment but altered the apparatus so that the start and goal boxes were clearly distinguishable. Resistance to extinction was found to be significantly greater for the 16-trial group than for the 8-trial group. Williams (1938) gave four groups of rats 5, 10, 30, and 90 acquisition trials on a bar-pressing instrumental reward CR and then carried out extinction. Resistance to extinction was found to increase as the number of acquisition trials increased. Perin (1942) obtained similar results for groups of rats given 5; 8, 16, 30, and 70 acquisition trials. Finan (1940) gave groups of rats equal practice on acquisition of an instrumental reward CR, but different periods of food deprivation (1, 12, 24, and 48 hours) prior to the acquisition training sessions. Resistance to extinction turned out to be significantly greater for the 12-hour group than for the 1-hour group but did not differ reliably for the groups with other periods of deprivation.

Another measure of the relation of acquisition to extinction is the number of trials for reacquisition following experimental extinction. In general the greater the extinction training or decrement, the more trials are required for reacquisition (Pavlov, 1927, p. 59; Finch and Culler, 1935; Brogden, Lipman, and Culler, 1938; Hilgard and Marquis, 1935; and Skinner, 1938, pp. 85ff.).

15-day interval was greater for animals given 40 acquisition trials than for animals given 10 trials. Brogden (1940*a*) found a high degree of resistance to extinction of instrumental reward and instrumental avoidance CR's in dogs after an interval of 6 months. The animals with instrumental reward CR's showed significantly less resistance to extinction than animals with instrumental avoidance CR's.

On the other hand, the reliability of measures of experimental extinction is usually less than the reliability of measures of acquisition. Individual differences in extinction time and extent are large, and, as has been mentioned earlier, instances of failure to obtain experimental extinction of CR's have been reported. Because of the diversity in the results, experiments in which a measure of experimental extinction is the dependent variable are treated as experiments on extinction, even though the inference may have been made that resistance to extinction is a positive measure of the strength of a CR or the magnitude of its acquisition.

Many studies have been reported that show experimental extinction to be a function of the conditions of reinforcement during acquisition or during extinction. The relative frequency of reinforcement during trials for acquisition may influence the course of experimental extinction. Finger (1942*a*) found that a mean of 15.2 trials was required to reach the criterion of extinction of an instrumental reward CR by rats given 16 acquisition trials with 100-per-cent reinforcement (group I), whereas a group (II) given 16 acquisition trials with 50-per-cent random food reinforcement required 27.1 trials to reach the extinction criterion. A third group (III) which was given 8 acquisition trials with 100-per-cent reinforcement reached the criterion in 23.8 trials. The confidence levels of the differences between groups I and II, I and III, and II and III are 2 per cent, 8 per cent, and 57 per cent, respectively. It is not clear from this study to what extent the influences of relative frequency of reinforcement, absolute number of practice trials, and absolute number of reinforced trials are separate. Finger (1942*b*) repeated the study with a 24-hour interval between the termination of acquisition and the start of extinction. No reliable differences in experimental extinction were obtained for the three different conditions of reinforcement. Skinner (1938, pp. 118ff.), Humphreys (1943), and Mowrer and Jones (1945) reported data on

the extinction of instrumental reward CR's in rats that were conditioned or reconditioned under different relative frequencies of reinforcement. These authors interpret their results as showing a greater resistance to extinction for relative frequencies of reinforcement less than 100 per cent.

Essentially the same problem was studied by Brogden (1939c) with a different technique. Conditioning of a salivary CR by classical training, of a flexion CR by classical training, and of a flexion CR by instrumental reward training was established in three groups of 4 dogs each. Frequency of CR was measured for each group, after the criterion of acquisition had been met, for 5 test periods each at 100-, 80-, 60-, 40-, and 20-per-cent reinforcement. The sequence in which the fractional levels of reinforcement were given was balanced. The results of this experiment are shown in Fig. 9. For the two food-reinforced CR's there is a progressive decrement as frequency of reinforcement decreases. For the shock-reinforced group, the CR shows a slight increment in frequency of CR as frequency of reinforcement is decreased to the 40-per-cent level, with a drop taking place at the 20-per-cent level. Even at the 20-per-cent level, frequency of CR is not less than 80 per cent for any one of the three groups. The results of other studies indicate that the extinction of any one of the three CR's might be expected to be complete or nearly so by the end of 100 trials of 0-per-cent reinforcement. Thus the critical frequency of reinforcement for experimental extinction probably lies between 20- and 0-per-cent reinforcement.

The period of food deprivation at the time the measure of extinction is made affects the rate and amount of extinction of instrumental reward CR's. Over a fairly wide range, increase in the period of food deprivation increases resistance to extinction (Finger, 1942a, b; Perin, 1942; Rohrer, 1947; Sackett, 1939; and Skinner, 1938, pp. 380ff.). Koch and Daniel (1945) showed that extinction takes place most rapidly when the animals

have been satiated with the food used for reinforcement just prior to the extinction tests. However, for dogs Brogden (1942) found no difference between the extinction of an instrumental reward CR that was extinguished immediately following satiation and the extinction of a CR extinguished after

FIG. 9. The effect of relative frequency of reinforcement upon the frequency of CR. Each point is the mean frequency of CR for 4 animals for 5 test periods of 20 trials. The acquisition of the CR for each of the 12 animals was brought to the criterion of 100 per cent. Four additional test periods of training at 100-per-cent reinforcement were given before the relative frequency of reinforcement was altered. Only the differences in frequency of CR between 100-per-cent reinforcement and 40 and 20 per cent are statistically significant for the group with the salivary CR. None of the differences in frequency of CR for the group with the classical flexion CR are statistically significant. For the group with an instrumental reward flexion CR, only the difference between 100- and 20-per-cent reinforcement is significant. (Brogden, 1939c.)

18 to 20 hours of food deprivation. The CR of this study was developed initially by instrumental avoidance training and was then converted to instrumental reward conditioning by the substitution of a food RS for the shock US. This may account for the lack of difference in rate of extinction.

When resistance to extinction is shown to increase with an increase in the period of food deprivation, it should be least for zero deprivation (satiation). The above studies have not dealt with periods of deprivation greater than 30 hours. Finch (1938) has shown that the magnitude of both the

salivary CR and UR of the dog increases with increase of the period of food deprivation up to 72 hours, but decreases again when the period is increased to 96 hours. This suggests that resistance to extinction will reach a maximum at some point beyond 30 hours and then decrease with further increase in the period of deprivation. Kendler (1945) studied resistance to extinction of an instrumental reward CR in rats under a constant food deprivation of 22 hours but with varying degrees of water deprivation. Resistance to extinction increases as the period of water deprivation increases through 0, 3, 6, and 12 hours. From the maximum resistance to extinction at 12 hours, the curve falls at 22 hours of water deprivation to a level below that for the 0-hour deprivation group.

The rate at which extinction takes place may be altered by a special condition of reinforcement. Brogden, Lipman, and Culler (1938) showed that extinction of an instrumental avoidance CR is speeded up when electric shock is given to the thorax of a dog for each flexion CR made to the CS during extinction. Extinction by this procedure takes place with only a few applications of thoracic shock and at about the same rate as that required for reconditioning with pedal shock. Skinner (1938, pp. 151ff.) reported a similar effect on extinction of the bar-pressing CR in rats when the mechanism is set so that pressure on the bar makes it jump upwards. The initial reaction of the rat to the "slapper" is an increase in the rate of CR. This is followed by a rapid extinction. Mowrer and Jones (1943) found that rate of extinction for an instrumental reward CR in rats increases as the pressure required to depress the bar is increased from 5 to 42.5 to 80 grams. All three groups of animals were trained to the same level of acquisition of CR for pressures of 5 and 80 grams. Solomon (1948) reported the rate of extinction of an instrumental jumping response in rats to be more

rapid for a jump of a long distance than for a jump of a short distance.

That stimulus components involved in reinforcement during acquisition of a CR may acquire secondary reinforcement was discovered in studies of resistance to extinction. Finch and Culler (1935) demonstrated that the presence of a buzzer during extinction training increased resistance to extinction of an instrumental avoidance CR in dogs, during the acquisition of which the buzzer sounded just after the CS. Skinner (1938, pp. 82ff.) showed that the click of the food-vending machine increases the resistance to extinction of instrumental reward CR's in the rat. There are secondary reinforcement situations that maintain the CR at full strength. Elimination of the US or RS results in no negative transfer or extinction.

Experimental extinction is affected by the distribution of the extinction trials. Pavlov (1928, p. 85) stated that the massing of trials produces a more rapid extinction than an equivalent number of distributed trials. However, Porter (1939) obtained no difference in the rate of extinction of an instrumental running CR in rats for three different intertrial intervals. No studies have been reported in which a distributed condition produced a more rapid extinction than some less distributed condition. Hilgard and Marquis (1935) found that massed practice produced more extinction of an eyelid CR in dogs than did distributed practice. Rohrer (1947) reported the extinction of an instrumental reward CR in rats to be more rapid when the interval between extinction trials was 10 seconds than when it was 90 seconds. Acquisition in both cases was based upon 90 training trials. The difference in favor of the massed group was greater when extinction was carried out after 30 hours of food deprivation than when the period of deprivation was only 6 hours. Less clear results were obtained for groups of animals given only 10 acquisition trials but with the same intervals between trials and the same periods of food deprivation. Gagné (1941a) found

a more rapid extinction of a reward CR in rats as the interval between trials was decreased. These results are complicated by an increase in the amount of the food RS with increase in the interval between practice trials.

The interval of time between the end of acquisition and the beginning of extinction appears to be a critical factor in resistance to extinction of instrumental reward CR's. Comparisons of immediate extinction with extinction after 24 hours have shown no difference, greater resistance for immediate extinction, and greater resistance for extinction after 24 hours. The diverse results of the currently available studies are complicated by differences in other variables. Time interval in these studies may not be independent of period of food deprivation. The number of acquisition trials, the relative frequency of reinforcement, and the method of measuring resistance to extinction also appear to be important complicating variables.

There are other variables that affect experimental extinction. Increase in the time between the CR and the RS during instrumental reward training, after acquisition has taken place, results in some experimental extinction (Brogden, 1941; Skinner, 1938, p. 73). When a CR has been extinguished, similar CR's show decrement in response, even though there has not been specific extinction training (Pavlov, 1927, p. 54; Ellson, 1938). This is called secondary extinction. Higher-order CR's are less resistant to extinction than are first-order CR's (Brogden and Culler, 1935). Delay and trace CR's are much less resistant to extinction than simultaneous CR's (Pavlov, 1927, 1928); the pseudo CR is less resistant to extinction than the simultaneous CR (Harris, 1943); and generalized CR's extinguish more rapidly than do primary CR's (Liddell, James, and Anderson, 1934; Brown, 1942). Walker (1942) has shown that extinction of an instrumental reward CR is delayed if a tone that was the positive stimulus in a dis-

crimination habit established after acquisition of the CR is present during extinction training. Similar results were obtained by Estes (1948).

Alterations of US or RS not producing extinction. Some circumstances involving change in the US or RS result either in no decrement of a CR, or in a temporary decrement followed by full recovery. Within limits that are not well defined, it is possible to change the food US or RS without appreciably altering the CR. Change in the magnitude of the food US has been shown by Gantt (1938) to be directly related to the magnitude of both the CR and UR, but such change did not affect frequency of CR. Brogden (1939a) found there was only a temporary decrement in an instrumental flexion CR in dogs when the shock US was replaced in the training procedure by a food RS. Once the transfer was made from shock to food reinforcement, the response level in dogs given this treatment was the same as that in dogs continued on instrumental avoidance training. Incidental observations have indicated that, once CR's based on a shock US have reached a criterial level of acquisition, the intensity of the shock may be varied considerably without affecting frequency of CR. Kellogg (1941) has shown that, once an instrumental avoidance CR has been acquired, if it is to be kept at a constant magnitude, the intensity of the shock US must be decreased within the test period, and the average intensity during the test period must be increased from test period to test period.

Reversal of experimental extinction. A terminal level of extinction represents a reference point in negative transfer of a CR by which positive transfer may be measured. Pavlov (1927, 1928) reported four procedures that are effective in reversing the decrement in CR obtained by extinction training. These procedures have been found effective for instrumental CR's as well as for CR's established by classical training. If the animal is removed from the experi-

mental situation at the close of extinction training and returned at a later time, the CR to the CS alone will be of greater magnitude than that to the CS alone at the end of the previous extinction training period. Pavlov named this phenomenon spontaneous recovery. Spontaneous recovery occurs only to the initial trials of the test period. Continuation of extinction trials soon results in a level of zero CR. Spontaneous recovery may be complete in the case of well-established CR's. More often the extent of recovery is small. In general, the extent of spontaneous recovery is proportional to the extent of experimental extinction.

The second procedure for reversing the decrement of extinction Pavlov called disinhibition. The CR rises above the extinction level when the animal is presented with a novel stimulus. Disinhibition is a temporary positive transfer, and its magnitude is a function of the extent of extinction and the intensity of the disinhibiting stimulus.

The third method involves presentation of the US (or RS) alone for a few trials. Then, when the CS is presented alone, it evokes a CR. Recovery of the CR is temporary, for continued extinction training results in a zero level of CR. Note that this procedure is exactly the same as the training procedure used initially for elaboration of the pseudo CR.

The fourth method for reversing experimental extinction is reintroduction of the US or RS to the training procedure. This return to the conditions of original training for acquisition results in a rapid recovery of the CR to its pre-extinction level, and this level is maintained as long as the US or RS is present in the training procedure.

The reestablishment of a CR after extinction to the zero level always takes place in less time and with fewer trials than were required for the initial acquisition. Although Pavlov (1927, p. 59) reported that reacquisition is directly proportional to the extent of extinction, this problem has received little investigation. Pavlov's statement was based

in part upon the fact that the magnitude of spontaneous recovery decreases with increase in the amount of extinction training. This relation holds when extinction training is continued beyond the zero level of CR. Brogden, Lipman, and Culler (1938) showed that the number of trials required for reacquisition of an instrumental avoidance CR in dogs is greater when extinction training is carried beyond the zero level than when reacquisition training is started immediately after the zero level of CR has been reached. These workers also showed that during "silent" extinction the response of the forelimb to the CS was one of extension (the CR was flexion) and that the amplitude of the extension response to the CS increased as the extinction training increased. However, with continued training for extinction beyond zero, reacquisition was found to be more rapid than the original acquisition. When alternate extinction and reacquisition training was given and the extinction training included trials beyond the zero level, the effect of these additional extinction trials on reacquisition eventually disappeared. Brogden (1940c) demonstrated that reacquisition of an instrumental left forelimb flexion CR in dogs takes place as rapidly after extinction when shock is applied to loci other than the left forepaw as when shock is applied to the left forepaw. For any given locus of electric shock, left forelimb flexion to the CS was alone instrumental in shock avoidance. It was further shown in this study that continuation of these conditions of reinforcement maintained the frequency level of CR as effectively as did shock to the left forelimb, flexion of which was the CR. This effect of change in locus of application of US is an example of the transfer phenomenon called generalization. Brogden suggested that this particular phenomenon be called incentive generalization to distinguish it from stimulus generalization and response generalization.

Generalization. Pavlov (1927, pp. 110ff.) early found that, when a CR was elaborated

to a specific CS, similar stimuli, neutral before formation of the CR, had become capable also of evoking the CR. This phenomenon he called generalization. In the present chapter, the term stimulus generalization (Hilgard and Marquis, 1940) is used for this phenomenon and also for the transfer of a CR that occurs when a similar stimulus to the CS is substituted for it in a continuation of acquisition training. In the latter situation the CR is rapidly built up to the level evoked by the previous CS. Tests of stimulus generalization therefore may be made by either acquisition or extinction training. Stimulus generalization has been studied more often by means of extinction training than by the acquisition method. Acquisition takes place so rapidly to the transfer CS that this latter method provides a relatively insensitive measure of stimulus generalization. Although measurement of stimulus generalization by extinction training is more sensitive, the results are complicated by secondary extinction. Only a small number of trials may be given for each stimulus in tests for sensory generalization. A larger number of trials results in experimental extinction of the CR, both to the generalized stimuli and to the primary CS. It is not possible after a few test trials of sensory generalization to reinforce the primary CS, since reinforcement of the primary CS and nonreinforcement of the generalized stimuli constitute the conditions for discrimination learning. In many situations generalization and discrimination are so measured that they are perfect inverse measures of each other.

Because of the inherent difficulties of the methods for studying sensory generalization, precise experimental information is difficult to obtain. Stimulus generalization occurs most readily for stimuli within a given sensory mode, but it also takes place across sense modalities. Evidence for stimulus generalization of many of the characteristics of stimuli within sensory systems, and for most sensory modes to the others, has been ob-

tained by Pavlov and his co-workers. Generalization curves based upon extinction tests have been reported by Anrep (1923) for the salivary response of dogs to tactile stimuli at varying distances from the locus of the CS; by Brown (1942) for measures of an instrumental running CR to visual stimuli of varying brightness from that of the CS; and by Blackwell and Schlosberg (1943) for an instrumental running CR to tones of different frequency from that of the CS. The curves in these studies show less response to generalized stimuli, the greater the difference between the CS and the generalized stimuli. Beritoff (1924) reported that generalization is greater early in acquisition training than later. Brogden (1939*b*) found cross-modal generalization to be enhanced by presenting a sound and a light together, prior to using one of these as the CS for an instrumental avoidance response. This result may be interpreted as evidence of sensory conditioning.

The term response generalization refers to transfer where there is alteration of the CR. In training for acquisition, the method of measurement may permit considerable variation in the CR. For example, in the acquisition of a bar-pressing response in the rat, any response that results in depression of the bar is recorded as a CR, whether it results from movements of the right or left forelimbs, the head, or the body. Response generalization thus occurs to some extent during the acquisition training of any CR. Arnold (1945) showed that variability in the magnitude of a bar-pressing CR in rats decreases during acquisition. When only a given magnitude of the CR is reinforced, variability in magnitude of the CR is reduced further. If, after acquisition has taken place, the CR is experimentally prevented from occurring, a similar response may be elicited by the CS. Bekhterev (1932, p. 216) reported that, when a dog's limb to which shock was applied during acquisition is tied down so that the flexion CR cannot occur, presentation of the CS elicits flexion of some

other limb. Lashley (1924) found that a manipulative performance was carried out by a monkey with the other hand, when the hand used in acquisition became paralyzed following brain surgery. Kellogg and Walker (1938*a, b*) studied bilateral transfer of CR in the dog by first conditioning the right forelimb and then giving acquisition training for the left forelimb. Positive bilateral transfer was found; acquisition of the left-forelimb flexion CR took place more rapidly than did the original acquisition of the right-forelimb CR. During acquisition training of the left forelimb, the right-forelimb CR became extinguished in about half the animals. The other animals continued to make right-forelimb CR's as well as left-forelimb CR's to the CS. During the period of left-foot training, these animals made more right-foot CR's to the CS than left-limb CR's. Thus CR's of both forelimbs occurred at the end of training. Kellogg and Walker called this latter phenomenon ambiguous conditioning. James (1947) found that ambiguous conditioning could be resolved by adding a work factor to the response of the limb involved in the transfer conditioning. Brogden (1940*c*) found transfer of conditioning to the right front, right hind, and left hind limbs to take as many trials as the original acquisition of the left-forelimb CR. However, there was an interval between the acquisition of the left-forelimb CR and the acquisition of the transfer CR's during which the left-forelimb CR was extinguished, reconditioned, and maintained for 100 trials. This may account for the failure to obtain positive transfer. In the transfer training, ambiguous conditioning as described by Kellogg and Walker was found with some of the animals.

Generalization of a CR may involve both stimulus and response generalization. Youtz (1939) reported the positive transfer of an instrumental reward CR in rats from pressing a horizontal bar to pressing a vertical bar and vice versa. Williams (1941) found transfer from a horizontal to a vertical bar

to be negative in rats when 7 trials were given on the horizontal bar, and positive when 18 or 45 acquisition trials were given. Graham (1944) reported negative transfer in the acquisition of an instrumental avoidance CR in dogs that was preceded by the acquisition of another instrumental avoidance CR. However, the US of the first CR was made the CS for the second CR. This factor may be responsible for the negative transfer. After Graham's animals had been given the training just described, the CS for the first CR was presented and it evoked the second CR. This latter transfer is a chainlike reaction that was originally studied by Miller and Konorski (1928*b*). Transfer that involves change in the general conditions under which the CR was established has been reported by James (1941). Positive transfer was found for flexion conditioning of dogs in a laboratory room to subsequent performance of this response in the kennel enclosure.

Retention of CR's

There has been less study of the retention of CR's than of their acquisition and transfer. Experiments on this topic have dealt almost wholly with the time interval between acquisition and the measurement of retention. There are no studies comparable to the retroactive-inhibition type of experiment. Studies that involve comparison of performance at a terminal stage of acquisition with performance under altered conditions have been treated already under transfer of CR's, even though such studies might be considered as experiments on retention. Retention of CR's has been measured by the savings method and by the method of reproduction. Other experimenters have studied retention in terms of resistance to extinction. The validity of this procedure for measuring retention of a CR depends upon the assumption of a high degree of positive relation between measures of acquisition and measures of resistance to extinction. The uncertain nature of this relation has led

to the discussion of such studies under the topic of experimental extinction, since this phenomenon was the dependent variable. However, the first few trials of an extinction test provide a measure of retention by the method of reproduction, and these studies can be treated under the topic of retention

FIG. 10. Retention by rats of an instrumental reward running CR as a function of interval of time between acquisition and retention. Retention following conditioning to a criterion of three consecutive CR's with a latency of 5 seconds or less is plotted for two measures: (1) number of trials of reacquisition to attain criterion of three consecutive CR's with latency of 5 seconds or less; and (2) the logarithm of the latent period of the CR on the fourth trial of reacquisition. Each point is the mean obtained from 4 animals. (Gagné, 1941b.)

if results are presented separately for the initial extinction trials.

The degree of retention of a CR is undoubtedly related to the extent of its acquisition, but systematic study of this relation for all varieties of CR has not been made. There is ample evidence that a well-established CR will be retained for long intervals of time. Liddell, James, and Anderson (1934) reported considerable retention after an interval of 2 years of a flexion CR in sheep established by classical training. Wendt (1937) found a high degree of retention after an interval of 2½ years of a flexion CR in a dog elaborated by instrumental

avoidance training. Good retention of CR's after 30 days has been reported by Hunter (1935) for instrumental avoidance CR's in rats, by Kellogg and Wolf (1939) after 6 months for instrumental avoidance CR's in dogs, and by Hilgard and Marquis (1935) after 6 months for classical eyelid CR's in dogs. Gagné (1941b) measured retention of an instrumental reward CR in rats after intervals of 3, 7, 14, and 28 days, following acquisition of the CR to a criterion of latency of CR of less than 5 seconds on 3 consecutive trials. Prior to being brought to this criterion, all animals were given 15 acquisition trials and extinction training until they met the extinction criterion of one CR with a latent period of 3 or more minutes. The results of this experiment, given in Fig. 10, show that retention decreases as the interval of time between acquisition and the measure of retention increases.

DISCRIMINATION LEARNING

Several distinctions may be made among the different kinds of discrimination learning. It was pointed out earlier that the stimuli to be discriminated may be presented to the animal either simultaneously or successively. With simultaneous presentation, the training method for acquisition is comparable to the instrumental reward or instrumental escape training of CR's. Response to the positive stimulus is reinforced by means of an RS; response to the negative stimulus is not reinforced. When there is successive presentation of stimuli, the training method is comparable to the classical or instrumental avoidance training of CR's. By this method, training for acquisition of a CR to the positive CS is usually the first step.* Once the CR is well estab-

* The point of view may be taken that, during the acquisition of a CR, a discrimination is being established between the presence of the CS and its absence. In the early stages of acquisition of a CR, "spontaneous" CR's occur during the intervals between trials of the training stim-

lished, the negative CS is presented alternately or in random order with the positive CS. The US is present on trials of the positive CS and absent on trials of the negative CS. These two procedures result in different baselines from which the course of acquisition is measured. In terms of frequency of response to the positive and negative stimuli, the zero level for discrimination with simultaneous presentation of stimuli is 50 per cent.* With successive presentation the zero level is not known because the positive CS has been brought to the 100-per-cent level through prior training, and there is positive transfer of CR to the negative stimulus (stimulus generalization). However, the criterion for the acquisition of discrimination learning is the same for both procedures: a frequency of response near 100 per cent for the positive stimulus and near 0 per cent for the negative stimulus.

There is usually a difference in the conditions of reinforcement for acquisition involving simultaneous and successive presentation of the positive and negative stimuli. Discrimination learning based on simultaneous presentation of stimuli involves heterogeneous reinforcement of response, and successive presentation involves homogeneous reinforcement of response. Because Pavlov (1927, pp. 117ff.) gave the name differentiation to discrimination that involved successive presentation of positive and negative stimuli and also homogeneous reinforcement, the term differentiation training is used in this chapter to refer to the latter pro-

cedure. This has been taken as support for the view stated above.

* In many discrimination training situations, the initial level of response has been found to differ from 50 per cent. Since animals frequently show an initial "preference" for one of the two stimuli, it is customary to run initial control trials to test for this phenomenon. If a proportion of response significantly different from 50 per cent is found, the group may be split in two with the positive and negative stimuli reversed and animals assigned to the subgroups so that the effect of initial bias is balanced.

cedure.† The term discrimination training is applied to discrimination learning acquired with the simultaneous presentation of the positive and negative stimuli, and heterogeneous reinforcement.

In the prosecution of discrimination training, two alternative procedures may be used, correction and noncorrection. When the correction procedure is used, if the first response of the animal is to the negative stimulus, the experimenter permits it to continue responding until response is made to the positive stimulus. The response to the positive stimulus brings forth the RS. The trial is then terminated. If the first response is to the positive stimulus, the RS follows immediately, and the trial is terminated. With the noncorrection procedure each trial is terminated immediately after the animal responds to either the positive or negative stimulus. If the response was to the positive stimulus, the RS is presented; if to the negative stimulus, the RS is withheld.

The noncorrection procedure provides the more uniform measure of the trials involved in acquisition. All trials are equal in the sense that the animal makes a single response in each. With the correction method the nature of the trial varies, for the animal may make several responses to the negative stimulus before the trial is terminated. The number of responses is not under the control of the experimenter, and it has no definite relation to the number of stimulus presentations or to the duration of the stimulus presentations. The conditions of reinforcement and nonreinforcement from trial to trial are differential only in terms of delay of reinforcement by the RS. The definition of error and correct response is poor, and there is less control over the amount of time consumed by the animal

† Differentiation training has been modified to provide a more efficient means of studying sensory acuity by making the positive stimulus one that changes within its duration and the negative stimulus one that does not so change (Brown, 1936; Kappauf, 1943).

during an acquisition trial. With the correction procedure, however, consistency from trial to trial is maintained in the sense that a trial always terminates with response to the positive stimulus and attainment of the RS.

Discrimination learning is usually carried out with two stimuli, one positive and one negative. From a practical standpoint it is difficult to increase the number of stimuli used in differentiation training because the stimuli must be presented successively. With discrimination training it is much easier to present more than two stimuli simultaneously. The number of positive stimuli, the number of negative stimuli, or both may be increased. Another variation of discrimination training makes use of two positive stimuli to which different responses are made. This procedure may also be used in differentiation training.

Acquisition of Discrimination Learning

The response. Any response that can be conditioned may be used in discrimination learning, since it is the degree of the absence of this response to the negative stimulus, relative to the degree of its presence to the positive stimulus, that is the measure of discrimination learning. The response itself has rarely been the independent variable. That it may be an important variable is shown by the results of Muenzinger and Newcomb (1936) and of Honzik and Tolman (1938). A black-white discrimination was acquired by rats more rapidly when the response was jumping a gap to the stimulus card than when the response was running across an elevated platform. Grice (1948) obtained a more rapid acquisition of a black-white discrimination in rats when the responses to the positive and negative stimuli were of different kinds than when a single response was used. Thompson (1944c) obtained similar results in a different discrimination training situation with rats.

The acquisition of a CR to the positive CS prior to differentiation training may re-

sult in a more rapid acquisition of discrimination than if differentiation training is started when the animal is naïve to both the positive and negative stimuli. Preliminary training is sometimes given with the US or RS, and some workers have assumed that this adaptation procedure facilitates the acquisition of a discrimination. Although this assumption has not been put to an adequate experimental test, the evidence for the effect of such preliminary training on the acquisition of CR's is equally relevant to the acquisition of discrimination learning.

The definition of the response is an important variable in the acquisition of discrimination learning as well as in the acquisition of other kinds of performances. Marcuse and Moore (1946) showed the factor of response definition to be important in the measurement of discrimination learning by the pig when differentiation training is used. Another variant of definition of response has received considerable study in the acquisition of discrimination learning. Orienting responses to the positive and negative stimuli frequently take place prior to the occurrence of differential responses. This kind of responding was called vicarious trial and error by Muenzinger (1938) and was abbreviated to VTE by Tolman (1938). Many investigators have noted the occurrence of VTE during discrimination training.* Girden (1938) reported its presence in auditory differentiation training of dogs. When VTE is recorded during discrimination learning of rats, its frequency is positively correlated with the frequency of response to the positive stimulus (Muenzinger, 1938), and it increases with increase in acquisition training

* VTE might be expected to play a similar role in the successive discriminations that must be made by the animal in the acquisition of a maze performance. Jackson (1943) found this not to be the case. The frequency of VTE in maze learning by rats was found to be directly related to errors rather than to correct responses. Tolman and Ritchie (1943) trained Jackson's animals on a black-white discrimination and found the usual negative correlation between VTE and errors.

to a maximum at the point where discrimination begins to appear and drops out when the discrimination is well established. It is more likely to occur on those trials where response is made to the positive stimulus than where response is made to the negative stimulus (Dennis, 1930). In general, independent variables that facilitate the acquisition of discrimination learning also increase VTE (Muenzinger, 1938; Tolman, 1938).

The US and RS. Differentiation training involves appropriate application of the US to maintain a CR to the positive CS and to extinguish the generalized CR to the negative CS. Discrimination training may be considered to involve the simultaneous development of a CR to the positive CS, and the generalization and subsequent extinction of the CR to the negative CS. Therefore any effect of the US or RS on either the acquisition or extinction of a CR should influence the course of discrimination learning. The kind of RS appears to affect the rate of discrimination learning, but experiments purporting to measure such differences are hard to evaluate because of the difficulty of equating the intensity of the different RS's. However, it is clear that the acquisition of discrimination learning is affected by the magnitude of the RS.

Dodson (1917) reports that the rate of acquisition of a brightness discrimination in rats increases when the electric shock US, given for response to the negative stimulus, is increased in intensity, up to a point. Beyond this point there is a decrease in acquisition with further increase in shock intensity.

The effect of a food RS has been studied directly by varying the magnitude, and indirectly through variation of the period of food deprivation. Grindley (1929) found the acquisition by chickens of a spatial discrimination to be more rapid for a large food RS than for a small one. Wolfe and Kaplon (1941) compared the rate of acquisition of a spatial discrimination for three groups of chicks that were given, respectively, for each

correct response, 1 one-quarter grain of popcorn, 1 grain of popcorn, and 4 one-quarter grains of popcorn. The rate of acquisition increased in the order in which the conditions of reinforcement are listed. Their results show that acquisition increases with the amount of the food RS, and with the amount of the food RS coupled with the amount of consummatory activity (4 one-quarter grains require 4 pecks). Dodson (1917) found an increase in the rate of acquisition of a brightness discrimination in rats as the interval of food deprivation was increased from 24 to 41 hours. But there was a slower rate of acquisition for 48 hours than for 24 hours of deprivation. Kendler (1947) reported that a greater degree of spatial discrimination learning was attained by rats given discrimination training under 22-hour food and water deprivation than that shown by animals given equivalent training but tested under food and water satiation.

The mode of application of the RS influences discrimination learning. Muenzinger (1934) found no difference in the acquisition of a black-white discrimination in rats when electric shock was given following response to the negative stimulus for one group and to the positive stimulus for another group, and when both groups received a food RS following response to the positive stimulus. Muenzinger, Bernstone, and Richards (1938) repeated this experiment with a control for the amount of shock given in the two conditions and found acquisition to be greater for wrong-response shock than for right-response shock. Acquisition of the discrimination by animals shocked for the right response was greater than that for animals given only the food RS for right response. A study by Drew (1938) confirmed these results.

Muenzinger and Wood (1935) showed that the facilitating effect of right-response shock does not occur when shock is given prior to the choice of response to the positive stimulus. Fairlie (1937) tested shock right

and shock wrong as the animal was about to enter the appropriate runway and found little acquisition of a black-white discrimination under these circumstances. However, the shock-wrong group showed significantly greater acquisition than the shock-right group. Wischner (1947) performed the shock-right, shock-wrong experiment on acquisition of discrimination learning by rats, but he used the noncorrection method of food reinforcement. The shock-wrong group was superior to both the shock-right and the no-shock (food RS only) groups. The latter two groups showed no significant difference in acquisition. Comparison of Wischner's experiment with the other experiments of this type, all of which used the correction method, is virtually impossible because of the different definitions of trial and error inherent in the correction and noncorrection procedures. A controversy between Muenzinger (1948) and Wischner (1948) centered mainly on the interpretation of trial and error when the correction and noncorrection procedures are used.

A decrease in rate or amount of discrimination learning takes place with progressive increase in the interval of time between the response to the positive stimulus and application of the RS. Seward (1943), Grice (1942), and Spence and Grice (1942) demonstrated this relation in terms of the distance the rat must travel between the point at which a distance discrimination response has been made and the goal box. Wolfe (1934) varied the interval of delay between 0 and 20 minutes and found a progressive decrease in the acquisition of a spatial discrimination and of a black-white discrimination in rats as the interval increased. Perin (1943b), Perkins (1947), Grice (1948), Riessen (1940), and Thompson (1944b) obtained similar results with smaller intervals. Cowles (1937) reported a decrease in rate of discrimination learning by chimpanzees when there was an increase in the time interval at which the token RS could be exchanged for food. Williams (1929), Perkins (1947), and

Grice (1948) showed that secondary reinforcement may play a role in delayed reward, depending upon how the delay was enforced.

The relative frequency of reinforcement to the positive stimulus might be expected to affect rate of acquisition. Denny (1946) found no difference in the acquisition of a spatial discrimination for a group of rats given the RS on 50 per cent of the correct responses from that of a group given 100-per-cent reinforcement.

However, when (1) the component parts of the discrimination apparatus were re-oriented, (2) the delay boxes were changed from day to day, and (3) a gray goal box replaced the white goal box on trials when the RS was omitted, a group of animals given 50-per-cent reinforcement acquired the discrimination at a reliably slower rate than animals given 100-per-cent reinforcement. Skinner (1938, pp. 325ff.) reported that differentiation training of rats with periodic reinforcement results in the acquisition of discrimination learning at approximately the same rate as with 100-per-cent reinforcement. Moss and Harlow (1947) gave 8 monkeys, that had received previous training on discrimination and discrimination reversal, training trials on discrimination learning in which the positive stimulus was reinforced 0, 50, and 100 per cent of the trials. The 90-per-cent level of correct responses was attained with 1 trial of 0-per-cent reinforcement, with 2 trials of 50-per-cent reinforcement, and with 10 trials of 100-per-cent reinforcement. Although the results of this latter experiment may be complicated by transfer from previous training, it shows that the effect of partial reinforcement is complex. Brunswik (1939) and Heron (1942) showed that discrimination learning occurs when both the positive and negative stimuli are reinforced but at a differential frequency.

Positive and negative stimuli. Discrimination learning may apparently take place to stimuli over a wide range. The limiting

factor is the differential acuity of the animal for a given stimulus dimension. In fact, the difference threshold is measured in animals by means of discrimination-learning techniques.

Although discrimination learning may be acquired by animals to pairs of stimuli both within and across the sense modalities that they possess, the task of equating conditions makes it difficult to assess the effect of sense modality upon the acquisition of discrimination learning. Over a wide range of conditions investigators report that a spatial discrimination is much more readily acquired than are other kinds of discriminations. Training for other discriminations requires that the position of the stimuli be varied at random in order that the solution cannot be based on spatial cues.

To demonstrate that a discrimination response is based upon a stimulus difference within a single dimension requires that the stimuli differ only in this one respect. This condition is difficult to fulfill. In general it can be said that the rate of acquisition of discrimination learning decreases as the degree of difference between the positive and negative stimuli is decreased. When the degree of difference reaches the threshold value, discrimination fails.

Grether and Wolfe (1936) have shown that rate of acquisition of a brightness discrimination by rats is decreased as the number of pairs of stimuli used during training is increased. The results of their experiment are shown in Fig. 11.

Training procedure. No experiments have been found that test the relative efficiency of discrimination and differentiation training in the acquisition of discrimination learning. Such a test would contribute little to the understanding of discrimination learning, but it would have practical value for the animal psychologist who is interested in the acquisition of a discrimination response as the first step in the study of other problems.

There have been studies comparing the relative efficiency of the correction and non-

correction procedures in discrimination training, perhaps because of the prominent role reinforcement plays in some theories of learning. Since a trial by the correction method may include more than a single response, a lack of difference in acquisition

FIG. 11. Relation between acquisition of a discrimination response and variation in stimulus conditions during training. The slopes of the acquisition curves for four groups of rats are plotted against the number of brightness pairs used in discrimination training in which the brighter of the pair was always the positive stimulus. The vertical line through each point indicates the standard deviation of the slope. (Grether and Wolfe, 1936.)

would favor the noncorrection method. Comparisons of the two methods have resulted either in no difference or in a more rapid acquisition with the noncorrection method. Hull and Spence (1938) found no difference in the acquisition of a spatial discrimination response by rats, but the noncorrection method was superior in learning a reversal of the positive and negative stimuli. Seward (1943) reported the noncorrection method to be superior for the acquisition of a spatial discrimination response by rats, and Kalish

(1946) obtained similar results for the acquisition of a delayed response.

Although most studies of acquisition of discrimination learning have made use of only two stimuli, one positive and the other negative, the effect of additional stimuli has been investigated. Smith (1936) studied the effect of increase in the number of negative stimuli upon the acquisition of a visual form discrimination in cats. Three groups of animals were trained with one positive stimulus and either one, two, or three negative stimuli. In terms of trials to the criterion there was no difference between the groups given training with one and with two negative stimuli, but the group trained with three negative stimuli required fewer trials to reach the criterion. However, the correction procedure was used, and the groups did not differ from each other in terms of the number of errors made in reaching the criterial level. Nissen and McCulloch (1937*a*) found acquisition of discrimination learning by chimpanzees to be more efficient in terms of trials, time, and error trials (the correction technique was used) when nine negative stimuli were used than when only one negative stimulus was used. Since there were fewer total errors with the single negative stimulus, these authors carried out a second experiment (1937*b*) in which conditions were the same except that, when there were nine negative stimuli, the animal was permitted to make only a single response to a negative stimulus on each trial. The results of this experiment showed acquisition to be more rapid for the situation with nine negative stimuli than for that with the single negative stimulus.

Although discrimination learning to the position of stimuli is acquired readily, the introduction of more than one negative position decreases the rate of acquisition. In some cases it results in no evidence of acquisition. However, studies of this kind, spoken of as multiple-choice problems, show that the location of the positive stimulus relative to

the negative stimuli is a more important variable than the absolute number of negative stimuli (Yerkes, 1916, 1934; Spence, 1939). Other arrangements of more than two stimuli have been used in discrimination learning, but not under conditions that permit comparison of rate or amount of acquisition as a function of the number or the arrangement of the stimuli.

Other variables. From studies on acquisition of CR's, variables such as distribution of practice and secondary reinforcement might be expected to influence the acquisition of discrimination learning. Verplanck (1942) found slower acquisition of a black-white discrimination by rats for a massed practice condition than for a distributed condition. Pavlov (1927) used a condition of distributed practice in presenting trials of the positive and negative CS's during differentiation training. Although Pavlov did not say so, his use of this training procedure suggests, perhaps, that massed trials during differentiation training slows acquisition.

Secondary reinforcement has been shown to increase the rate at which acquisition takes place (Perkins, 1947; Grice, 1948; Denny, 1948). Wolfe (1936) and Cowles (1937) have shown that discrimination learning by chimpanzees may take place when a food token is the RS for response to the positive stimulus. Jenkins (1943*c*) found a space factor to operate in discrimination learning by chimpanzees. Discrimination performance was superior when the stimuli were at a distance of 1½ inches from the restraining cage than when they were 7½ inches away.

Transfer of Discrimination Learning

Perhaps the greatest interest in discrimination learning has centered in the problem of its transfer. Both positive and negative transfer can occur under a number of conditions, many of which are complex. Furthermore the transfer of discrimination learning is similar in many respects to the transfer

of CR's. Consequently the discussion of transfer of discrimination learning will be limited.

Experimental extinction. Once a discrimination response has been acquired, if the US or RS is removed from the training procedure, there is a progressive decrement in response to the positive stimulus similar to the experimental extinction of a CR (Farber,

say, by reversing the conditions of reinforcement. This training procedure may also be regarded as one of reacquisition of response to the previously negative stimulus, since at the time of initiation of discrimination training the negative stimulus elicited responses. Studies of this kind, and also those in which the reversal procedure has been changed back and forth, have resulted in

FIG. 12. Acquisition and extinction of a discrimination response. Each point is the mean for 4 animals given 25 trials each at the rate of 5 trials per day on a temporal discrimination. Training for acquisition was given by presenting the food RS following response to one side of a discrimination apparatus in which there was detention for an interval of time, and by withholding the RS when response was made to the other side, for which there was a different interval. Extinction was carried out by equalizing the detention period and by presenting the RS following response to either side. (Anderson, 1937.)

1948). The variables that affect the extinction of discrimination learning are probably similar to those that affect the extinction of CR's.

Negative transfer of a discrimination similar to experimental extinction has been shown by Anderson (1937) to take place when the positive and negative stimuli are made equal to each other, and the RS is applied when a response occurs to either of the two stimuli. The acquisition of a discrimination response and its extinction by this procedure are pictured in Fig. 12 for one group of Anderson's animals.

Experimental extinction of discrimination learning may also be studied by reversing the positive and negative stimuli, that is to

positive transfer, no transfer, and negative transfer. The many differences among these studies do not make it possible to resolve the differences in results.

Generalization. Stimulus generalization is demonstrated for discrimination learning by the same procedures that are used with CR's, and the same problems of measurement therefore hold. Both cross-modal and within-modal generalization occur. Smith (1936) obtained cross-modal generalization of discrimination learning in cats from visual to auditory stimuli. Many studies have shown stimulus generalization within a given sense modality both for single and multidimensional stimuli. Kluever (1933) and Harlow (1944) have shown that extensive generali-

zation may take place in visual discrimination learning by monkeys. Some studies of stimulus generalization in discrimination learning have been designed to obtain curves of generalization similar to those found for conditioning procedures (Schlosberg and Solomon, 1943; Felsing, 1944; Czehura, 1943), but others have sought to determine whether during the original discrimination learning the animal has been responding to the positive and negative stimuli in an absolute or relative manner. These experiments have come to be known as transposition experiments. Other studies of stimulus generalization and of response generalization have been directed towards investigation of complex symbolic behavior. This is also true of the generalization studies on discrimination learning that involve both stimulus and response generalization.

Retention of Discrimination Learning

The retention of discrimination learning has apparently received no systematic study. Incidental observations for short periods of time show retention to be of a fairly high degree, but retention of discrimination learning has not been reported for the long time intervals that have been found to produce little loss in proficiency of CR's. Many of the studies of transfer of discrimination learning would have provided data on retention if appropriate measures of performance in the initial discrimination training situation had been made following the transfer tests or training. However, as has been pointed out before, the majority of studies of discrimination learning have been designed for the investigation of complex symbolic behavior.

SERIAL LEARNING

Serial learning has much in common with both conditioning and discrimination learning. However, the spatial mazes in which serial learning is most often studied require the animal to respond sequentially to the

different stimulating conditions in a serial space-time dimension.* It is equally possible to present conditions requiring the sequential occurrence of CR's or discrimination responses, but this technique has been little used even though it offers more precise control over the presentation of the stimulus conditions and measurement of the animal's responses to them.

Measurement of serial learning may be in terms of the overall performance as a unit, or in terms of the component parts. Time or errors per trial provide the units. The beginning of a trial is defined by the introduction of the animal to the experimental situation, and its end by the removal of the animal when the terminal response has occurred and the RS has been applied. The food RS has been used most frequently in studies of serial learning; but electric shock, escape from water, and similar RS's have been applied successfully. Since both time and errors are a function of practice trials, acquisition is expressed by the quantity of time or errors after a given number of trials, or in terms of trials, time, or errors to attain a given criterial performance.

Acquisition of Serial Learning

Maze pattern. The acquisition of serial learning has been demonstrated for many different kinds of maze pattern.† Kind of maze is undoubtedly an important factor in rate of acquisition, but data on acquisition as a function of this variable are limited in range because of the difficulty of quantifying maze pattern and because of the wide range of reliability of different maze patterns. Sectional T- and Y-shaped units are joined to form mazes that have high reliability for measuring acquisition (Tryon, 1930; Jack-

* Although temporal mazes have been used for the study of serial learning in animals, the acquisition of this kind of performance is considered to involve complex symbolic processes.

† Since the white rat has been used most often as the experimental subject in animal studies of serial learning, the animal will not be named unless it is other than the rat.

son, 1932). When the same maze pattern is constructed in both an alley and elevated runway form, rate of acquisition is more rapid on the elevated maze (Miles, 1930). The multiple-unit maze may be varied in length without altering the basic pattern. Warden and Hamilton (1929) reported that absolute measures of acquisition increase as the length of the maze increases for 2, 4, 6, 8, and 10 units, but that error and time scores per unit vary inversely with increase in the length of the maze. Ballachey (1934) found a similar relation between measures of acquisition per unit and length of maze; but in terms of absolute measures of acquisition the order of difficulty was 12, 4, and 8 unit lengths. Warden and Riess (1941) reported that with chicks an increase in the number of units of the maze produced a progressive increase in rate of acquisition per unit.

Maze pattern may also be varied by the presence or absence of doors to prevent retracing. The presence of doors that prevent the rat from retracing back beyond the section it is in has been shown to increase the rate of acquisition and the reliability of the maze (Tolman and Nyswander, 1927; Leeper, 1932). The length of the blinds for a given maze pattern affects the rate of acquisition. Peterson (1917) found elimination of blinds to be more rapid when the blinds were 9 inches long than when they were 22 inches long. White and Tolman (1923) studied this same variable with longer alleys that also had a right-angle elbow and found elimination to be more rapid for the long alleys than for the short ones. Although the discrepancy between these studies may be a function of other differences, White and Tolman suggested that Peterson's results were a function of differential visibility for the long and short blinds.

Analysis of the frequency of errors for the different sections of mazes has shown that unbalanced maze patterns result in characteristic performances by rats. Centrifugal swing is the tendency of the animal to go to the outer wall of an alley maze after a

turn and to continue this direction of response at the next turn. The number and direction of turns in the true path of the maze determine the extent to which errors will be made as a function of this factor (Ballachey and Krechevsky, 1932; Ballachey and Buel, 1934; Witkin and Schneirla, 1937). Schneirla (1933) observed this same phenomenon in the acquisition of certain maze patterns by ants.

Goal orientation is the term given to the occurrence of a greater frequency of errors for blinds that lie in the direction of the goal box (Dashiell, 1930; Tolman and Honzik, 1930a; Spence and Shipley, 1934). W. L. Brown (1946) showed that this performance occurs in a maze for which the start and goal box are common.

The direction before the last turn of a maze may be an important factor in goal orientation, since Buell (1934) found more errors to occur on blinds in the same direction as that of the last turn when the food box of the maze was on the central axis. Jones and Taylor (1938) used a maze similar to that of Spence and Shipley, with the goal box to the left for one group of animals and to the right for the other group, but with the direction of the last turn the same for both groups. A greater frequency of errors was made by animals of both groups on the side of the last turn, irrespective of the direction of the goal box. Thompson (1944a) failed to find evidence of goal orientation in mazes that were of a different pattern from those used by the above investigators but that were designed to produce goal orientation.

Differential frequency of errors within the maze. The frequency with which blinds are entered has been found to be a function of the distance of the blind from the start and goal positions. When the frequency of entering blind alleys increases as a function of the distance from the start box, it is spoken of as an entrance gradient. A goal gradient occurs when the frequency of entrance increases with the distance of the blind from

the goal box. Since blind-alley entrance is affected by both general and specific factors of maze design, by certain characteristics of the rat, and by most variables that influence the acquisition of maze habits, investigators have obtained conflicting results concerning the order of elimination of blinds.

Spence and Shipley (1934) found that during the initial acquisition trials the relative frequency of errors gives an entrance gradient, but that during the later trials a goal gradient occurs. Hill (1939) found a goal gradient for the initial 10 acquisition trials and a bidirectional gradient (error frequency greatest for middle blinds) for the next 10 acquisition trials. Other investigators have found goal, entrance, and bidirectional gradients or no gradients at all. Bidirectional gradients have also been found in mazes with the food box located in the middle of the maze (Thompson and Dove, 1943; Jenkins, 1943*a, b*). Jenkins (1943*a, b*) showed that both the period of food deprivation and the amount of incentive affect the bidirectional gradient.

The distribution of errors is influenced by many variables other than the goal and the entrance. There are tendencies for the animal to prefer certain sides of the maze, to repeat entrance into certain blinds, and to alternate in making certain errors. Arnold (1947*a, b*, 1948) studied gradients in serial learning in terms of the latency of manipulative responses. The gradients were shown to be a function of the kind and locus of the RS, the stage of acquisition, and the alteration of the manipulanda.

Stimulus conditions. The acquisition of a maze pattern depends upon the animal's responses to cues that differentiate the true pathway from the blind alley at each choice point. Each bifurcation of the maze thus presents the animal with a problem in discrimination. The problem of sensory control of the maze has a long history. It has been approached traditionally by comparing the efficiency of acquisition by animals that have been deprived of the sense organs for

different sense modalities, or by making the cues at choice-points of the maze nondifferential for a given sense modality. Visual, auditory, olfactory, kinesthetic, and tactile cues have all been shown to play a role in the acquisition of maze learning. The relative importance of these modalities is not known precisely, although many investigators have concluded that the kinesthetic-tactile cues play the dominant role.

The RS. The effect of the RS upon rate of acquisition has been the subject of a number of studies. Food, sex object, and offspring have been found to be nondifferential for rate of maze learning (Moss, 1924; Simmons, 1924; Stone and Sturman-Hulbe, 1927). Escape from water is comparable to food as an RS (Dunn, 1935; Moss, 1924; Ruch, 1930). Electric shock for errors results in more rapid acquisition than food in the goal box; however, the use of shock for errors and food in the goal box produces more efficient acquisition than either one alone (Bunch and Magdsick, 1938; Doreus and Gray, 1932; Ni, 1934; Valentine, 1930). Arnold (1947*a*) found acquisition of a serial button-pressing response by rats to be more rapid with a food RS than with a shock RS.

Studies of the effect of variation in magnitude or intensity of RS upon acquisition of serial learning have been restricted largely to food. Increase in magnitude of RS, increase in period of food deprivation at the time of training, and decrease in the delay of reinforcement all produce an increase in rate of acquisition (Blodgett, 1929; Elliott, 1929; Williams, 1929; Macduff, 1946; Tolman and Honzik, 1930*a, b*; Hamilton, 1929; Simmons, 1924). Although the range of independent variable has been small, the results are comparable to the effect of the same variables upon the acquisition of CR's and of discrimination learning. Macduff's study showed acquisition to be directly related to degree of deprivation for both a condition of distributed practice and one of massed practice.

Distribution of practice. Some degree of distributed practice has often been found to

be a more efficient condition for the acquisition of a maze performance than has a condition of massed practice (Brockbank, 1919; Lashley, 1917, 1918; Ulrich, 1915). Warden (1923) showed both for blocks of trials and for intervals between trials that distribution produces a more rapid acquisition than massing. Other experimenters have reported no difference, or a difference in favor of massed practice (Cook, 1928; Pechstein, 1921). Mayer and Stone (1931) found no difference between massed and distributed conditions of practice for young rats but found an increase in rate of acquisition with an increase in distribution of practice for adult animals. It has been suggested that difficulty of maze (Cook, 1928) and the stage of acquisition at which the massing or distribution of practice is applied (Lashley, 1917, 1918) may be critical factors.

Other variables. The whole-versus-part problem in the acquisition of serial learning has been studied by Pechstein (1917) and by Hanawalt (1931). Opposite results were obtained in the two studies. Since Hanawalt's experimental control was superior to that of Pechstein's study, her results are given greater credence. They show the whole method to be most efficient, the intermediate part method to be next, and the pure part method to be least efficient for acquisition.

A variety of pretraining treatments have been shown to facilitate the acquisition of serial learning. Preliminary handling by the experimenter (Jackson, 1932), preliminary feeding in the goal box (Anderson, 1941; Jackson, 1932), preliminary exploration of the maze without application of the food RS (Blodgett, 1929; Haney, 1931; Lashley, 1918), and general laboratory adjustment (Jackson, 1932) result in more rapid acquisition. Bunch and Lund (1932) found that guided trials in a maze facilitate its subsequent acquisition. Stone and Smith (1941) gave preliminary training on a discrimination that was to be required later in the acquisition of serial learning. Training of blind, vibrissalless rats on an inclined-plane

discrimination and training of blind rats on a rough-smooth discrimination resulted in a rapid acquisition of mazes making use of these cues. Similar results were obtained with normal animals that were given preliminary training on a black and white runway section of an elevated maze made up of such units. Negative results were obtained for normal rats trained to use visual cues in alley mazes of variable pattern and for blind rats given training on an odor trail.

Transfer of Serial Learning

Transfer of serial learning has been found to be both positive and negative. The variables that affect transfer of serial learning are similar to those that affect transfer of conditioning and discrimination learning. Stimulus generalization (alteration of maze pattern) is usually positive, but, because the nature of stimulus conditions within a maze pattern is obscure, the extent and course of generalization as a function of change in maze pattern are not known precisely. Response generalization and stimulus and response generalization have been little studied for serial learning. Transfer as a function of alteration of the RS has received much study, and both positive and negative transfer have been found. Other variables have also been shown to influence transfer.

Maze pattern. Acquisition of one maze pattern usually results in positive transfer for acquisition of other maze patterns. Webb (1917) found positive transfer to 4 mazes designed to produce negative transfer. The extent of positive transfer appeared to be a function of the degree of similarity between the first and second mazes acquired. Hunter (1922) reported positive transfer from one maze to another that differed only in reversal of the start and goal boxes, but Alm (1931) obtained negative transfer with reversal of direction of the goal box. Wiltbank (1919) reported positive transfer in the acquisition of a succession of different mazes. Amount of transfer was not cumulative from one maze to another, but the extent of trans-

fer was found to be a positive function of the number of practice trials on the original maze. Marx (1944) found transfer to be positive and cumulative through a series of 12 mazes. Ho (1928) reported that the extent of positive transfer is a direct function of the amount of acquisition training on the

tion is comparable to the terminal level of acquisition attained by rats given training with no food RS (Tolman and Honzik, 1930*b*). Reintroduction of the food RS would undoubtedly produce a rapid recovery of maze performance, but this appears not to have been studied. Nor have conditions

FIG. 13. Retention and transfer of maze performance measured by the saving method as a function of lapse of time following initial acquisition. Each point is the mean saving score in terms of trials for the reacquisition or initial acquisition of a multiple T-maze performance by a group of rats ($N = 24$ or greater). The filled circles are the saving scores of animals who reacquired the maze pattern after varying intervals of time. The solid line connecting them thus constitutes a retention curve. The open circles are the saving scores of animals who acquired the same maze as did the retention animals at varying intervals of time after they had acquired a different multiple T-maze pattern. The dotted line connecting these circles is therefore a curve of transfer as a function of time interval. (Bunch, 1941.)

initial maze pattern. Bunch (1941) found that the positive transfer from one maze pattern to another was of the same extent when there was a lapse of 0, 2, 7, 30, 90, or 120 days between the learning of the two mazes (see Fig. 13).

Alteration of RS. Removal of the food RS results in negative transfer of serial learning similar to the experimental extinction of a CR (Bruce, 1930; Sharp, 1929; Tolman and Honzik, 1930*b*; Warden and Lubow, 1942). Complete extinction of the maze performance was not obtained in these studies, but both time and errors show a marked increase. The terminal level of ex-

comparable to spontaneous recovery, to disinhibition, and to the application of the US alone on recovery from extinction of CR's been studied for serial learning.

Change in the nature of the RS results in a temporary decrement in maze performance from which there is rapid recovery. Elliott (1928) reported that a shift from bran mash RS to sunflower seed RS results in positive transfer. A shift in amount of RS has also been shown by Elliott to produce a temporary decrement in performance from which there is quick recovery. Bruce (1930) showed that the decrement produced by removal of a food RS is further increased

by increasing the period of food deprivation from 18 to 42 hours. He also reported a decrement in response when the food RS is placed behind a screen (1932*b*) and a temporary decrement when the food box is altered (1932*a*). A shift from food to water RS with appropriate change in deprivation conditions also results in the positive transfer of maze performance (Elliott, 1929). The range of incentive generalization in serial learning is probably much greater than is demonstrated by the foregoing experiments.

Other variables. Jackson (1932) found that stimulus and response generalization takes place from acquisition of a problem box performance to the acquisition of a maze. Gengerelli (1930) found that rats trained on a maze with all right (or all left) blinds carried the acquired response pattern over to a maze of different design. The degree of acquisition and the interval of time between acquisition of the first performance and acquisition of a subsequent performance have been shown by Bunch and Lang (1939) to affect the degree of transfer. Guidance given animals on one maze increases the rate of acquisition on a second maze (Bunch and Lund, 1932).

Retention of Serial Learning

The retention of serial learning has been studied no more systematically than has the retention of conditioning and discrimination learning. It has been tested after intervals of time both with and without interpolation of acquisition training for other performances and with alteration of the conditions under which the initial acquisition took place. A number of variables have been shown to affect the extent of retention tested under these three conditions.

Passage of time. Many investigators have reported a fairly high degree of retention for an interval of time up to several months. Tsai (1924) studied retention in groups of rats after intervals of 7, 14, 21, 28, 42, 56, and 84 days and found less retention for the longer intervals. Bunch (1941) studied

retention after 14, 30, 60, 90, and 120 days and found a similar relation. Figure 13 gives the retention curve obtained by Bunch and also shows that the degree of retention after 30 days and longer is roughly comparable to the savings involved in transfer to the same maze after intervals between 0 and 120 days.

Macduff (1946) found that rats that had acquired a maze performance under different periods of food deprivation showed an amount of retention positively related to the period of deprivation during acquisition, when retention tests were made for all groups after the same interval of time and under 24-hour food deprivation. Similar results were obtained in two experiments, for one of which practice was distributed and for the other, massed.

Interpolated activity. The acquisition of another performance may impair the retention of a previous acquisition. This phenomenon is called retroactive inhibition. Evidence of retroactive inhibition for serial learning has been obtained with acquisition of another maze as the interpolated activity by Webb (1917) and by Wiltbank (1919). Brockbank (1919) found no evidence for retroactive inhibition of serial learning when the interpolated activity was training on a rope-ladder problem. Ho (1928) studied the effect on retention of the number of trials given on the interpolated maze. The results were not uniform, but there was a trend of increase in retention with increase in training on the interpolated maze. Waters and Vitale (1945) failed to obtain evidence of retroactive inhibition or of differential retention for different amounts of training on an interpolated maze in two experiments, each of which involved a different interval of time between acquisition and the measurement of retention. Marx (1944) found not only clear-cut evidence of retroactive inhibition of serial learning by interpolation of training on other mazes but also that the degree of retroactive inhibition was a function of the number of mazes on which inter-

polated training was given. Retroactive inhibition increased as the number of mazes increased up to 8 but decreased for the group given 12 interpolated mazes.

Alteration of stimulus conditions. The effect of this variable on the retention of maze performance has been studied primarily in terms of rotation of the maze within the experimental room. Rotation alters a number of stimulus conditions whose identification and isolation are difficult. In general, rotation of the maze results in poorer retention of serial learning (Carr, 1917; Higginson, 1930). Higginson showed that alteration of the position of the maze within the experimental room reduces the efficiency of performance, and that retention is poorer when tested in the dark than when tested in the conditions of light under which the performance was acquired. Higginson found no effect of rotation in the dark on retention when acquisition took place in the dark. This suggests that alteration of visual cues accounts for most of the drop in retention found with rotation of the maze.

Human Learning and Retention

CARL I. HOVLAND
Yale University

This chapter deals with experimental studies of the acquisition and the retention of verbal, perceptual, and motor learning of human subjects. For simplicity of exposition, acquisition is stressed in one portion of the chapter, transfer of training in a second portion, and retention in a third. It is apparent, however, that these phases are highly interdependent: acquisition involves a series of trials, each of which is based on retention of the effects of previous practice, and retention is influenced by the conditions under which acquisition took place. Furthermore the acquisition of new material is greatly affected by previous learning, and retention is influenced by the intervening learning of new material between acquisition and recall.

Several arbitrary restrictions of subject matter have been necessary to avoid overlap with other chapters. For example, the content is restricted to human learning, although it will be recognized that many infrahuman studies are conducted primarily to increase our understanding of human learning. The restriction of coverage to human learning necessarily gives the treatment a strongly empirical flavor, since analytical treatment of theoretical variables often requires the type of simplification and control attainable only with animal experimentation.

The writer expresses his appreciation to Professors Arthur Melton, Arthur Lumsdaine, and Fred D. Sheffield for their helpful suggestions, and to Seymour Feshbach for aid in checking the bibliography.

More extensive coverage is given in this chapter to the research of the last decade than to earlier studies, although the intervention of the war during this period reduced greatly the amount of fundamental research on learning performed. The reader is referred to McGeoch's excellent treatment of the period up to 1940 in his *Psychology of Human Learning* (1942). It is impossible to write a chapter on the same subject without being profoundly influenced by his thoughtful and comprehensive review of the earlier work.

Definition of Learning

Although scores of definitions of learning have been proposed, none has become uniformly accepted. There is, however, considerable agreement on what phenomena are to be included and what excluded: it is desired to include the trend of improvement in performance that comes about as a result of practice and to exclude changes in performance due to fatigue, sensory adaptation, and drugs, changes due to physical development (maturation), and artifacts in measurement, such as changes in rapport between subject and experimenter. The definition used by Hunter (1934) seems to fit these specifications best and hence will be used with only minor modifications. Learning will be defined as the change in performance associated with practice and not explicable on the basis of fatigue, of artifacts of measurement, or of receptor and effector changes.

Three Major Traditions in Human Learning Experimentation

From the pioneer experiments of Pavlov, Ebbinghaus, and Bryan and Harter three main currents in research on human learning have developed. Pavlov's influence has shown itself in the contributions of Watson, Hull, Guthrie, and a long line of other students of conditioning. The Ebbinghaus tradition has continued strong to the present day through the work of Müller, Carr, McGeoch, and others who have studied verbal learning. Research on motor learning and skills springs primarily from the work of Bryan and Harter (1897) who developed the methods, but it has been greatly influenced on the theoretical side by the work of Thorndike (1911 and later) on trial-and-error learning.

A challenging task facing contemporary psychology is the integration of these three major traditions with their diverse methods and concepts. When this integration has been achieved, the chapter on human learning can be made more rigorously systematic.

Many characteristics of learning are already known to be common to the different types of experiment. Accordingly, this chapter will discuss the phenomena common to all three of these types of learning. First, however, a brief description will be given of each of the three main types of human learning experiments and of their most salient characteristics.

CONDITIONING

Much of the research on conditioning has been done with animals. Consequently the treatment here is restricted to a review of the principal phenomena of conditioning and of the relevant reference experiments performed with human subjects. The presentation is arranged in the framework of experimentally investigated phenomena rather than in terms of theoretical formulations. For a discussion of conditioning concepts, theories, and research methods, the reader is referred to the excellent review of the field in Hilgard

and Marquis' *Conditioning and Learning* (1940).

The handbook review of conditioning by Hull (1934) lists the large number of different responses that have been conditioned and the types of stimuli used. The responses most commonly used in human studies have been hand withdrawal, eyelid closure, knee jerk, and vasomotor and psychogalvanic responses. Recent experiments have employed

FIG. 1. Course of acquisition of conditioned eyelid response. Subjects were divided into positive acceleration, negative acceleration, and double inflection types on the basis of their individual performance, and the means of each such group were determined. (From Hilgard and Campbell, 1936.)

such esoteric responses as the occipital alpha rhythm (Jasper and Shagass, 1941) and the autokinetic phenomenon (Haggard and Rose, 1944).

Acquisition curves. The strength of connection between stimulus and response increases with the number of reinforcements. Samples of acquisition curves obtained in human eyelid conditioning by Hilgard and Campbell (1936) are illustrated in Fig. 1.*

* Here and in subsequent discussions of verbal and motor learning, acquisition curves have been plotted against trials or number of repetitions. This may suggest that repetition is the critical factor in producing increments in learning, in line with our popular expression "Practice makes perfect." This generalization has even been given the status of a law—the law of frequency. But it must be pointed out that there is a wealth of evidence that frequency per se is not a sufficient condition for learning. The principal lines of evidence, which are presented throughout the chapter, are (1) the failure to learn without motivation even if the situation is frequently re-

The authors remark, "Possibly all of the curves belong to the same family of ogival or S-curves, differing simply in the rapidity with which the positive acceleration phase is completed" (p. 232). The S-shaped type of curve is commonly obtained when frequency of response is used as an index of response strength. Amplitude of response, on the other hand, characteristically shows a nega-

FIG. 2. Percentage of conditioned finger withdrawals with varying time intervals between the conditioned and the unconditioned stimulus in studies by Spooner and Kellogg (1947) and by Wolfe (1930, 1932). (From Spooner and Kellogg, 1947.)

tively accelerated learning curve (cf. e.g. Hovland, 1937d).

Temporal relations. Conditioned responses are most strongly established when the unconditioned (or "reinforcing") stimulus follows the conditioned stimulus by a short time interval. The most widely known studies of temporal factors in human conditioning are those of Wolfe (1930, 1932). She used a finger-withdrawal technique, with sound as the conditioned stimulus and electric shock as the unconditioned stimulus. The highest percentage of conditioning was found when the conditioned stimulus preceded the unconditioned by 0.5 second. Some condition-

peated, (2) the reduction in the strength of response with repetition when reinforcement does not follow (experimental extinction), and (3) negative practice, where frequent repetition may actually reduce the strength of an association. Frequency is thus seen to be a necessary, but certainly not a sufficient, condition of learning.

ing was also obtained when the unconditioned stimulus preceded the conditioned, a phenomenon called *backward conditioning*. Spooner and Kellogg (1947) confirmed the general outline of Wolfe's results (Fig. 2) but found that the forward conditioned responses are distinctly different from backward conditioned responses in frequency, latency, and threshold, suggesting that "forward and backward conditioning are fundamentally distinct processes" (p. 334).

Temporal relations for eyelid conditioning were investigated by Reynolds (1945a). Conditioning was best with a 450-millisecond interval between conditioned and unconditioned stimuli (Fig. 3). Within the interval from 0 to 400 milliseconds the level and rate of eyelid conditioning were shown by Kimble (1947) to be an increasing, negatively accelerated function of the length of interval between conditioned and unconditioned stimuli.

FIG. 3. Percentage of conditioned eyelid responses (on trials 81 to 90) with varying time intervals between conditioned and unconditioned stimuli, following learning by distributed practice (1 to 2 minutes between trials). (Data from Reynolds, 1945a.)

When the conditioned stimulus precedes the unconditioned stimulus by a considerable time interval, there is a corresponding delay in the response after the onset of the conditioned stimulus. When the conditioned stimulus continues during the delay until the unconditioned stimulus is presented, the conditioning is called *delayed conditioning*. Other conditioned responses occurring in the interval of delay show a decrement (Rodnick, 1937). When the conditioned stimulus

is terminated and the unconditioned stimulus is given after an interval, the response is called a *trace* conditioned response. The study by Reynolds just cited and his subsequent article on extinction (1945*b*) both investigated this type of conditioning.

Decremental factors. Prolonged reinforcement may ultimately produce an actual decrease in the measured strength of response (Pavlov, 1927). This effect is relevant to other conditioning phenomena, particularly the initial rise in the extinction curves (Hovland, 1936) and the efficacy of distributed practice in conditioning to be discussed later. An analysis of decremental factors in conditioning, and their relation to work phenomena, is given by Solomon (1948).

Extinction. When, after learning, the conditioned stimulus is repeatedly presented without reinforcement by the unconditioned stimulus, the response decreases and eventually disappears. A sample curve of extinction is presented in Fig. 4. Extinction is more rapid when there is reinforcement on every trial during conditioning than when there is partial reinforcement, i.e. when reinforcement during acquisition is sometimes present and sometimes not (Humphreys, 1939*a*).

External inhibition. An extraneous stimulus presented just before or during the presentation of the conditioned stimulus often reduces the strength of conditioned response. The influence of such distracting stimuli upon conditioned salivary responses in human subjects was analyzed by Razran (1939*c*).

Disinhibition. When an extraneous stimulus is presented after a conditioned response has become extinguished, a temporary increase in the conditioned response occurs. This phenomenon was studied in human subjects by Razran (1939*c*) who used a buzzer as an extraneous stimulus to restore an extinguished conditioned salivary response.

Spontaneous recovery. When time is allowed to elapse after a conditioned response is extinguished, the response may increase in strength and reappear spontaneously (i.e.

without further reinforcement). Spontaneous recovery is sometimes counteracted by simultaneous "forgetting" of the conditioned response (Razran, 1939*b*).

Stimulus generalization. When a response is conditioned to a particular stimulus, the conditioned response is also made to similar stimuli without specific reinforcement. Immediately following the conditioning trials generalization may be almost complete, i.e.

FIG. 4. Extinction curve showing galvanic skin responses on successive unreinforced trials following conditioning. (Data from Humphreys, 1940*a*.)

as large a response being made to stimuli not previously paired with the unconditioned stimulus as to the stimuli given paired presentation (Hovland, 1937*a, b*). With subsequent testing the generalized responses appear to extinguish more rapidly than those established to the original conditioned stimulus (Hovland, 1937*c*).

The factors affecting the *form* of the generalization gradient have not yet been adequately determined. Bass and Hull (1934) obtained a positively accelerated gradient when the conditioned and generalized tactile stimuli were spatially separated on the body. Hovland (1937*a*), using auditory stimuli separated by fixed jnd distances in frequency, found a negatively accelerated gradient of mean galvanic responses. Spence

(1939), however, contended that Hovland's median values, which showed a positively accelerated gradient, are more representative. Repetition of Hovland's experiment by Humphreys (1939*b*) gave a somewhat steeper curve, but a repetition by Littman (1949) gave a gradient with less slope. Results from the last three experiments are presented in Fig. 5.

FIG. 5. Generalization curves showing relative response to stimulus used in conditioning and to other stimuli differing from conditioned stimulus by varying numbers of just noticeable differences. Average responses on first two cycles of testing. (Data from Hovland, 1937*a*; Humphreys, 1939*b*; and Littman, 1949.)

Work on the form of generalization gradients is seriously limited by the lack, at the present time, of adequate scales of stimulus similarity and of response magnitude. Studies are also needed on the factors influencing the form of the gradient. One relevant factor (Brown, 1942) is the strength of the unconditioned stimulus. The stronger the unconditioned stimulus, the wider the generalization. Another factor reported by Humphreys (1939*b*) is the method of reinforcement. He found a negatively accelerated gradient with 100-per-cent reinforcement but positive acceleration with 50-per-cent reinforcement (i.e. with reinforcement present on only half of the trials).

Generalization appears to increase with amount of training in the initial stages of conditioning and to become restricted with further training (Hovland, 1937*d*). The extent of generalization appears to increase for a much longer period with complex patterns

of stimuli than with single stimuli (Razran, 1940).*

Discrimination. If reinforcement is always present when the original conditioned stimulus occurs, but is always absent when the generalized stimulus occurs, the combination of increased strength of the conditioned response and extinction of the generalized response reduces the degree of generalization until finally the response occurs to only a very narrow range of stimuli. The accuracy of discrimination is reduced when the stimuli are presented rapidly and in irregular order (Cole, Woodbury, and Philleo, 1942).

Stimulus patterning. In real-life situations the stimuli to which conditioning occurs are seldom simple, but are complex patterns or "configurations." With practice, identical elements in different combinations can readily be discriminated. A good discussion of this phenomenon, which is referred to as "stimulus patterning," may be found in a study by Hull (1940).

Higher-order conditioning. After a conditioned response has been set up to a particular conditioned stimulus, the conditioned stimulus will sometimes function as an "unconditioned stimulus" in setting up a second conditioned response to a third stimulus. This process can sometimes be con-

* Phenomena somewhat analogous to stimulus generalization are obtained on the response side. That is to say, the stimulus used in initial conditioning may elicit a number of responses similar to the response involved in the initial training. This phenomenon has been called by some writers *response generalization*. An illustrative study is that of Wickens (1943). Human subjects learned to extend their finger to a tone signal reinforced by an electric shock. When the hand was then turned over, the subjects characteristically flexed rather than extended their finger to the conditioned stimulus. With human subjects, however, this may illustrate not a response generalization but rather a transfer to the new situation of a host of pain-avoiding responses learned in other situations, not at all specific to the anatomical relations of the responses. Language may also be involved in the mediation. Until better evidence is available on the nature of the phenomenon, it appears unwise to list response generalization as a primary phenomenon of conditioning.

tinued for several steps. The higher-order conditioned responses are more easily extinguished and presumably require some continued reinforcement of the prior conditioned responses in order to remain effective. This form of conditioning is particularly important in attempts to explain complex human learning in terms of concepts derived from conditioning experiments, because in human learning we deal primarily with secondary motives generated from primary motives on the basis of learning. Much work remains to be done if we are to understand in terms of conditioning principles the persistence of learning in human beings when so much dependence is placed on derived reinforcement that rarely receives primary reinforcement. Undoubtedly the mediating function of language is important in this connection.

Pseudoconditioning. A number of experiments have been done on the phenomenon reported by Grether (1938) that repetition of the unconditioned stimulus alone (without pairing of the conditioned and unconditioned stimuli) results in the evocation of a response to a conditioned stimulus that had previously been inadequate. These responses are retained with little loss for at least a week and do not appear to extinguish (Grant, 1943). Pseudoconditioning may be involved in backward conditioning (Harris, 1941).

Relation of human to animal conditioning. The foregoing brief review of human conditioning phenomena indicates a close parallel between the human and the animal studies of conditioning. At the same time at least two important differences have been suggested. The first relates to the importance of attitude in human conditioning. Studies by Miller (1939), Razran (1936), Grant (1939), Hilgard and Humphreys (1938), and other investigators show the extent to which conditioning phenomena are affected by verbal instructions. An extreme position on this point is held by Woodworth (1938) who described human conditioning as a "game" between the experimenter and the subject.

If given no instruction they [adults] usually assume that E wishes them to take the shock and that they are beating his game if they escape the shock by hand withdrawal; whereas E regards the experiment as a success if O does withdraw. Suppose E were frank with O and instructed him as follows: "I will give you strong shocks preceded (or accompanied) by sounds. I wish to discover how soon you will learn to avoid the shock by withdrawing the hand at the sound." The experiment would lose all point. [P. 110.]

Other experimenters have taken the position that "set" is always present in conditioning and that verbal instructions are just one way of producing sets. With animals one could produce the same results by other procedural means.

The second difference between human and animal conditioning is also attributed to the role of language in human behavior. In one form this is shown in the extensive role of language in mediating other forms of behavior, exemplified in studies such as that of Foley and Cofer (1943) on gradients of response to synonyms and antonyms. Even more significant is the increase in the complexity of discrimination that is made possible by the ability of human subjects to reduce complex patterns to verbal formulae. A particularly important phase of this process is that of counting, which permits discriminations completely impossible for animals.

VERBAL LEARNING

Because of the obvious importance of the learning of verbal material in human affairs, work has been more extensive in this area than on any other phase of research on human learning. Nevertheless much remains to be known about the process, particularly at the basic level of symbolization and the functioning of language. The methods used in the field of verbal learning were well described by Woodworth (1938, pp. 6-17). The reader is also referred to the important

article of Melton (1936) on methodology of experimentation in learning.

Factors Influencing Form of Acquisition Curve

Almost every study provides some evidence concerning the changes of performance with practice. Customarily the results are presented graphically with performance plotted on the ordinate and units of practice on the abscissa to provide "acquisition curves."

Length of material. Extensive investigations by Kjersted (1919), Robinson and Heron (1922), Robinson and Darrow (1924), and a number of other researchers have indicated that the form of the acquisition curve is substantially similar over a wide range of lengths of material. The generalization that the proportion of material learned during corresponding fractions of the total learning time is relatively constant for different lengths of material is often referred to as the Kjersted-Robinson law. Typical results obtained on this problem are presented in Table 1 from the study of Robinson and

learned during successive fractions of the learning time.

Meaningfulness of material. Another factor affecting the form of the learning curve is the meaningfulness of the material to be learned. But the most extensive compilation of data on this point, that of R. A. Davis (1935), fails to provide clear-cut results. Davis concluded that improvement with

FIG. 6. Curves of learning derived from tasks of varying difficulty. A, 5 easy items; B, 15 easy items; C, 50 easy items; D, 100 easy items; E, 5 difficult items; F, 15 difficult items; G, 50 difficult items; H, 100 difficult items. (From W. C. F. Krueger, 1946.)

TABLE 1

PERCENTAGES OF LISTS OF DIFFERENT LENGTHS LEARNED IN SUCCESSIVE SIXTHS OF THE TOTAL LEARNING TIME (FROM ROBINSON AND DARROW, 1924)

Percentages of Total Learning Time	Length of List (Numbers)			
	4	6	8	10
16.7	19.4	31.8	29.3	30.4
33.3	36.1	44.5	45.9	45.3
50.0	49.8	54.0	55.3	54.6
66.7	63.1	62.7	64.0	64.7
83.3	82.3	71.0	75.8	70.4
100.0	100.0	100.0	100.0	100.0

Percentages of Total Learning Time	Length of List (Syllables)				
	6	9	12	15	18
16.7	23.3	33.9	34.6	30.9	33.1
33.3	45.0	51.2	52.3	52.2	53.2
50.0	60.5	62.0	66.3	62.0	66.3
66.7	72.3	73.6	74.9	74.2	76.3
83.3	83.4	80.8	80.5	80.3	82.8
100.0	100.0	100.0	100.0	100.0	100.0

Darrow. Note the similarity (except for the shortest list) in proportions of material

meaningless material is very erratic whereas that for meaningful material is more constant. But it is not clear why his procedure of averaging the curves of different investigators would not tend to smooth out "erratic" fluctuation. In any case the procedure of averaging curves employed by him is open to serious criticism.

Difficulty of material. A factor that appears significant in the few studies devoted to it is the difficulty of the material to be learned. In Fig. 6 results of W. C. F. Krueger (1946) are presented to show the change in the acquisition curve for nonsense syllable learning as the difficulty of the material is increased. With easy material the curve is negatively accelerated, but as the difficulty is increased the curves become linear, and with maximal difficulty the curves are positively accelerated. Similar results

are obtained when the learning curves for the easy and for the difficult items in a list are separately plotted (G. M. Peterson, 1928).

Factors Influencing Time Required for Learning

The factors of length and meaningfulness affect not only the form of the acquisition curve, but also the overall ease or difficulty of learning.

Meaningfulness of material. Meaningfulness is an obvious factor affecting ease of learning. A typical experiment compares the number of repetitions required to learn the same number of nonsense syllables and three-letter words. Illustrative results obtained by Guilford (1934) are presented in Table 2. It is further known that, if analy-

TABLE 2

NUMBER OF TRIALS REQUIRED TO LEARN VARIOUS KINDS OF VERBAL MATERIAL (FROM GUILFORD, 1934, p. 122)

Material	Number of Trials
15 nonsense syllables	20.4
15 unrelated words	8.1
15 related words	3.5

sis is restricted to relatively meaningless material (e.g. nonsense syllables), those units that are more "meaningful" in the sense of calling forth more related associations are learned more rapidly than those evoking few associations (McGeoch, 1930).

Amount of material. The relation between quantity of material and time required for learning has been studied by a large number of investigators. When nonsense syllables are used, results generally indicate not only a general increase in length of learning time with increased length of list but also an increase in time required *per unit*. The most extensive range of lengths and materials is found in the study by Lyon (1914) although the number of subjects employed was small. His results are presented

in Fig. 7. Much more extensive data are available over the range of lengths up to 36 syllables. Results over this range by Ebbinghaus (1885), Meumann (1913), and

FIG. 7. Time required to learn nonsense-syllable lists of varying lengths. (Data from Lyon, 1914.)

Hovland (1940*b*) are presented in Fig. 8. They show a negative acceleration in difficulty with increased lengths. The same negative acceleration is obtained when various lengths of lists are scaled by the Thur-

FIG. 8. Mean number of repetitions required for learning various lengths of lists. (From Hull et al., 1940.)

stone-Woodrow absolute scaling technique (Fig. 9). Repetition of Lyon's experiment with more subjects appears desirable to cover a wide range of lengths.

A number of writers have sought mathematical expressions for the relation between

increases as the square root of the number of items (beyond the memory span). That is,

$$T = \frac{c}{k} (n\sqrt{n-a})$$

FIG. 9. Scaled difficulty of nonsense-syllable lists of varying lengths. (From Shurrager, 1940.)

where T is total learning time, k the subject's learning constant, c a constant for the criterion, n the number of items in the list, and a the subject's memory span. A rational derivation for the relation between length of series and number of trials required for rote learning is given by Hull et al. (1940).

The relation between length and learning time has also been studied for meaningful material. In Fig. 10 the results of Lyon (1914) are presented for the learning of poetry. It will be observed that the increased learning time with increased length is much less pronounced than that obtained by him for nonmeaningful material. Similar results were reported by Cofer (1941), who showed that with *logical* learning, where the learner had only to master the essential ideas

length of material and difficulty in connection with the learning of simple materials. Thurstone (1930a) found that empirically many studies show that the time per item

FIG. 10. Time required to learn poems of varying lengths. (Data from Lyon, 1914.)

of the material, the increases in difficulty with increased lengths were much less than with *verbatim* learning. We are still far from an adequate understanding of the reasons for this difference.*

Phenomena of Serial Learning

In most verbal learning the materials learned have serial character; i.e. the units are successively associated. In some situations the objective may even be primarily that of learning the order in which the items appear, as when one knows all the words involved and has only to learn to put them in correct order, as in a poem. In many studies the learning of the serial order and the learning of the units themselves are confounded, as in most nonsense syllable learning studies where the discrimination and fixation of the syllables and the learning of the serial order proceed simultaneously.

One important phenomenon in studies of serial learning is the formation of associations not only between adjacent items but also between items that are more remote. In learning the series $A \rightarrow B \rightarrow C \rightarrow D$, for example, not only will there be associations between A

and B , B and C , C and D (that is to say, between adjacent items) but also between an item and others that follow in the series, and even between an item and others that precede it in the series. The associations between an item and those that follow it are called *forward associations*, and those between an item and its predecessors are called *backward associations*. The forward and backward designations refer to the order of the associated items in the original lists. The associations are all, of course, forward at the time of subsequent operation.

The strength of these associations and their change with practice have long interested students of learning. Ebbinghaus' pioneer study (1885) is widely known. His method involved first learning a series in the usual manner, and then rearranging the items by skipping alternate syllables. Other lists contained the items with successively more remote association. He found he could save nearly 11 per cent of learning time when the items in the derived list were one unit apart initially, but only 3 per cent when the syllables were seven syllables removed. Ebbinghaus extended his study by preparing some lists derived by presenting previously learned items in reversed order. He found a saving of about 12 per cent for immediate backward associations and of 5 per cent for lists with two degrees of removal in a backward direction.

Ebbinghaus' method assumes that saving in the derived lists is due solely to remote forward and backward associations, a questionable assumption. A method that is somewhat superior involves testing by controlled association. These responses can then be classified in terms of their remoteness from the original learning. A progressive decrease in frequency of both forward and backward associations is observed (McGeoch, 1936). A limitation of this method is that the more remote degrees of association have artificial limitations placed upon their extent, owing to the fact that immediate associations are necessarily more numerous than remote ones.

* A number of explanations have been offered for the greater ease of learning meaningful material. Ebbinghaus (1885) attributed the greater speed of learning meaningful material to the savings resulting from previous familiarity with the material. McGeoch (1942) had a similar explanation when he spoke of meaning as being a special case of transfer, by which he implied that meaningful material is initially more familiar to the learner. The Gestalt psychologists stress the fact that meaningful material is structured and differentiated whereas nonmeaningful material is unstructured and indistinguishable (Koffka, 1935; von Restorff, 1933). This conception was tied in to conditioning principles by E. J. Gibson (1940), who described meaningful material as having a higher degree of differentiation and attributed the increased number of trials needed to learn meaningless materials to the time required to bring about differentiation of the items. An important attack on the problem of meaning was carried out by Sheffield (1946) who gave stimulus and response terms "meaningfulness" under controlled conditions. Individuals interested in this problem are also referred to the work of Katona (1940) who contrasted the phenomena obtained with meaningful and meaningless types of learning.

Raskin and Cook (1937) applied a correction to take account of the differential possibility of associations of differing remoteness. Their results are shown in Table 3.

Serial position effects. Ordinarily the items toward the beginning and end of the series are easier to learn than those in the center. This is illustrated in Fig. 12, which shows

TABLE 3

FREQUENCY OF FORWARD AND BACKWARD ASSOCIATIONS WITHIN A SINGLE REPETITION OF THE SERIES (DATA FROM RASKIN AND COOK, 1937)

	Forward Associations			Backward Associations			
	Raw Frequency	Correction Factor	Corrected	Raw Frequency	Correction Factor	Corrected	
Immediate direct	195	7/7	195	6th backward remote	11	7/1	77
1st forward remote	44	7/6	51	5th backward remote	12	7/2	42
2nd forward remote	19	7/5	27	4th backward remote	12	7/3	28
3rd forward remote	8	7/4	14	3rd backward remote	12	7/4	21
4th forward remote	9	7/3	21	2nd backward remote	11	7/5	15
5th forward remote	10	7/2	35	1st backward remote	25	7/6	29
6th forward remote	5	7/1	35	Immediate backward	45	7/7	45

A significant factor affecting strength of remote associations is the degree of learning. Ebbinghaus (1885) used three degrees of

the number of errors made in learning a series of 12 syllables to the criterion of one perfect recitation. The relative difficulty of the various items can also be indicated by showing the acquisition curves of the individual units. Results on this point reported

FIG. 11. Gradients of forward associations with low and high degrees of learning mastery. (Data from Hertzman and Neff, 1939.)

learning and found that the extent of remote association decreased with increased practice. The progressive gradient of forward associations with varying degrees of mastery as reported by Hertzman and Neff (1939) is shown in Fig. 11.

FIG. 12. Serial position curves showing mean number of failures made in learning nonsense syllables in various positions in list. (Data from Hovland, 1938c.)

by Robinson and Brown (1926) are shown in Fig. 13. Note the rapid curves of acquisition for the items toward the ends (2 and 18) and the slower rates for those nearer the center (6 and 12).

Another indication of serial position effects is found in the oscillation between the correct and incorrect response which occurs with

FIG. 13. Learning curves plotted for individual syllables in end positions (2 and 18) and central positions (6 and 12) of list. (From Robinson and Brown, 1926.)

partial learning. This phenomenon was first described by Hull (1935) who showed that an association may often be correctly recalled on one trial and then not be recalled on a

Serial position effects play a prominent part in the rote-learning theory advanced by Hull et al. (1940). An important alternative theory is that of Foucault (1928) who explained serial effects as due to "proactive" and "retroactive" inhibition within the units of the list to be learned.

FIG. 14. Fluctuation in learning, showing mean number of repetitions preceding first success and up to and including last failure for syllables in various positions. Data from Hovland (1940b). (From Hull et al., 1940.)

subsequent trial. Finally, the association is recalled on every trial. The end units are much less apt to show such oscillation than are the middle syllables. This phenomenon is shown in Fig. 14.

MOTOR LEARNING

In laboratory studies of motor learning there is usually an attempt to find a relatively simple type of activity with which the learner has had little previous experience. A good example is the task of tracing a star with a stylus when the star is seen not directly but in a mirror. Here one has to learn to reverse his response to cues, since what he sees in the mirror as up is actually down, and vice versa. In Fig. 15 there are illustrated the changes in performance on successive trials in the learning of such a task. The qualitative change with practice is noted by comparing the shaky erratic tracing on the first trial with the relatively smooth tracing on the fifteenth trial. The quantitative changes are seen when results are plotted in terms of the number of errors

FIG. 15. Qualitative changes with practice. Tracings made on various trials in mirror drawing experiment. (From Kingsley, 1946.)

made on each trial, or in terms of the time required to trace the star on successive trials. Both measures show a gradual decrease with practice (Fig. 16).

Quantitative Changes with Practice

If acquisition is recorded in terms of speed and accuracy (rather than in terms of time and errors, as in Fig. 16), a rising curve is typically found. The curves obtained by Bryan and Harter (1899) are presented in Fig. 17 to illustrate the nature of such changes. Their records indicate a gradual but negatively accelerated improvement. The feature of their curves that has caused the most controversy is the arrest in improvement, the *plateau*, midway through the learning. Bryan and Harter believed that the plateau occurs at the region of transition

from one order to the next in a hierarchy of habits. They summarized their results on telegraphic receiving as follows:

All the facts point to the conclusion that the telegrapher must acquire, besides letter, syllable, and word habits, an array of higher language habits, associated with the combination of words in connected discourse. . . . Learning to receive the telegraphic language consists in acquiring a hierarchy of psychophysical habits. . . . A plateau in the curve means that the lower-order habits are approaching their maximum development, but are not yet sufficiently automatic to leave the attention free to attack the higher-order habits. The length of the plateau is a measure of the difficulty of making the lower-order habits sufficiently automatic. [Pp. 356-357.]

FIG. 16. Acquisition curves showing improvement in time and in errors on successive trials in learning to trace star seen in mirror. (From Starch, 1910.)

FIG. 17. Acquisition curves for learning to receive telegraphy. *A*, connected discourse; *B*, words; *C*, letters. Tests began with seventh week of practice. (From Bryan and Harter, 1899.)

Plateaus have also been found for learning ball tossing (Swift, 1903), learning a foreign language (Swift, 1906*a*) and learning to type (Book, 1908). Swift attributed the appearance of plateaus in large part to changes in motivation. Book added the idea that plateaus are due partly to practice on incorrect and useless responses which do not contribute to immediate improvement.

Later work on telegraphic receiving has failed to confirm the generality of plateaus in learning. Taylor (1943) reported an unpublished study of Rees Tulloss in which he failed to obtain a single plateau among his 25 subjects. Reed and Zinszer (1943) likewise reported the absence of prolonged plateaus among their 43 subjects. Studies since 1940 have shown that plateaus are sometimes absent, but we are still confronted with the task of untangling the factors of learning, motivation, and work decrement in the causation of plateaus.

Numerous other investigations have been made of the form of the learning curve for the acquisition of motor skills. For many types of skill acquisition a curve of negative acceleration is obtained; for others positive acceleration is obtained. Differences in results are due sometimes to the units of measurement (J. Peterson, 1917), sometimes to starting the new learning after varying amounts of prior practice (E. Culler, 1928; Ehrlich, 1943*a*), and sometimes to difference in the character of material and types of learners. From a compilation of nine studies of simple motor learning and twenty studies of complex motor processes (like typewriting or piano playing) R. A. Davis (1935) concluded that the initial rise is more rapid in simple than in complex learning, and that plateaus and fluctuations are more frequent in complex learning. Davis' compilation is given in Fig. 18. Closely related to complexity is the difficulty of a task. An interesting experiment on this factor was reported by W. C. F. Krueger (1947). The curves of each of four groups of subjects learning to toss rings from differing distances were

compared. As the task increased in difficulty, the curve of learning shifted from negative to positive acceleration.

Qualitative Changes with Practice

The pioneer studies on the qualitative changes at various stages of learning skills are those of Lashley (1915) on archery, Ruger (1910) on puzzle solving, Book (1908) on typewriting, Kline (1920) on card sorting, and Starch (1910) on mirror tracing.

FIG. 18. Acquisition curves. Composite of 9 studies of simple motor learning and 20 studies of complex motor learning. (From Davis, 1935.)

A good review of these and other studies will be found in Woodworth (1938).

An important change with practice in motor learning is change in muscular tension. In some learning, as the task becomes highly skilled, the amount of tension declines (Stroud, 1931; Ghiselli, 1936). In other tasks the tension appears to increase. Telford and Swenson (1942), for example, found that muscular tension during mirror tracing was initially low and was increased and maintained at a high level as learning progressed. Places of increased difficulty were correlated with increased tension. Tension, however, was not diffuse; with progress in learning, there was improved localization of tension in the muscles specific to the task. The relation of tension to performance in various types of learning is an important problem needing further research.

Telford and Swenson's paper provides a good bibliography on the topic.

Some of the studies cited above, particularly those of Lashley and Ruger, stress the sudden improvements that occur with practice, often attributed to "insight" (Köhler, 1929). There has been no sizable recent contribution to our understanding of this problem to alter the summary by McGeoch (1942):

The abrupt changes which occur are functions of transfer from prior training, of the subject's experience with the particular problem he is trying to solve, of passage from one level to another in a hierarchy of response, and of many other conditions which are continuous with such concepts as trial and error and association. The subject's trials and errors need not be overt to be trials and errors, but may take place symbolically or in some other fashion beyond the direct observation of the experimenter. Actually, many of the descriptions of insight behavior contain rich descriptions of pre-resolution trials and errors. [P. 47.]

Intraserial Phenomena

When a motor task calls for a series of movements to be learned in sequence, serial phenomena similar to those shown earlier for verbal learning are found. The apparatus most frequently used to investigate these phenomena is the maze. The remote associations in a forward direction are called *anticipatory* errors, and those in a backward direction, *perseverative* errors. In a maze where the alternatives are the same at each choice-point it is not possible to know for sure what the degree of remoteness of a particular association is. With mazes in which different elements obtain throughout the series, however, this difficulty is obviated. Lumley's (1932) typewriter "maze" was of this type. The subjects were required to press a series of letters on the typewriter when an auditory signal was sounded until, through trial and error, they discovered the correct letter. Errors could be related to

position in the sequence. Lumley's results are given in Table 4.

TABLE 4

AVERAGE NUMBER OF ERRORS MADE, ANTICIPATING THE FIRST, SECOND, THIRD, ETC., LETTERS AHEAD (FROM LUMLEY, 1932)

	Number of Letters Ahead						
	1	2	3	4	5	6	7
Maze I	66.7	49.8	43.3	32.9	31.3	31.1	24.7
Maze II	15.1	11.4	9.8	6.8	7.1	8.4	6.4
Maze III	28.6	17.6	22.8	15.5	17.4	9.7	12.4

Other data presented by Lumley indicate that with increasing practice there is a decrease in the more remote errors. Serial

FIG. 19. Mean number of total failures per blind made in various portions of Warden maze learned either to a metronome beat of 100 per minute or with unlimited time in experiment of Husband (1929). (From Hovland, 1938c.)

position effects show that the first units and the last units in the maze* are less difficult than those in the middle, exactly as in the case of verbal material. Husband's (1929)

*For readers interested in the learning of mazes apart from their use as instruments for studying the general field of learning there is an extensive literature on the kinds of cues involved, the role of "centrifugal swing" (e.g. Bitterman and Bretz, 1946), the relative efficiency of finger versus stylus learning (Welsh and Waters, 1944), the patterns of error elimination (McGeoch and Peters, 1933), etc. A good review of early studies will be found in Woodworth (1938) in his chapter on maze learning.

results with college students learning a visual maze are shown in Fig. 19.

Role of Verbalization in Motor Learning

Human learning is seldom quite like animal learning. Language makes the difference. Even in the learning of such a highly motor task as a maze, human subjects rely heavily on language. Warden (1924), for example, reported the frequent use of a verbal formula on the part of his subjects. The subject guided himself through the maze by saying, "First a right turn, then a left turn, then another right," etc. Other subjects used visual images of the maze. Sometimes the subject followed "the lead of his hand" without consciously organizing his movements ("motor learning"). The relative efficiency of subjects using each of these methods is shown in Table 5.

TABLE 5

MAZE LEARNING WITH VARIOUS TYPES OF APPROACH (DATA FROM WARDEN, 1924)

Method of Learning	No. Using	Average No. of Trials to Learn	Range
Word reaction	25	32.2	16-62
Visual imagery	18	67.9	41-104
Motor reaction	17	123.9	72-195

The "verbal" learners showed a clear superiority over the other two groups. This outcome may be due to the superiority of this technique, or it may be that superior individuals are more apt to employ this particular method of learning.

Other evidence of the importance of verbalization is furnished by L. M. Thompson (1944). The task was the assembly of a mechanical puzzle. Six groups of children were given different amounts of aid toward verbalization of the procedure. As shown in Table 6, the greater the verbalization, the more rapid the learning.

TABLE 6

ROLE OF VERBALIZATION IN LEARNING FROM DEMONSTRATION (FROM THOMPSON, 1944)

Group	Procedure	No. of Subjects Learning	Average No. of Trials
1	Silent demonstration. Child prevented from verbalizing by being required to count.	3	25
2	Silent demonstration. Child describes proceedings orally.	22	22.00
3	Demonstrator describes partly. Child watches silently.	25	16.16
4	Demonstrator describes fully. Child watches silently.	25	14.12
5	Child describes process. Teacher watches but makes corrections when child's description is in error.	25	12.44
6	Same as group 5 except that blocks are numbered in the order in which they are to be assembled.	25	9.52

THE ROLE OF MOTIVATION IN HUMAN LEARNING

Research with human subjects has added much less than that with animals to the analysis of basic issues concerning the relation between motivation and learning. This is due in part to the fact that, whereas with animals we can subject to experimental control such basic drives as hunger, thirst, or sex, we must, in the case of human subjects, deal with complex acquired motives that are little understood.

The earliest work on the problem of motivation in human learning was the demonstration of the importance of intent to learn. The study of Myers (1913) is a good example. The task assigned the subjects was to count the number of O's distributed among letters printed in color on colored paper. Subsequently the subjects were asked questions about what other letters were present and about the color of the paper and the letters. Their inaccurate answers indicated that they failed to learn much of the material to which they had been exposed but which they had not been instructed to learn. Many other experiments indicate the su-

periority of intentional learning (e.g. Bromer, 1942, and Huang, 1944).

Even without explicit instructions from the experimenter, subjects often learn under self-instruction. This is brought out in Jenkins' (1933) study. Although his subjects were not instructed to learn the material they read, ten of them reported deliberate and self-instructed attempts to learn, and no subject failed to report the presence of occasional self-instruction. Self-instruction may account for the negative results reported by Biel and Force (1943) who found that the group instructed only to observe the syllables presented to them learned as many as the group instructed to learn the syllables.

Considerable circularity is involved, however, if we contend that low memory for material learned incidentally is due to lack of motivation, but seek other possible motivating factors when sizable incidental learning is obtained. To get around this problem Postman and Senders (1946) suggested that we draw a distinction between "explicit" and "covert" instructions and avoid the distinction between "intentional" and "unintentional" learning. In their study they systematically varied the instructions to the subjects. With no instructions only general comprehension of the material was attained, whereas instructions that covered details of content, details of wording, or the sequence of individual events in the material to be tested produced highly specific learning.

Other evidence for the importance of motivation in human learning comes from the immense number of studies showing that learning was facilitated when this or that motivation was employed with adults or children. Positive evidence is valid here, but when negative results are obtained (as when Rubin-Rabson, 1941a, reported that musicians did not learn faster when they were given cash rewards) we do not know whether the incentive was inadequate or whether motivation was aroused but did not affect learning.

Since much basic work remains to be done on how complex human motives are acquired and how they affect learning, the studies mentioned here will be illustrative only. In a widely quoted study, Hurlock (1925) indicated that school children showed large and consistent improvement in the learning of arithmetic problems when publicly praised for their performance, but adverse effects when reproved or ignored. Another well-known study is that of Sims (1928) on the role of competition in learning. Sims had two subgroups compete with each other; the subjects were told the scores of each subgroup but not their own individual scores. These results were compared with those of groups in which each subject had a personal rival and the subjects were told their own scores and those of their rivals. His results indicated that both forms of rivalry are superior to those of a control group with no rivalry, and that individual rivalry is more motivating than that between groups.

An important type of motivation in many human studies is based on competing against one's own record. Experiments here have usually gone under the name "knowledge of results." The classical study on this problem is that of Thorndike (1927) who had his subjects try to draw a line 4 inches long. A group of 7 blindfolded subjects drew 400 times with no indication of whether they drew the line correctly. The errors averaged almost an inch at the beginning of the experiment and remained practically the same at the end. The subjects were then given 25 more trials, with an opportunity after each trial to open their eyes and check the line they had drawn. In only 4 trials were they able to reduce their error to $\frac{3}{16}$ inch.

Thorndike's experiment also calls attention to the importance of information as a motivating condition in human learning. The role of information was not clearly understood among early workers. For example, electric shock was assumed to be a punishment, as it frequently is in animal

experimentation. But it was found that shock, if given when the correct response is made, helps bring about fixation of the response. Its informative role exceeds its function as a punishment. This was brought out clearly in the experiment of Bernard and Gilbert (1941) on human maze learning. Alleys in which shock was received were eliminated more readily than those in which no shock was received. They concluded from these and similar results:

From the evidence available it seems reasonable to postulate that any well defined stimulus introduced consistently in connection with either right or wrong responses will tend to favor their repetition if they are right or their elimination if they are wrong, provided that the stimulus is not of such type or strength as to introduce a distracting effect. . . .

In human subjects, knowledge of the significance of a "punishment" stimulus appears to mean much more than direct affective reactions to the stimulus. [Pp. 184-185.]

Work on this topic has assumed such proportions that a brief review of it would be completely inadequate. Fortunately, however, this topic has been thoroughly covered in a review by Postman (1947). The interested reader is also referred to the critique of Postman's article by Stone (1948).

The one area of research on motivation in which human experimentation has played a significant part has concerned Thorndike's (1933) "spread of effect" phenomenon. "Spread of effect" was obtained when subjects were asked to respond to each word in the reading of a long list of words by giving the correct associated number between 1 and 10. Arbitrarily the experimenter said "right" after some combinations and "wrong" after others. Not only was there a greater tendency for the same number to be given as an associate on subsequent trials when the experimenter had announced that the number was "right" and less tendency when he had said "wrong," but also the effect was not restricted to the rewarded or punished pairs

but showed a "spread" to words preceding and following the reference word-number pair. The type of curve obtained is illustrated in Fig. 20. Thorndike interpreted his results to mean that the after-effect of reward or punishment is not highly specific but "irradiates" to adjacent associations.

Subsequent experimenters have confirmed the empirical results of the experiment but

FIG. 20. "Spread of effect" gradient. Percentage of repetitions of word-number pairs when reward pair (labeled "Right" by experimenter) is preceded or followed by punished pairs (labeled "Wrong" by experimenter). (From Thorndike et al., 1933.)

have quarreled with the interpretation. Two interpretations are of especial interest. Zirkle (1946) stressed perceptual factors, finding that, the more isolated the rewarded response, the greater the repetition of correct responses and the steeper the gradient of errors. This explanation is closely related to the theory of Wallach and Henle (1941, 1942) that the avoiding of items interferes with the subject's memory for wrong responses and contributes to his tendency to repeat them.

A quite different explanation was advanced by Jenkins and Sheffield (1946). They believed the spread of effect to be due to the subject's guessing habits: his tendency to repeat the same sequences of responses from trial to trial. A repeated rewarded response thus insured that the errors following reward would frequently be preceded by the

same response. Evidence is presented by the authors that the gradient failed to appear when the rewarded response itself was not repeated, but that the typical gradient was obtained when the rewarded response itself was repeated.

The interpretation proposed by Jenkins and Sheffield was extended by Smith (1949), who pointed out that people do not use numbers (or other responses) in a random fashion. These deviations from randomness can be used to predict both the before- and after-gradient in the spread-of-effect experiment. Smith set up a modified experimental situation that allowed him to assign the "correct" and the "incorrect" numbers. When the assignments were from a table of random numbers, there were no gradients; but, when the assigned numbers reflected sequential response tendencies (empirically observed), the gradients promptly appeared. These results seem to indicate that learning factors influence only the extent to which the rewarded response is repeated, and that spread of effect around the rewarded response is an artifact of the experimental situation: it is the spurious result of non-random response habits in the learner.

INDIVIDUAL DIFFERENCES

Much of the literature on human learning is presented in terms of the broadest types of generalization possible. But every worker in the field is struck by the wide variability from individual to individual in even the simplest types of learning. Greatly needed are systematic investigations of the sources of variability. The three factors that have been most extensively studied are age differences, sex differences, and differences in mental ability.

Age Differences

The available evidence on learning at various chronological ages has been summarized by Munn (1946). Learning of the conditioned response variety is found even

before birth. Findings concerning changes with age in the speed of conditioning, however, have been inconsistent, some studies showing more rapid learning with increasing age, and others obtaining diametrically opposed results. In motor learning there appears a rather consistent trend of improvement in the *performance* of learning tasks with increasing age (cf. e.g. Pyle, 1925a) but Munn concluded that there is no clear evidence that a given amount of practice causes a greater *improvement* with older than with younger individuals. Munn did not, however, stress the methodological difficulties inherent in such studies of providing a learning test in which the "gain scores" are of adequate reliability. A test may be quite reliable over a wide range of abilities and still be of practically zero reliability as a measure of gains during practice sessions. Evidence on the reliabilities of the gains is not given in the studies reported, and hence the lack of correlation may be attributable primarily to the attenuation produced by low reliability. Other questions that must be raised are whether the duration of practice was long enough to be significant and whether the range of items was great enough to permit the better learners to indicate the true extent of their learning.

Studies of verbal learning and problem solving have rather consistently shown a progressive improvement in learning with increased age (cf. Heibredner, 1928; Stroud and Maul, 1933). Even in these studies, however, we cannot be sure that the changes in learning with age are attributable to improved learning *ability* rather than to more extensive previous experience or to greater motivation to learn.

From maturity to old age most studies show a continuous decline in speed and accuracy of learning. Typical are the results of Miles (1933) on an alphabet substitution task (Fig. 21). Again it is difficult to know how much of the decline is attributable to changes in learning ability and how much to differences in motivation. A widely quoted

investigation of learning during adulthood is that of Thorndike et al. (1928). They concluded that considerable decline occurs in those of the tests designed to measure "basic modifiability," but that in school subjects the learning of older subjects shows relatively little decline. The absence of decline in the latter is explained as perhaps being due to greater motivation and increased organizing skill. Relatively few cases were involved

of completely new verbal habits. The third task required learning false products (like $2 \times 4 = 9$) where old associations had to be broken down and new ones substituted. The subjects had to learn to give the second part of the pair or equation upon seeing the first.

The motor learning task in which prior learning could be used showed less loss with age than the task in which the subjects were required to learn new habits that conflicted with those they had already acquired. Similarly with the verbal material, the tasks involving old associations were better mastered with increased age than were those in which the old associations had to be unlearned and new ones acquired. It is Ruch's (1934*b*) interpretation that senescence brings about lower functional plasticity of nervous tissue. As a consequence, older people should encounter greater difficulty in learning tasks whose mastery demands a greater amount of reorganization of previously formed habit patterns than in learning tasks whose mastery demands less of this reorganization.

Much work remains to be done to permit a satisfactory explanation of the changes in learning with age. A part of the initial improvement and subsequent decline may be explicable on grounds of physical maturation and degeneration, although little support for this explanation is furnished by Hunter (1934) in his review of the evidence (based mostly on animal studies). Particularly difficult to separate are the concomitant variations in motivation, transfer of past learning to new situations, and true changes in learning ability per se. The disentanglement of these factors is a genuine challenge.

Sex Differences

In many studies of the learning of school children no systematic differences between the sexes have been obtained (Munn, 1946). Some studies have found differences favoring males, and others favoring females. Any consistent differences have usually been explicable in terms of differences in interest in

FIG. 21. Scores in learning a substitution task, for groups of various ages. (Data from Miles, 1933.)

in some of the crucial comparisons, however, and the representativeness of many of the samples was certainly not established.

The actual extent of the decline of learning ability with age is much affected by the type of learning task involved. One of the most interesting studies on this problem is that of Ruch (1934*a*). He chose tasks representative of different types of psychological function. Two motor tasks were used. One, a direct-vision pursuit rotor, required the use of habits previously acquired by the subject in the normal course of his activity. The other was a mirror-vision rotor that required breaking down previous habits and building up new ones. Three types of verbal learning were also employed. The first, paired associates, involved the use of old associations between logically connected words (like horse-sheep). The second, nonsense equations (like $F \times P = V$), required the learning

the material and consequent practice. The way in which such differences in content may affect differences between the sexes in learning is illustrated in a study by Pyle (1925*b*). Boys and girls of high school age were compared on the learning of several types of prose material: some referred to technical processes (physical, chemical, and mechanical), some to fur and fur-bearing animals, and some dealt with geography. The boys learned the technical material somewhat more rapidly than did the girls, but the girls learned the material about furs somewhat more rapidly than did the boys. Similar evidence of differences between the sexes for particular items of content in recalling a motion picture has been reported by Conrad and Jones (1931). Experiments have not supported the common belief that girls learn more rapidly than boys during the period before adolescence (McGeoch, 1942).

Intelligence Differences

Since mental age and chronological age are highly correlated during the first fifteen or sixteen years of life, any increments with age in learning ability are concomitantly associated with increments in intelligence. Thus, when mental age is partialled out of the correlation between learning and chronological age, the correlation is markedly reduced (Roberts, 1933). But, when chronological age is partialled out, the correlation between mental age and learning scores remains quite high. Studies almost invariably show poorer learning by the mentally retarded (Werner, 1944; Gardner, 1945; Kulcinski, 1945). After maturity is reached, the correlation between learning scores and intelligence tends to be fairly high for complex ideational tasks and for verbal learning, but rather low for simple motor learning (McGeoch, 1942). A good bibliography of studies of the relation between intelligence and learning ability is provided in the paper by Thompson and Witryol (1946). They believe their own results support the contention of a sizable relation between IQ and

learning ability, but their data in support of this point are not completely convincing. They report, for example, a correlation of 0.027 between IQ and trials to learn a high-relief finger maze, but they raise this to 0.731 by correcting for range!

A close relation between intelligence and learning ability is implied in most definitions of intelligence. In fact, intelligence is frequently defined as "the ability to learn." This definition has recently been challenged by a number of writers. Simrall (1947) states: "Operationally, the theory that intelligence is the ability to learn means that the sum or average of the scores made on a number of tests given once are highly related to gains due to the practice of a test or tests similar to those which compose an intelligence test" (p. 41).

Mental ability tests (Otis Group) were administered by Simrall to 95 high-school students before the experiment. Then the subjects were given intensive practice on spatial (backward writing) and perceptual (jumbled words maze) tests. An alternate form of the Otis test was given at the end of practice. Her results indicated that, although initial performance on the tests correlated 0.60 with mental age, the *gains* due to practice had very low correlations with intelligence test scores (-0.079 for the perceptual test and $+0.277$ for the spatial test). She concluded from these data that "under no circumstances do these data support the hypothesis that the ability to learn these tests is related to mental age" (p. 41). She presented no data on the reliability of the *practice gains* (not to be confused with the reliability of the test scores themselves). To establish the fact that correlations of the magnitude of 0.277 (reported on the spatial test) are not indicative of significant relation between intelligence and ability to learn requires extremely reliable measures of gain, since otherwise the low correlation may be due merely to attenuation. Nevertheless the most comprehensive review to date of

this topic by Woodrow (1946) concludes that "the ability to learn cannot be identified with the ability known as intelligence" (p. 148).

Tilton (1949) reported that, when a test having adequate reliability and suitable difficulty is used to measure gains in learning, a correlation of about 0.50 is obtained between amount of history learned during a school year and scores on the Otis intelligence tests. This correlation is about the same as that obtained between intelligence test scores and initial score on the learning test. Tilton points out that a very high correlation is not to be expected because of the influence of other factors such as motivation and because of the specialization of learning ability.

Is There a "Learning Ability"?

Questioning the definition of intelligence as the "ability to learn" also raises the fundamental issue of whether there is a unitary "ability to learn." Research on this problem has made such a general ability appear doubtful (Woodrow, 1946). Low intercorrelations among learning tasks have been the general rule (Husband, 1939; Brace, 1941; Carlson and Carr, 1940). The methods of factor analysis have also failed to reveal any general learning factor (Woodrow, 1940; Heese, 1942). Heese was able to isolate three common factors — (1) speed of movement, (2) memory, and (3) perception — factors certainly not unique to learning scores. Woodrow (1946) concluded from his review of the evidence:

In general, the statistically discovered high degree of specificity of practice gains may be interpreted as meaning that each particular activity can best be performed by methods which to an important degree are peculiar to that activity. Improvement with practice depends very largely upon the adoption at repeated trials, to a degree varying with the individual, of these particular methods. [P. 157.]

Changes in Variability with Practice

An early review of the problem of whether individual differences increase or decrease with practice was made by Kincaid (1925). Later studies have not served to resolve the differences in results obtained: they show that variability increases (Ryans, 1939), decreases (Ehrlich, 1943*b*), or stays the same (Owens, 1942) with practice. There is no obvious reason for the discrepancies among different studies. Greene (1943) believes they may be attributable to variation in the complexity of the learning task.

There are serious problems of method involved in determining the appropriate measure of variability — whether absolute or relative, whether in terms of units performed or rate of performance, etc. The problem is further complicated by the lack of true scales for the measurement of learning. Such scales must have absolute zeroes and possess units of equal size throughout the range if the questions raised are to be answered adequately. A discussion of method in experiments of this type will be found in Anastasi (1934) and Woodworth (1938). Until some of the problems of adequate scales of measurement are solved no clear-cut generalization is likely to emerge. Hunter (1934) prophesied that when adequate procedures become available it will be found that individual differences in degree of skill increase rather than diminish with training.

EFFICIENT METHODS OF LEARNING

A high percentage of the studies of human learning have sought the conditions giving greatest efficiency in learning. These studies have not usually been focused on the analytical study of principles, but in many instances they do isolate factors having relevance in a systematic theory. In the present treatment stress will be placed on those investigations that are oriented toward determining such general factors.

DISTRIBUTION OF PRACTICE

Should material be studied continuously or learned in a series of short sessions? This practical problem has theoretical importance when viewed as an analysis of the roles of learning, motivation, and work decrement in acquisition.

Ebbinghaus (1885) found it better to spread practice over 3 days than to concentrate a greater number of trials into one sitting. Most subsequent investigations favor some form of distributed practice, but there are enough studies favoring massed practice to indicate that there are certain factors that favor massing of practice and others that favor distribution of effort. Accordingly, the task is to ascertain which factors are which, and how they interact.

Two basic designs are commonly used in research on this problem. In the first design, single readings are separated by varying intervals of time. This method is illustrated in the design used in a recent study by Kientzle (1946), shown in Table 7. In the

and Hilgard, 1938). In still others the time between trials is kept constant but the time between items in the series is varied (e.g. Hovland, 1938c).

Material

The nature of the material learned does not in itself seem to affect the advantage of distributed practice. For acquisition of conditioned responses, Calvin (1939) showed that 3 trials per minute were superior to 9 or 18 per minute. A somewhat similar but less striking difference was found by Humphreys (1940b). Two blocks of 48 trials, each with an interspersed rest period, gave better results than a single block of 96 trials presented without rest period. Humphreys, Miller, and Ellson (1940) attributed this result to "decremental" rather than "expectancy" factors.

Studies of verbal learning have generally given the advantage to distributed effort. The early studies of Ebbinghaus and Jost have already been mentioned. Studies by

TABLE 7

	Practice	Rest Period	Practice	Rest Period	Practice	Rest Period	Etc.
Group 1	Trial 1	None	Trial 2	None	Trial 3	None	Trials 4 to 20 with alternation of trials and rest periods as before
Group 2	Trial 1	10 seconds	Trial 2	10 seconds	Trial 3	10 seconds	
Group 3	Trial 1	60 seconds	Trial 2	60 seconds	Trial 3	60 seconds	

other design, varying numbers of trials are given at each sitting with a constant time interval between successive blocks of trials. Such a design is illustrated in Jost's (1897) study (Table 8).

Lyon (1914) and Hovland (1940b) will be discussed shortly. To these should be added the studies of Bumstead (1940, 1943) on the learning of prose and poetry. He found (1943) that, the longer the interval between

TABLE 8

	Practice	Rest Period	Practice	Rest Period	Practice	Rest Period	Etc.
Group 1	Trials 1-2	24 hours	Trials 3-4	24 hours	Trials 5-6	24 hours	7-8, Rest, 9-10, Rest... 23-24
Group 2	Trials 1-4	24 hours	Trials 5-8	24 hours	Trials 9-12	24 hours	
Group 3	Trials 1-8	24 hours	Trials 9-16	24 hours	Trials 17-24		

In some studies both the interval between blocks and the number of trials within a block have been varied. In others the number of trials within a block is kept constant but progressively larger or smaller intervals are interpolated between blocks (e.g. Doré

readings, the more rapid was the learning. His results, presented in Fig. 22, show an increase in learning time with decreased rest intervals that is even more pronounced than the increase due to greater length of material.

The majority of studies of motor learning have also shown distributed practice to be superior to massed. When equal units of learning are employed, with varying pauses between trials, the results usually show greater benefit from increasing length of pause, up to a maximum beyond which there is either no additional benefit or an actual reduction in benefit. For the pur-

Travis (1937) believed that a maximum is reached at about 20 minutes, and that longer intervals are less effective.

When the rest pauses are kept uniform it appears that there is usually an optimal length of practice period peculiar to each motor task. Pyle (1928) found that in a substitution task a 30-minute practice period was optimal, being superior to either the

FIG. 22. Tridimensional drawing showing difficulty of learning (represented by height of bars) for various lengths of material and with varying intervals between readings. (Data from Bumstead, 1943.)

suit rotor (1-minute trials), Doré and Hilgard (1937) found that 11 minutes between trials was better than 3 minutes, which was in turn better than 1 minute. Lorge (1930), using a mirror-drawing task, found both 1-minute and 1-day intervals between trials considerably superior to massed practice, but he found little difference between the two distribution intervals. Kientzle (1946) got similar results with an inverted alphabet task: Distributed practice was more effective than massed, and the predicted upper limits of learning were a negatively accelerated function of duration of rest interval. The curves flatten out in the vicinity of 1 minute, which confirms the lack of difference in Lorge's data. For the pursuit oscillator,

shorter (15-minute) or the longer (40- and 60-minute) sessions. For the manual pursuit rotor, Travis (1939) found 2-minute practice sessions superior to 1-minute and 4-minute lengths. Snoddy (1945) reported that, in learning to trace a star pattern reflected in a mirror, the group that had only 1 trial per day performed better than the group that had 10 trials per session with 48 hours between sessions.

The short intervals between trials necessary to reach maximal advantage of distributed practice may help explain the results of Franklin and Brozek (1947) who found no difference between 3, 2, and 1 trials per day and 3 trials per week in pattern tracing and other psychomotor tasks.

Important early articles on the distribution of practice are those of Book (1908), Pyle (1914), and Lashley (1915).

Factors Favoring Massing of Trials

Massing is favored when a period of time is required to "get set" or to "warm up." As many can testify, when a writer works at his job only when he can squeeze in the time between other activities he starts each writing session "cold" and uses much of his time in warming up to the task (getting set or oriented toward what he has done and still has to do, etc.). This contrasts with his behavior as the deadline approaches and the writing is crowded into successive days. He then stays warmed up to the end. The relevance of "warm up" to distribution of practice is stressed by Bell (1942).

A second factor favoring massing of practice is the fact that with very long intervals so much is forgotten that one has to start practically from the beginning on each new trial. This factor has been stressed by Cook (1944).

A third factor is the difference in variability reported under massed and distributed practice. Erickson (1942) has summarized the studies showing that distributed practice tends to produce a fixation of response, whereas massed practice results in greater variability of behavior. Supporting this hypothesis were his own results: a puzzle box that allowed for great variability of attack was learned more quickly with massed practice. Indirect support has also been furnished by Garrett's (1940) study showing greater variability in the complex tasks and the superiority of massed practice for these materials.

Factors Favoring Distributed Practice

In some situations the superiority of distributed practice may be due to surreptitious extra practice in the form of overt or implicit rehearsal during the rest pause. This can be prevented by filling the interval with controlled activity, provided this does not

interact with the task itself. (See below for a discussion of this problem as it applies in reminiscence.) That rehearsal is not a sufficient explanation is established by the fact that distributed practice is beneficial in many situations where rehearsal is prevented.

Undoubtedly many of the results that show an advantage for distributed practice are attributable to work decrement rather than to learning factors. In some studies fatigue produces an artificial lowering of performance, which is overcome by interpolation of rest pauses. Hull (1943) sought to bridge the gap between work decrement and learning principles by the concept of "reactive inhibition." He postulated that all effortful responses, whether reinforced or not, produce a tendency to avoid the repetition of the response. Reactive inhibition is thus a negative drive state similar to what is usually called fatigue. The greater the effort involved in the response, the greater the amount of inhibition. Reactive inhibition develops more rapidly, the shorter the time interval between reactions. Reactive inhibition is believed by Hull to dissipate as a simple decay function of the amount of time allowed for rest, a relation indirectly verified by the experiment of Kimble and Horenstein (1948). An excellent formulation of the implications of this concept for distribution of practice in motor skill is given by Ammons (1947*a*). The reader is also referred to the comprehensive summary by Solomon (1948) of the work on the relation between work-decrement factors and learning.

In some simple types of learning, barriers to response similar to the phenomenon of "refractory phase" in nerve-muscle studies have been found. Telford (1931) showed that there is a tendency to avoid repeating responses at short time intervals and also that serial reaction time is increased with closely spaced stimuli. In a very limited number of studies this factor may be responsible for poor learning under massed

practice. Another related explanation derived from physiology is that of some kind of neural after-effect, called by Müller and Pilzecker (1900) *perseveration*. Woodworth (1938) supported this type of explanation:

The muscle profits from an alteration of exercise and rest and cannot be forced into rapid increase of strength by massing the exercise. The size and internal structure of the muscle fibers improve after exercise, and this nutritive after-effect takes some hours to reach completion. The same after-effect, occurring in the nervous system, may "consolidate" the memory trace of an activity . . . and this consolidation may well be one of the factors in giving advantage to spaced learning. [P. 216.]

Prolonged practice can easily result in reduced motivation with attendant reduction in learning. An alternation of work and rest appears to increase alertness and attentiveness. This may be a factor in the alleged greater effectiveness of distribution of practice with meaningless than with meaningful material. Undoubtedly this motivational factor operates in some prolonged learning series that would, consequently, benefit by distributed practice. Data difficult to explain without resort to motivation were obtained by Gentry (1940). He found that the introduction of spaced practice after massed practice rapidly brought the group to the level of a group that had formerly had spaced practice right along, and vice versa.

Perhaps the most important factor favoring distribution of practice is the chance for interferences built up during learning to dissipate during the rest pauses. Unfortunately it is not easy to disentangle the effects of interferences from those of fatigue and motivation.

As one means of trying to isolate the interference factor, Hovland (1938c) presented nonsense syllables at two different rates — one every 4 seconds and one every 2 seconds — and compared the effectiveness of

distributed practice under these conditions. If the height of serial position curves is used as a criterion, both intraserial interference and the advantages of distributed practice were greatly reduced at the slower rate of presentation (Table 9). As would be ex-

TABLE 9

MEAN NUMBER OF TRIALS REQUIRED FOR LEARNING BY MASSED AND BY DISTRIBUTED PRACTICE AT TWO RATES OF SYLLABLE PRESENTATION (FROM HOVLAND, 1938c)

Two-Second Rate of Presentation		
	Mean	σ_M
Trials required by massed practice	14.89	0.93
Trials required by distributed practice	11.18	0.87
Difference	3.71	
σ_{diff} .	1.05	
C.R. σ	3.53	
Four-Second Rate of Presentation		
	Mean	σ_M
Trials required by massed practice	6.78	0.56
Trials required by distributed practice	5.85	0.54
Difference	0.93	
σ_{diff} .	0.77	
C.R. σ	1.21	

pected, however, the learning at the slower rate of presentation required fewer trials; hence there is not complete proof that fatigue and motivation remained unaffected. In another study Hovland (1939b) compared the effect of massed and distributed practice on serial material (where high interference is to be expected) with paired-associate material (where less interference would be predicted theoretically). The advantage of distributed practice was more marked with the serial material. When the rate for paired associates is made sufficiently rapid, however, distributed practice is more economical than massed (Hovland, 1949).

The three factors of motivation, work decrement, and interference all tend to operate in the same direction when the quantity of material to be learned is increased. Thus it is not surprising that the advantage of distributed practice appears to increase with increased length of lists. This was first shown by Lyon (1914). His results are presented in Fig. 23. They have been con-

firmed by Hovland (1940*b*) who showed that the increase in length is accompanied by increased intraserial interferences, which were reduced under conditions of distributed practice. His results are shown in Fig. 24.

WHOLE-PART LEARNING

A practical problem is whether to learn an entire sequence from beginning to end or

FIG. 23. Advantage of distributed practice over massed practice (in minutes saved) relative to length of time required for learning by massed practice. Data from Lyon (1914). (From Hull et al., 1940.)

to break the whole into parts and to learn each part before combining them into the total sequence. Early workers seemed to think that this problem had a universal answer. They asked, "Which is superior, whole or part learning?" Phrased in this way, the question has no answer. A number of the early studies, starting with the work of Steffens (1900), showed the whole method to be more effective than learning by parts. But other studies, beginning with those of Pechstein (1917), found the part method more effective. In the absence of a universal superiority of one or the other method we must seek the conditions determining the relative advantage of each. Some of these factors will be mentioned.

Motivation

Motivation is obviously relevant. How it might operate has been described by Kingsley (1946):

With the whole method much more time and work is required before any results of learning are manifest. One may read a long poem through a dozen times without being able to recite a single line, while with the same amount of work by the part method the learner would probably be able to recite several stanzas. For this reason a learner gets the feeling of success sooner with the part method. The recitation of parts become sub-goals, which provide a series of steps toward the main goal, the ability to

FIG. 24. Composite curves showing mean number of failures for various syllables during learning of three lengths of list by massed (solid line) and distributed (dashed line) practice. (From Hovland, 1940*b*.)

recite the whole. These intermediate goals and the satisfactions derived from reaching them no doubt favor the part method, particularly with children and with adults unaccustomed to rote memory work. The whole method is likely to be discouraging because the learner has to work so long before he can see any returns for his effort. He may feel that he is not making any

progress or that he is wasting his time with this "new-fangled method." This attitude operates against the success of the method. The experienced and informed learner knows that the readings in the whole method are not a waste of time. He knows, as Ebbinghaus demonstrated, that every reading yields an increment of learning, which is spread over the whole, and that if he continues, he will eventually find the whole selection rising above the threshold of recall. He knows that while he must work longer before results are manifest, the final returns fully justify his patience and endurance. [Pp. 314-315.]

Material

No systematic differences in the relative advantage of the whole method for different kinds of material have been obtained. Mazes, for example, were found to be learned more rapidly by the whole method (E. M. Hanawalt, 1934), by the part method (Pechstein, 1917; Barton, 1921), and about equally rapidly by the whole and part method (Cook, 1936, 1937). Nonsense syllables were learned more rapidly by the whole method (Steffens, 1900) and by the part method (Pechstein, 1918), and without decisive difference (Pentschew, 1903). Similarly, for poetry the whole method was found superior by Steffens (1900) and by Meyer (1926), the part method by Winch (1924) and by Reed (1924), and the two methods were found to be about equal by G. O. McGeoch (1931). In the case of the complex skills required in memorization of music, both Rubin-Rabson (1940*b*) and O'Brien (1943) found that some subjects learn better with the whole method, others with the part.

Curiously, the amount of material in relation to the advantage of whole or part learning has not been studied very extensively. There is probably an upper limit to the amount of material that any given learner can grasp as a unit, and there is a lower limit within which subdivision into parts is probably inefficient. McGeoch (1942) stated that the part method is superior if the dif-

ference between the time required to learn by the whole method and the time required to learn the parts separately is greater than the time required to combine the parts. Orbison (1944) tested this point experimentally, using the hypothesis that increase in length of list involves disproportionate increase in interference. Lists of 8, 12, 16, and 24 paired associates presented in random order were learned by the whole and by the part methods. At no length was the whole method superior, but as the length of list increased the part method became increasingly superior to the whole method. His results are presented in Table 10.

TABLE 10

MEAN NUMBER OF PRESENTATIONS PER PAIR REQUIRED TO REACH CRITERION OF ONE PERFECT RECITATION (FROM ORBISON, 1944)

Number of Paired Associates	Whole Method	Part Method	Difference
8	18.75	18.67	0.08
12	20.58	16.96	3.62
16	28.75	23.42	5.33
24	38.50	25.21	13.29

The relation between length and the advantage of whole over part may help to explain the fact that, when distributed practice is employed in learning, the whole method is superior (Pechstein, 1917; Winch, 1924; Crafts, 1930; Davis and Meenes, 1932). It is well known that the relation between length and number of trials for learning is much more linear with distributed than with massed practice. If, for example, 50 trials are required to learn a 20-unit list by massed practice and 15 trials are required to learn a 10-unit list, the division into parts may take advantage of the relative ease of learning the shorter parts. On the other hand, if with distributed practice the 20-unit list requires 18 repetitions and a 10-unit list requires 8, the advantage of subdividing may be sufficiently small to permit

other advantages of the whole method to manifest themselves.

By and large, it appears that the greater the continuity and meaningfulness, the more advantageous is the whole method. When poems are understood as a whole, the whole method was found by Northway (1937) to be best for memorization. When the parts are better integrated than the whole, the part method is superior (Seagoe, 1936*a, b*).

Individual Differences

Both Pechstein (1926) and G. O. McGeoch (1931) showed that, the higher the level of mental development, due to age and higher IQ, the greater the superiority of the whole method. Similar results were obtained by Rubin-Rabson (1940*b*) for memorization of piano music. She reported that the ability to work comfortably with larger units is specific to the more capable subjects.

Stage of Learning

Practice with both methods appears to bring about a superiority of the whole method. Steffens (1900) found that the advantages of the whole method became evident only when the learner had become accustomed to using this method. Similarly Lakenan (1913) found that at first the part method was better but after practice the whole method proved superior.

Summary

Hunter in his handbook review (1934) concluded: "We cannot generalize and say without qualification that either method is superior to the other" (p. 518). The present writer will be somewhat more rash and attempt the following summary: In a practical situation, factors like fatigue, interest, etc., may play an important part in the relative advantage of whole or part learning. But, if these are held reasonably constant, the best advice seems to be to learn by using the largest units that are meaningful and within the individual's capacity. The older the individual, the higher his in-

telligence, the more practice he has had, the greater is the size of the unit he is able to handle. This generalization is in line with the results of Cook, who found that individuals differ in the size of the unit they can handle with maximum efficiency, and that the size of this "most favorable unit" increases with practice (Cook, 1936). When the size of the unit to be learned was smaller than the optimal length, learning by the whole method was most efficient, but, when the size was larger than the optimal length, the part method was superior (Cook, 1937).

RECITATION

Ebbinghaus, in his experiments, recited the words he knew and then looked up those he did not know. Witasek (1907) showed that this method requires fewer trials than does the method of reading the material over and over until it can be recited completely. Subsequent work has thoroughly confirmed these early observations. The best-known experiment on this problem is that of Gates (1917), who compared the effectiveness of various subdivisions of the total learning time between reading over the material and attempting to recall it. The results he obtained with eighth-grade school children on the learning of nonsense syllables and short biographical prose selections show a pronounced advantage for recitation (Table 11). That the learning of nonsense syllables is affected more than the learning

TABLE 11

INFLUENCE OF DIFFERENT AMOUNTS OF RECITATION UPON LEARNING (FROM GATES, 1917)

Percentage of Total Time Spent		Materials Learned	
In Reading	In Recitation	Syllables	Biographies
100	0	65.4	87.8
80	20	92.2	94.6
60	40	99.7	105.0
40	60	105.5	105.5
20	80	137.3	106.8

of prose has been confirmed by later investigators. Woodworth (1938) attributed the small advantage of recitation in prose to the fact that in rereading such material time after time one inevitably anticipates what is coming and consequently recites while reading.

The advantages of recitation probably depend upon a number of factors. First, recitation arouses a more active attitude on the part of the learner. This point was brought out clearly by Hovland, Lumsdaine, and Sheffield (1949). Soldiers were taught the phonetic alphabet, in which word equivalents are learned for letters, e.g. *Able* for *A*, *Baker* for *B*, *Charlie* for *C*. The standard method of instruction was to employ a film in which each letter was presented on the screen, followed by its word equivalent. After a number of individual letters were presented, a portion of the list was repeated by the narrator. In the "participation" method the same film was used, but, instead of the narrator's repeating the words in groups, the trainees were instructed to recite aloud the word equivalent when the letters were presented. The effectiveness of this procedure is shown in Fig. 25.

A second factor favoring rehearsal is the fact that the material is learned in the way it is going to be used. This closely relates to the problem of whole-part learning discussed above. Gates says, "In reading, the syllables are handled more as isolated terms; the learner tries to imprint each by itself. In recitation more of an attempt is made to make the material over into some sort of pattern, a more or less highly organized structure" (p. 75).

Lastly, recitation is probably effective in part because of motivational factors. Recitation guarantees that the effort will be expended where it is needed most, since the subject will be aware of what he knows and what he does not know. When he gets the material correct immediate satisfaction ensues, and when he is in error he is imme-

diately apprised of this fact and motivated to improve.

There is not complete agreement on the optimal point at which recitation is to be introduced. Woodworth (1938) stated that "recitation, attempted too early, wastes time and may establish errors" (p. 211). He found reading to be most effective in the first or exploratory stage of learning, whereas during the organization and mechanization stages recitation favored rapid learning. Skaggs

FIG. 25. Average number of phonetic names correctly recalled within designated periods of time per name, with and without participation technique. (From Hovland, Lumsdaine, and Sheffield, 1949.)

and Grossman (1930) found recall with prompting to be most effective after a small number of initial readings, whereas L. O. Krueger (1930) found introduction of a single recall without prompting to be most effective late in practice.

An experiment of H. A. Peterson (1944) supports Gates' (1917) finding that recitation is much less effective with meaningful prose. Peterson attempted to make the material and conditions as close to real-life learning as possible. He used regular assignments for college sophomores and tested learning by means of objective tests. His results for immediate recall are given in Table 12. The highest proportion of recall appears the least effective. Peterson pointed out that one must take into account the amount of time necessary to read and understand, and that, when learning time is not greatly

TABLE 12

RECALL WITH VARYING DISTRIBUTIONS OF READING AND RECALL (FROM PETERSON, 1944)

Condition	Number of	Number of
	Items in Immediate Recall	Items in Delayed Recall
All reading, no recall	16.03	16.26
$\frac{2}{3}$ reading, $\frac{1}{3}$ recall	16.33	15.98
$\frac{1}{2}$ reading, $\frac{1}{2}$ recall	13.94	14.46

in excess of the time required to read a passage once, devoting all the time to reading is substantially as effective as giving part time to recall.

With nonverbal materials the equivalent of recall is "imaginary practice." This has been found to be effective, although usually not so effective as direct practice. In Perry's (1939) study imaginary practice was found better than direct practice with a peg board, about equal for symbol-digit substitution and card sorting, and less effective in mirror tracing. Introduction of such practice appears to be most effective in the middle of learning of complex skills like piano playing, according to Rubin-Rabson (1941*b*). After minimal learning was reached, direct practice was more effective (Rubin-Rabson, 1941*d*). Perry has a good discussion of the nature of imaginary practice. In an experiment on dart throwing, Vandell, Davis, and Clugston (1943) found mental practice about as effective as direct physical practice (Table 13).

"Mental" practice	+4	+22

OTHER PROBLEMS

There are many other practical problems of learning that have great relevance for training. A number of these are discussed in a review by Hovland (1941) of the relation of learning principles to problems of industrial training. One of these problems is the amount and type of guidance given the learner. The most extensive work on this problem was done by Carr (1930), who also presented a good summary of the literature. Guidance given early apparently helps to establish the correct habits right from the start. Since, however, the learner will later have to perform the task without help, guidance must not continue too long, for the learner may become overdependent upon outside assistance. A recent experiment showing the role of guidance in motivating the learner was reported by Davies (1945).

Another problem is the relative efficiency of learning with the stress on accuracy or with the stress on speed. This problem was discussed by Hovland (1941) in the following terms:

... the correct pattern must be practiced from the very start, if at all possible. We must, therefore, analyze the operations to determine whether the performance at slow speeds is the same as that at high speed. If it is, we should start our training with emphasis upon accuracy so that the exactly correct performance is carried out from the very beginning. This would certainly be the situation in learning typing. No fundamental change in the nature of the movement occurs as greater speed is achieved. If, on the other hand, the operation changes significantly from low to high speeds, we should strive toward the form of the finally correct performance even if some accuracy is sacrificed. This type of situation apparently exists in learning bricklaying. Gilbreth found that an entirely different method is involved when the job is done slowly, one which hardly resembles the form used when the job is done rapidly. Speed would therefore have to be stressed from the start, even if

the work done would have to be redone by an experienced laborer. [P. 12.]

In learning ballistic movements like batting a baseball one would expect that the performance would differ markedly at slow and fast speeds. Hence, on the basis of the foregoing, it is not surprising that Fulton (1942) found that stressing speed from the beginning was superior in learning to bat a baseball. An excellent analysis of the speed-accuracy problem with a review of earlier studies will be found in a monograph by Fulton (1945).

PRINCIPAL PHENOMENA OF RETENTION

In the preceding sections the principal interest has been in changes in performance *during* practice. In the present section attention shifts to the changes in performance at various time intervals *following* a given stage of practice. When retention decreases with the passage of time, the change is referred to as *forgetting*; when retention improves, the term *remiscence* is applied.

Conditioned Responses

A great deal of anecdotal evidence points to the fact that conditioned responses once acquired are retained with little diminution over considerable periods of time (Guthrie, 1935, pp. 116ff.), but little systematic research has been done on the retention of conditioned responses. The study of Hilgard and Campbell (1936) supports the earlier informal observations in showing sizable retention over a considerable period of time. Using a conditioned eyelid response to a light stimulus, these investigators measured the magnitude of eyelid responses on 5 unreinforced trials following intervals of 1 day, 1 week, and 4, 8, and 20 weeks. Their results are shown in Fig. 26.

Verbal Learning

The classical study of the retention of verbal material is that of Ebbinghaus (1885)

for memorization of nonsense syllables. His curve of retention has become such a commonplace that it is almost invariably graphed in elementary textbooks, often labeled *the* curve of retention. Ebbinghaus' curve shows a rapid initial drop in retention followed by a gradual fall thereafter (Fig. 27).

Another widely quoted curve for retention of nonsense syllables is that of Radossawljewitsch (1907).

FIG. 26. Retention of conditioned responses at various intervals. Reconditioning retention ratio is performance on third day after retention interval divided by performance on second day of original conditioning. Ratio of retest before reconditioning compares 5 extinguishing trials after the interval with 5 at the end of the original conditioning. (From Hilgard and Campbell, 1936.)

jewitsch (1907). His curve showed a more gradual beginning drop than did that of Ebbinghaus. Waters (1941) believed the discrepancy here to be due to the fact that Ebbinghaus learned 8 lists at a time whereas Radossawljewitsch learned only 3 at a time. The latter arrangement might result in less interference and hence show higher retention.

In general, the *form* of retention curve for meaningful material (poetry and prose) is similar to that for nonsense syllables, but the *level* of retention is higher throughout. The difference in level as a function of meaningfulness of material is brought out clearly in the compilation of 18 studies employing meaningless material and 24 involving mean-

FIG. 27. Retention curve showing percentage of original learning trials saved when relearning is at various intervals following original learning. (From data of Ebbinghaus, 1885.)

ingful material prepared by Davis and Moore (1935). (See Fig. 28.)

1. *Method of measuring retention.* The extent of retention is affected by the method

FIG. 28. Retention curves. Composite of 18 studies of meaningless material and 24 studies of meaningful material. (Data from Davis and Moore, 1935; from Davis, 1935.)

of measurement. In Fig. 27 the results are based on the *savings method*: here the subject relearns, after an interval, material he has previously mastered, and the relearning is compared with the original learning in terms of time, number of trials, or number of errors. The "saving score" is often pre-

sented as a percentage referred to the original learning.

In Fig. 28 the results are based on the *recall score*, the percentage of original material that can be recalled at a later time. In a third method the individual is shown material he has learned earlier, together with items not studied earlier. He is asked to identify the items in the original material. The amount he identifies correctly is a measure of his *recognition* memory. When material has been learned in serial order, a fourth procedure is often used in which the individual is required to arrange the items in the order used in the original learning. This is called the method of *reconstruction*.

None of these measures is completely satisfactory. Recall is sometimes a rather insensitive index. Material may be entirely "forgotten" in the sense that none of it can be recalled and still it may be relearned easily and quickly, or it may be readily recognized as material once studied. The recognition method does not measure the entire sequence of events previously involved, and the deviation from the order of original learning tends to confuse some learners (Davis, 1935). The relearning method, on the other hand, encounters the objection that it is not purely a measure of retention but of learning ability as well. Using original

learning as the control time neglects the possibility of positive transfer (Bunch, 1941). Woodworth (1938) pointed out: "In strictness we should compare the relearning time, not with the original learning time but with the time it now takes to learn an equivalent lesson" (p. 10).

The most systematic study of the relation between the curve of retention and the method of measuring retention is that of Luh (1922). His subjects learned lists of

collaborators (cf. e.g. English, Welborn, and Killian, 1934) showed considerable forgetting for verbatim memory, whereas either no forgetting or an actual increase ("reminiscence") was shown for substance memory. Closely related is the study by Briggs and Reed (1943) on retention of ideas, an idea being defined as a concept that cannot be derived from a single sentence in the text. The curve of retention for this material falls at a decelerating rate, but retention is at a much higher level than curves heretofore published for other verbal materials. These results may be related to those reported by Katona (1940) on the superior retention of meaningful learning as compared to senseless learning.

2. *Characteristics of the material learned.* Some of the effects of difference in material have already been alluded to. Meaningfulness, for example, has been shown to affect the level of retention, but how this comes about we do not fully know.

Vividness of material is another factor favoring good retention. Van Buskirk (1932) had his subjects learn a list of nine syllables in which ordinary black-on-white type was used. In the experimental list, one syllable was printed in red on a green background. This syllable was retained better than the corresponding syllable in the control list.

Closely akin is the finding of von Restorff (1933) that if a syllable is inserted in a list of numbers or a number in a series of syllables the exceptional (she calls it "isolated") item will be better recalled (22 per cent for average unit, 70 per cent for isolated). As the number of isolated items is increased, the advantage in recall is gradually reduced (Pillsbury and Rausch, 1943), although there is some advantage even when half the items are of a different type (Siegel, 1943). Gibson (1940) believed that these phenomena could be explained in terms of generalization and differentiation.

AFFECT. The affective character of material has an important influence on retention. Research on this topic stems largely

FIG. 29. Retention curves obtained by five different methods of measuring retention. (From Luh, 1922.)

12 nonsense syllables to a criterion of one perfect recitation. Retention was subsequently tested at various time intervals up to 2 days by use of recall (anticipation and written reproduction), recognition, and reconstruction. His results are presented in Fig. 29. All the curves, with the possible exception of that for recognition, show an initial rapid drop and a more gradual fall thereafter. But, whereas 72 per cent is retained after 2 days when measured by recognition, when measured by anticipation only 11 per cent is retained. Analysis of other studies on this topic will be found in Davis and Moore (1935).

Several studies have been made of the difference between exact retention of the material covered (verbatim memory) and retention of the gist of the material (substance memory). Studies by English and his

from Freud's conception of forgetting as an active process that protects the individual from disturbing memories. On the basis of the more frequent recall of pleasant experiences, many studies have concluded that pleasant material is better retained than unpleasant. Flügel (1925) has shown, however, that most people describe more of their experiences as "pleasant" than as "unpleasant," which may account for the higher frequency of recall of pleasant experiences. A number of studies record the subject's initial reaction to his experiences and then compare their retention. Pleasant experiences are better recalled than unpleasant (Jersild, 1931; Stagner, 1931; Meltzer, 1930; O'Kelly and Steckle, 1940). Both pleasant and unpleasant experiences are better remembered than neutral (Koch, 1930).

A second method, originally used by Gordon (1925), studied the retention of material associated with pleasant and unpleasant sensations (e.g. odors). No significant differences were found. A closely related procedure compared the learning and retention of words judged by the subjects to be pleasant, unpleasant, or neutral. With adults, Pintner and Forlano (1940) found a loss of 24 per cent for pleasant words, 29 per cent for unpleasant, and 27 per cent for neutral. Children retained unpleasant material better than pleasant. Reviews of studies using these various methods will be found in Meltzer (1930) and Gilbert (1938).

Edwards (1942) has criticized many of these studies on the grounds that it is not necessarily the affective tone that is basic, but rather the presence or absence of conflict between the experience and the individual's values or "frame of reference." Edwards (1941) and Watson and Hartmann (1939) showed that retention was significantly greater for material that was compatible with the attitudes of the subjects than for material that was incompatible. Sharp (1938) took essentially the same point of view — that the acceptability of material

in terms of the individual's values favors retention.

The majority of the results indicate that pleasant experiences are better retained than unpleasant. But, until we know that there are no differences in rehearsal (Jersild, 1931) nor in intensity of experiences (Menziez, 1935) for the two types of material, we cannot conclude that they support Freud's theory of repression.

LENGTH. Length of material bears an interesting relation to retention. At least in the case of verbal materials, when a small and a large quantity of material are learned to the same criterion, later retention is higher for the longer material (Robinson and Heron, 1922; Robinson and Darrow, 1924). Data on this point are presented in Table 14.

TABLE 14

RETENTION OF VARIOUS LENGTHS OF LIST

Length of List	Average Percentage Recalled	Average Percentage Saved
	Nonsense Syllables *	
6	71.3	68.7
9	78.3	78.8
12	78.7	78.1
15	77.0	80.7
18	81.7	86.3
Three-Place Numbers †		
4	60.0	25.0
6	66.5	72.5
8	66.6	69.4
10	70.8	78.9

* From Robinson and Heron (1922).

† From Robinson and Darrow (1924).

A large part of the difference is attributable to the greater amount of practice required to learn the longer material. When paired associates were removed from learning as soon as the response had been given correctly three times, lists of 8, 10, 12, and 15 pairs were retained about equally well over a 10-minute period (Sand, 1939).

3. *Degree of learning.* An important determiner of the amount of retention is the

degree of original learning. In the study of Luh (1922) already referred to, the superior retention with higher degrees of learning is clearly shown, but the forms of the curves are similar. W. C. F. Krueger's (1929) data for serial learning (Fig. 30) show the same general results—the higher the degree of learning, the higher the retention. A subsequent study by the same author showed similar results for the retention of finger mazes

was a difference in favor of distributed practice.

The advantage of material learned by distributed practice is closely related to the results of Ebbinghaus (1885), who found that, when lists are learned on successive days to the same criterion, the number of trials becomes progressively less. On the basis of Ebbinghaus' work and his own, Jost (1897) formulated what has since been known as Jost's laws:

First law: "Given two associations of the same strength, but of different ages, the older one has greater value on a new repetition."

Second law: "Given two associations of the same strength, but of different ages, the older falls off less rapidly in a given length of time" (p. 472).

A comprehensive study of Jost's laws has been made by Youtz (1941). She confirmed the fact that the older habit shows a larger

FIG. 30. Retention curves showing recall when material is learned to criterion of one perfect repetition or overlearned by being given 50 per cent more trials (150 per cent or double the number (200 per cent)). (Data from W. C. F. Krueger, 1929.)

(W. C. F. Krueger, 1930). Diminishing returns may be found with high degrees of overlearning (Rubin-Rabson, 1941c).

4. *Methods used in acquisition.* The methods used in learning a task have a significant effect on how well it is retained. If, for example, material is learned to the same criterion by massed as by distributed practice, that learned by distributed has been shown to be retained better, even though more trials were used for massed practice in the original acquisition. Hovland's (1940a) results on this point are shown in Fig. 31. Other studies have also shown superior retention of material learned by distributed practice (Cain and Willey, 1939; Robinson, 1921; Strong, 1914). Rubin-Rabson (1940a) found no significant difference in number of trials to learn piano music by massed and distributed practice, but in relearning there

FIG. 31. Mean number of syllables recalled at various time intervals following learning to one perfect recitation by massed and distributed practice. (From Hovland, 1940a.)

learning increment after a single relearning trial. When comparable parts are initially equated, as on the first recall, the amount of increment from new repetitions tends to increase logarithmically from the time since learning:

$$y = K \log t + c$$

where y is the increment on a new repetition, t is the time since learning, and K and c are

constants. Older associations required fewer trials to relearn than did younger associations.

Since younger habits display an excess of errors in the middle of rote series, the ratio of errors in the central position to those in the end positions was used as one of the indicators of age. On the basis of this fact Youtz reformulated Jost's first law in these terms: "Of two series of associations which are overtly remembered to the same degree, the one exhibiting the most extensive dissipation of intralist inhibition will profit more on a new repetition" (p. 46).

Material learned by the whole method has been reported to be better retained than that learned by parts (Larguier des Bancels, 1901; Pentschew, 1903. Hsiao (1940) reports that superiority of the whole method becomes more manifest with longer intervals for retention.

The amount of retention is also affected by whether or not recitation was used in the original learning. In the experiment by Gates (1917) cited earlier it was found that retention was greatest when a large portion of the time was spent in practice, although this type of learning may have influenced the original degree of learning directly.

Motor Learning

The classical study of the curve of retention for mazes is that of Tsai (1924) on a stylus maze. Learning was to the criterion of three perfect trials in succession. The maze was relearned to the same criterion at various intervals up to 9 weeks by different groups of subjects. His curve of retention is shown in Fig. 32.

Skills are retained with little loss over very long periods of time. Swift (1906b) reported retention of about 67 per cent of his typing speed over a 2-year period, and Hill, Rejall, and Thorndike (1913) reported little loss after 4 years. Unfortunately there are few systematic studies of retention of skills at various time intervals. One of the best studies of retention of motor learning

is that reported by Leavitt and Schlosberg (1944) for the pursuit rotor. Their retention curve for tests at 1, 7, 28, and 70 days is shown in Fig. 33.

FIG. 32. Retention curves for a stylus maze habit. (From Tsai, 1924.)

The data of Leavitt and Schlosberg are also relevant to a long-standing controversy concerning the relative retention of motor

FIG. 33. Comparison of retention curves for pursuit-rotor and nonsense-syllable learning. Retention was measured at first relearning, and the last learning trial was taken as 100 per cent. (From Leavitt and Schlosberg, 1944.)

and verbal learning. Retention of pursuit-rotor learning was found by them to be superior to that of nonsense syllables. This

confirmed earlier findings by Freeman and Abernethy (1930, 1932), but, in view of the fact that the majority of other studies have not found this result, they searched for specific factors within the tasks to account for the difference. The degree of integration of the tasks appeared to be one such factor. In a follow-up study Van Dusen and Schlosberg (1948) compared verbal and motor tasks that had a similar simple and clear-cut organization. The subjects learned to operate switches that had nonsense-syllable labels. One set constituted the first terms of paired associates; the other set provided the second terms of the pairs. Simultaneously the subjects learned the names of the syllables that appeared as labels on the paired switches. No significant difference was obtained in the retention of the two types of habits (Table 15). The authors did not believe that the

TABLE 15

COMPARISON OF RETENTION OF SYLLABLES (VERBAL LEARNING) AND SWITCHES (MOTOR LEARNING) (DATA FROM VAN DUSEN AND SCHLOSBERG, 1948)

	Tests			
	Immediate *	1-day	7-day	28-day
Syllables	4.68	5.42	3.00	1.39
Switches	6.45	5.67	4.00	2.48

* Unweighted mean for the three groups given delayed tests.

similarity in retention was due to the fact that learning to actuate the switches was more a verbal than a motor habit. They attributed the superior retention of many motor skills to their organization rather than to the fact that they are motor. In any case it appears that the popular belief that verbal material is readily forgotten but motor skills well retained over long periods is probably exaggerated and, when true, is probably due to differences in the organization of the tasks and the typically greater overlearning of motor skills.

Limits of Retention

Since most studies employ relatively short-time intervals to test retention, little precise information is available on the real limits of retention. The many studies furnishing incidental evidence of long-term retention are summarized in McGeoch and Melton (1929). To their summary should be added two later studies.

Burt (1941) reports long-term retention of material presented during childhood. Each day for 3 months 3 selections in Greek were read aloud once to a 15-month-old child. Between the eighteenth and twenty-first months 3 other selections were read daily. This procedure, with a different set of selections for each successive 3-month period, was continued until the child was 3 years old, making a total of 21 selections presented. At the age of 8½ years the subject learned 7 of these selections and 3 new ones by the anticipation method. At 14 years he learned a second third of the original 21, together with 3 new selections for control; at the age of 18, the remaining 7 and 3 new ones. At age 8½ (after about 6 years) a 30-per-cent saving was found. At age 14 (after about 11 years) 8 per cent was retained. No retention was found at age 18 (after 15 years).

Another study on long-term retention is by Cofer (1943). Appreciable retention 4 years after original learning was found for only three of his six subjects, stressing the importance of individual difference in retention.

REMINISCENCE

As suggested earlier, retention curves sometimes show a period of increased retention immediately after the cessation of practice. This phenomenon of an initial rise has been labeled *reminiscence*. The literature before 1935 is reviewed by G. O. McGeoch (1935) and for the period from 1935 to 1943 by Buxton (1943b).

The first study showing reminiscence was that of Ballard (1913). He had school children learn long selections of poetry, with a

time limit somewhat shorter than that required for mastery. At the end of the learning period the children were asked to recall all they had learned. Some of the children were asked to recall the material again on the following day without previous knowledge that they would be retested. Another group had its recall test after 2 days. Others were retested at 3, 4, 5, 6, and 7 days. The amounts recalled after the various pe-

FIG. 34. "Reminiscence" curves showing ratios, in per cent of amounts reproduced after varying numbers of days to amount reproduced immediately after learning. The three curves are for the following: A, "The Wreck of the Hesperus"; B, "The Ancient Mariner"; C, nonsense verses. (From Ballard, 1913.)

riods are shown in Fig. 34. It will be observed that retention is higher after 2 or 3 days than immediately after learning. The amount of reminiscence was found to be greater for younger than for older children. Williams (1926) confirmed Ballard's observations but found that the improvement occurred only with poetry and not with short abstract words. Only the youngest group of his children showed pronounced reminiscence.

A related phenomenon is the post-learning increase in retention of "substance learning." English, Welborn, and Killian (1934) had their subjects study a long (1100-word) article. True-false tests were then administered to some subjects immediately after study, to others after intervals of 1 or 2 days. One form of the test contained items requiring

specific memory; the other required only general comprehension of the material. The first test showed a conventional forgetting curve, but the second showed either no loss or an increase in retention (Fig. 35).

It is important to note that in the Ballard-Williams studies each subject was tested twice — once immediately after learning, and a second time in the delayed test of retention. This, of course, permits the recitation on the first test to improve recall on the second. Before these results can be accepted as showing real improvement in retention there must be more convincing evidence that the improvement is not due principally to the effect of prior recitation.

Ward (1937) called attention to an initial rise in retention for very short periods (2 to 10 minutes) following the learning of non-

FIG. 35. Comparison of retention based on tests requiring memory for specific facts (lower curve) and for general comprehension of material learned (upper curve). (Data from English, Welborn, and Killian, 1934.)

sense syllables (Fig. 36). In his study the effect on a second recall was eliminated by using a different group for each time interval (including the zero interval). Thus one of the criticisms of the results of Ballard was eliminated. Another possible explanation bobs up however — that of unobserved implicit review during the rest interval. In his main experiment the subjects read a humor

magazine, but it might have been possible for rehearsal to take place anyhow. In order to reduce this possibility still further, Hovland (1938a, b, 1939a) had his subjects name colors presented at the rate of one every 2 seconds during the rest interval. Melton and Stone (1942) have since stepped up the rate of color naming further to reduce the factor of implicit rehearsal. In their study no reminiscence was obtained, but their materials and methods also differed in several

(Hovland, 1936). Sizable reminiscence has also been found for pursuit rotor learning (Ammons, 1947b; Buxton, 1943a; Doré and Hilgard, 1937, 1938; Hilgard and Smith, 1942; Leavitt, 1945; Leavitt and Schlosberg, 1944), for mirror tracing (Snoddy, 1935), and for other skills (Buxton, 1942a).

There is therefore no doubt about the *fact* of reminiscence. But what is the nature of the phenomenon? Before it can be considered a fundamental *learning* phenomenon, explanation of it in terms of fatigue, motivation, and artifacts of measurement must be eliminated. For example, repeated trials may bring about fatigue and a rest interval may result in recovery from the fatigue with a resulting improvement in performance that may more than offset the forgetting that occurs in the interval. There is evidence that this cannot be the sole explanation of reminiscence, for reminiscence is sometimes found with learning periods so short that they could hardly cause fatigue. Motivational factors could operate in an analogous manner. It is possible that subjects who have become bored with the task may show renewed interest after a rest interval. On the other hand, the appearance of reminiscence after a very limited period of learning makes it unlikely that this is the sole explanation of reminiscence.

The problem of eliminating artifacts of measurement as an explanation of reminiscence requires some discussion.

1. *The effect of immediate recall.* In the studies of Ballard and of Williams the post-learning improvement may have been the result of the practice obtained on the test given immediately after learning. In this sense the recall is like another practice trial and could well cause an apparent improvement of a second trial over that of the first (cf. experiments by Bunch, 1938; Gray, 1940; Spitzer, 1939; and Spencer, 1941). In the experimental design used by Ward and Hovland the practice effect of an immediate recall is eliminated by the use of a separate

FIG. 36. "Reminiscence" curve showing initial increase in number of nonsense syllables recalled at short-time intervals following original learning. (Data from Ward, 1937.)

other respects from the methods used by Ward and by Hovland.

Reminiscence has also been reported by McClelland (1942a, b) for what he calls "serial verbal discrimination learning." Subjects learned to read aloud the "right" words and to remain silent to the "wrong" words in a list of 20 words. The learning was interrupted when a criterion of 15 out of 20 correct was reached. The half of the subjects who had a 2-minute rest pause filled with color naming performed better on subsequent trials than those who did not have the rest pause. In a later article in the series McClelland (1943a) found that reminiscence occurred only among those who had a high average score on the original learning.

Although most of the work on reminiscence had used verbal material, the appearance of reminiscence is not restricted to verbal learning. An analogous phenomenon of increased retention occurs in conditioning

control group to assess the extent of learning at the end of practice.

2. *Rehearsal.* Williams (1926) was inclined to explain his results as due to voluntary and involuntary rehearsal of the material during the interval between test and retest. It is extremely difficult to control this factor. G. O. McGeoch (1935) found that 84 per cent of her younger subjects and 70 per cent of the older ones reported that they had rehearsed in the interval between learning and recall. But those who reported rehearsing showed no more reminiscence than those who denied reviewing during the interval. Ballard (1913), on the other hand, found that children who reported going over the material in their mind showed more reminiscence than those who did not report doing so. As noted above in the Ward-Hovland design, color naming has commonly been used during the rest interval in an attempt to reduce rehearsal. But it is difficult to be absolutely sure that this eliminates all rehearsal.

3. *Positive transfer.* In some of English's experiments (e.g. English, Welborn, and Killian, 1934) the material used dealt with general topics in psychology, and the subjects were students continuing their study of psychology during the interval. What they learned in their courses could, therefore, make it easier for them to give correct answers on the items requiring just the substance of the material. The verbatim material would presumably be less affected and hence show more forgetting.

4. *Difficulty of items.* The experiments of English have also been criticized on the grounds that the results deal with *absolute* numbers of reminiscent or forgotten items (Buxton, 1942*b*). This does not take into account the fact that, since the "substance" test items were more often wrong on the first test, the opportunity for reminiscence in them was much greater than for the verbatim items. When difficulty was ruled out, Buxton found no difference in the amount of reminiscence for the two types of item.

Some differential trends were, however, presented in English's (1942) reply to Buxton's criticisms.

5. *Reproductive interference.* Activities during the rest interval may affect adversely the recall after the interval. It is conceivable, for example, that the "double-quick" color naming used by Melton and Stone (1942) may have had an interference effect and reduced the chance for reminiscence to appear, although other differences between their experiment and those of Ward and of Hovland may have been responsible. Absence of reproductive interference may increase the likelihood of obtaining reminiscence when fatigue is dissipated (Leavitt and Schlosberg, 1944).

6. *Set.* Difference in practice and in instructions may affect the subjects' set to recall. Subjects may, for example, be set to recall on each trial, and this pattern may be disrupted by the introduction of a rest interval. This would depress the level obtained. This factor could be important in accounting for variations in the results of experimenters who used varying numbers of practice series to give the subjects familiarity with the interruption of learning required to test for reminiscence. This point has been made by Buxton (1943*b*) in these terms:

A possibility needing exploration is that reminiscence may not be found in experiments employing interpolated activities (e.g. color naming) unless S is well-practiced at shifting from learning to naming and back again. That is, at the time of recall S may not have the appropriate set unless he is accustomed to making the rapid shifts required in such experiments, and his recall score will suffer accordingly. [Footnote, p. 316.]

Design Requirements for Reminiscence Experiments

Truly crucial experiments have still to be performed to demonstrate that reminiscence is a genuine phenomenon of learning, rather

than merely of performance. It is easier to write the specifications for such experiments than to arrange the appropriate conditions. Control of the following variables is essential. First, we must be sure that an intervening practice trial is not inserted as a measure of recall. Second, rehearsal must absolutely be prevented. This, as we have seen, is an extremely difficult condition to achieve without other complications. Third, the activity during the rest interval must show neither positive nor negative transfer to the original activity. Fourth, it is necessary that the motivation be the same at each interval. Fifth, sufficient practice in the pattern of the experiment must be given to make the subject highly practiced in shifting from learning to the interpolated activities during rest. Last, conditions must be so arranged that fatigue and other work decrement factors are not produced by prolonged learning periods.

Other Factors Influencing Reminiscence

1. *Stage of learning.* It goes without saying that reminiscence occurs only with incomplete learning. If the learner can recall the material perfectly, no post-learning improvement is measurable in terms of recall. From Hovland's (1938a) data it appears that a low degree of learning (one trial) or a very high degree of learning (one perfect repetition) is less conducive to reminiscence than a moderate degree (7 out of 12 correct). Relative amount of reminiscence has also been found to decline with increased amount of pursuit-rotor learning (Buxton, 1943a).

2. *Materials.* In addition to the effects of material, discussed above, there have been a few studies on the effects of different types of learning on reminiscence. Of the studies using the Ward-Hovland design, those with nonsense-syllable materials have shown reminiscence, whereas the study of Melton and Stone (1942) in which meaningful adjectives were employed failed to show absolute reminiscence, but their retention curve

did not show the usual rapid decline. In a study using nonsense syllables Stone (1946) found some evidence of reminiscence at a 2-minute interval, but its amount was not statistically significant. Buxton (1949) found that under identical experimental conditions reminiscence occurs with nonsense syllables but not with meaningful syllables. But what factors in meaningfulness account for the difference? The difference may be related to the difficulty of learning, the effect of previous familiarity, the effect on motivation, or a host of other factors. It is to be recalled that with the Ballard-Williams procedure meaningful material showed reminiscence. Martin (1940) even suggests that, the more meaningful the material, the greater the reminiscence.

Reminiscence was found by Hovland (1939a) to be greater for serial than for paired-associate learning. This may be due to the differences in the extent of remote associations in the two situations (which might be expected to increase the amount of interference). It may also be due to the fact that to make the time per syllable constant (2 seconds per syllable in each pair or in the series) the subject gave responses once every 2 seconds with the serial lists but only once every 4 seconds with paired associates (cf. Hovland, 1949).

3. *Method of learning.* Closely related to the type of material is the method by which learning takes place:

a. *MASSSED-DISTRIBUTED PRACTICE.* On the theory that reminiscence is due at least in part to dissipation of interferences accumulating in learning, Hovland (1938a) tested for reminiscence following learning by massed and by spaced practice (where the interferences would presumably be dissipated between trials). He found that reminiscence was greater following learning by massed practice.

b. *SPEED OF PRESENTATION.* Another way to reduce interference is to slow down the rate of presentation of material. Hovland (1938b) found that reducing the rate of

presentation from one syllable every 2 seconds to one every 4 seconds decreased the amount of reminiscence. McClelland's (1942a) results also appear to indicate that reminiscence is more likely to obtain with more rapid presentation. Melton and Stone (1942), however, found that, with rapid rates of presentation of their syllables, numerous signs of intraserial interference occurred, but reminiscence was not obtained.

c. "CROWDING." Interference in verbal material is presumably increased when several lists are learned in a period. The effect of this factor has been studied by Newman (1939). One group of subjects learned and recalled single lists of eight nonsense syllables. The other group learned and recalled the lists in blocks of three. The retention intervals were 1, 24, and 48 hours. Newman found that the single list showed a more or less conventional forgetting curve but that lists learned together (under what he calls "crowded" conditions) showed reminiscence.

4. *Individual differences.* Although early investigators believed that age was an important variable in the amount of reminiscence, a careful review of the literature by G. O. McGeoch (1935) convinced her that there was no reliable evidence that reminiscence is related to age, sex, or intelligence of the learner. McClelland (1943a) suggested that the brighter and faster learners may reminisce more than those who are less able, although this may depend on the particular time interval used. Leavitt (1945) found that fast learners show greatest reminiscence with a short interval, whereas slow learners showed greater reminiscence with a longer interval.

UNLEARNING

In the preceding studies of retention the losses with time were those occurring spontaneously ("forgetting"). Much less studied is the problem of deliberately reducing the strength of habits ("unlearning").

One of the earliest studies of unlearning was carried out by Jones (1924), who attempted to eliminate children's fears of being alone or in a dark room, or of snakes, rabbits, or other animals. She tried a number of methods. Despite the common belief that fears disappear spontaneously if no further contact with the feared object occurs, she found no diminution in fear by simple "disuse." Verbal appeal, in which the experimenter talked about the feared object and connected it verbally with pleasant experiences, was likewise quite ineffective.

The method of negative adaptation was also tried, in which the child was exposed to the feared object repeatedly. In one case considerable improvement occurred under this procedure, but in other cases the child actually became more frightened. Ridicule of the fear caused the children to hide or repress their fear, but there was no real reduction in the fear itself.

Under certain conditions distraction was effective. When toys were placed near the animal the child was sometimes so eager to get the toys he would ignore the animal. But this method required the constant presence of an adult to arrange the distractions, and the effects seemed temporary.

The two most effective ways of overcoming the children's fears were: (1) reconditioning and (2) social imitation. In the first method direct conditioning was used to associate the feared object with a stimulus capable of arousing positive reactions, e.g. food. Tolerance was gradually built, up until the child became indifferent to the feared object and in some cases finally responded positively to the object. This method must, however, be very carefully applied. If the object is feared intensely and introduced too rapidly, the treatment may "boomerang" so that the child becomes negatively conditioned to the eating rather than positively conditioned to the object feared.

The other method found effective was to allow the children to participate in the activity of other children who reacted to the

object without fear. When the social group in which the child was placed was one of high prestige, the child behaved the way the group behaved, and, when the other children approached the object without fear, the child soon imitated them.

Another method of breaking habits is the "negative practice" method described by Dunlap (1928). He showed that a "bad" habit like typing *hte* instead of *the* could be eliminated by deliberately practicing the typing of *hte* repeatedly. A systematic study of Dunlap's hypothesis was conducted by Holsopple and Vanouse (1929) with typing students who were just learning to transcribe from shorthand notes. Eleven students who had consistently misspelled four words were given practice on two of the words in misspelled form, and on the other two words in correct form. On a later test no errors were made on the words that had been given negative practice, but 10 of the 11 students made errors on the words practiced correctly.

A repetition of this study using words misspelled in spelling tests was conducted by Peak, Brooks, and Hobson (1941). They found no superiority of one method over the other. Dunlap's (1942) criticism of this experiment and Peak's (1942) reply should be read by readers interested in the problem. A good review of experiments on negative practice and their implications in terms of theories of learning will be found in Peak (1941).

Guthrie (1938) describes three general ways in which unlearning can be brought about: (1) The stimulus is introduced at such weak strengths that it does not cause the response, and then its intensity is gradually increased but is kept below the "threshold of response." (2) The cues for the unwanted action are presented at a strength that would ordinarily cause the response, but at the same time the situation is controlled in such a way as to prevent the occurrence of the response so that it becomes inhibited. (3) Stimuli for an act are presented at a time when some of the instruments necessary

for carrying out the act are not present. If the means of execution are absent, something else is done, which then becomes the associated habit. These three methods all reduce to the presentation of cues for an undesired action whose performance is prevented. These points of Guthrie are based largely upon armchair analysis and clinical judgment.

QUALITATIVE CHANGES IN RETENTION

The heavy emphasis on quantitative changes in learning has almost crowded out interest in qualitative changes. With the publication of Bartlett's book on *Remembering* (1932) there has been a renewed interest in the nature of changes taking place in retention. Bartlett used stories, pictures, and figures as material and studied the details recalled.

These and other studies have brought out the fact that considerable simplification occurs and that material not relevant to the central theme drops out. Inconsistent material tends also to be omitted, and the story takes on a simple structure. Similar phenomena are found in studies on memory for events, and on the reliability of testimony. A good survey of these experiments will be found in Lipmann (1935).

The experiment of Tresselt and Spragg (1941) uses the Bartlett approach. A verbal passage was read twice to a subject who reproduced it as accurately as possible after 15 minutes. This reproduction was in turn read to a second subject, whose reproduction was in turn passed on, etc. The changes reported by these investigators were in the direction of "simplification, cohesion, and symmetry."

A related problem of considerable interest, but one that has not yet yielded to rigorous analysis, is that of retention of visual forms. The best review to date is to be found in Woodworth's (1938) chapter on memory for form.

Much of the research on this topic was inspired by the work of Wulf (1922) who believed that memory was influenced by the Gestalt principles.

The most general law which governs all the memory changes is the law of pregnance [Prägnanz] which says that every gestalt becomes as good as possible. In perception the 'possible' is sharply limited by the existing stimulus complex, but in memory the 'engram' or trace, freed from this limitation, can transform itself in the direction of pregnance. Therefore figures, in memory, tend toward definite outstanding forms. [P. 372; quoted from Woodworth, 1938, p. 80.]

Results of Perkins (1932) and others seem to support the theory by showing changes in the direction of balanced and symmetrical patterns, but judgments of this sort have usually been made only by the experimenter. Publications have shown only "representative samples." Sorge (1940) confirmed earlier results: his subjects improved the symmetry of abstract figures, introduced right angles and straight lines, and clarified the functional role of ambiguous parts. Other studies have shown increases in complexity and size of visually perceived forms (Burton and Tueller, 1941; Wallen, 1943).

This field presents difficult problems of procedure. In the first place, the usual method is for the subject to draw the figure. The correlation between memory and ability to draw the figure is questionable. The second difficulty is that in most studies the subject is asked to keep repeating his drawing. This has been shown by N. G. Hanawalt (1937) to operate, for both visual forms and verbal material, in the direction of increasing retention. When only a single reproduction is involved, a normal type of forgetting curve is obtained. Goldmeier (1941) has contended, however, that Hanawalt's results are attributable to the material used, finding in his own study "autonomous changes . . . directed toward outstanding or prägnant value and toward consistent struc-

ture of the whole" (p. 503). Philip (1940) showed that memory for figures is influenced by proactive and retroactive interferences in the same way as other material.

INDIVIDUAL DIFFERENCES IN RETENTION

All the factors of individual differences discussed earlier in connection with acquisition also affect retention. The close relation makes it difficult to know in many cases whether the differences in retention of different groups (analyzed by age, intelligence, or other factors) are due to real differences in retention or to superior initial acquisition.

Results on one phase of the problem of individual differences in retention are of special interest. It is popularly thought that those who learn readily forget readily, and that the individual who acquires material slowly retains it for a long time. This relation may sometimes exist owing to the fact that the "slow" learner may greatly overlearn the material, whereas the "rapid" learner is satisfied with barely reaching the criterion. But if we compare the retention of individuals who reach a criterion performance rapidly with individuals who reach the same criterion slowly, we find that the retention of the fast learners is better than that of the slow learners. This is borne out by the study of Gillette (1936) whose subjects learned paired associates. As soon as a pair was repeated correctly it was removed from the series so that the pairs learned early would not be so greatly overlearned. The fast learners retained significantly more material than the slow learners. Gillette's monograph contains a bibliography and a good discussion of the problems of method involved.

The time interval at which retention is tested may affect the relation between speed of learning and amount retained. This is indicated by a recent study of Leavitt (1945) on the learning and retention of nonsense syllables and a pursuit-rotor task. The cor-

relation was positive between speed of learning and amount of retention at short-time intervals, whereas at long-time intervals it was negative.

A fascinating aspect of individual differences, on which there has been little work, concerns the qualitative changes in memory with age. There is a great deal of speculation about this topic, with anecdotal evidence of superior retention by old people of early youthful experiences, but few systematic studies are available. It will also be recalled that we still have no satisfactory explanation for the differences in retention between various age groups found by Ballard (1913) and Williams (1926) in their studies of reminiscence.

EFFECT OF PRIOR LEARNING ON ACQUISITION (TRANSFER OF TRAINING)

Even under highly controlled conditions the learning of a new task is not independent of previous learning but is built upon previous acquisitions. In everyday life we count heavily on past learning to make it easier for us to add new material. On the other hand, we often find our old habits interfering with the formation of new ones. The fact that past learning makes it sometimes easier and at other times harder to learn new materials points up the need for systematic exploration of the problem.

How previous learning affects new learning has customarily been dealt with under the label "transfer of training." The central interest is usually in determining how the learning of one activity "transfers" to the learning of a new activity. The effect of previous learning may either *improve* or *retard* the new learning. The first result is referred to as *positive transfer*; the latter as *negative transfer*. In some cases, of course, the learning of the first material has no measurable effect on the learning of the second.

Good reviews of this topic have been provided by Orata (1928, 1935, 1941) and by Woodworth (1938). Only a brief summary of early studies will be presented here as an introduction to recent investigations.

Bilateral Transfer

The earliest reports of transfer come from observations on how habits learned with one hand can be performed without further practice by the other. Thus Weber is quoted by Woodworth (1938) as having reported that a noted surgeon of his day found it economical, in teaching certain delicate operations that must be performed sometimes with one hand and sometimes with the other, to train his students only in the use of the left hand. They were then able to perform the operation with the right hand without further training. Significant early studies of bilateral transfer (sometimes called cross-education) were those of Scripture, Smith, and Brown (1894) and of W. W. Davis (1898, 1900) on dynamometer grip, steadiness, and tapping. Their research design, however, was faulty, for it lacked a control group.

Later studies have been conducted with better controlled conditions. A good example is that of Munn (1932) who used a game involving a wooden cup on a handle, from which a wooden ball was suspended by a string. The task was to grasp the handle and flip the ball into the cup. Subjects were given 50 trials with the left hand to provide a measure of initial skill. Then one group was given 500 trials with the right hand while the other group rested. Each group was then given 50 practice trials with the left hand. The experimental group improved 61.14 per cent, whereas the control group improved only 28.5 per cent.

Bilateral transfer effects are not limited to bilaterally symmetrical members. This was shown by Bray's (1928) experiment on aiming at a target seen in a mirror, where he found that there was positive transfer not only from hand to hand but from hand

to foot. Similar findings have been reported by Cook (1934): a stylus path was learned by blindfolded subjects with one hand and was subsequently positively transferred not only to the other hand but to the feet as well.

Reports by the subjects and observations by the experimenters in the Munn and Bray experiments indicate in a general way how transfer was mediated. Various "tricks of the trade" which the subjects learned could subsequently be transferred to the other side. There was also a reduction in the nervousness and self-consciousness of the subjects.

Analogous results on bilateral transfer of perceptual discrimination date back to the studies of Volkman (1858). He found that practicing with the left hand in two-point threshold discrimination helped the right hand to make the discrimination. From introspective reports (Boring, 1920) it appears that the improvement in discrimination is the result of becoming acquainted with the difference in feel between two points and one.

Perceptual Transfer

A pioneer study by Thorndike and Woodworth (1901) showed that practice in estimating areas of figures improves the accuracy of estimation of other areas, and that, the more similar are the new areas to those on which there had been practice, the greater is the transfer. But far greater improvement was brought about through direct practice than through transfer. It was in connection with this experimental work that the authors drew the conclusion which seemed so revolutionary at the time:

Improvement in any single mental function need not improve the ability in functions commonly called by the same name. It may injure it. Improvement in any single mental function rarely brings about equal improvement in any other function, no matter how similar, for the working of every mental function-group is conditioned by the

nature of the data in each particular case. [P. 250.]

In his later writings (cf. particularly 1913) Thorndike made more explicit his famous theory of "identical elements."

In another classical study Coover and Angell (1907) showed that practice on discriminating sound intensities improved subsequent discrimination of shades of gray, which they attributed to the knack of "divesting the essential process of the unessential factors" (p. 333).

Motor Transfer

When successive units of the same type of motor performance are learned, there is commonly a positive transfer. A good example is furnished by the experiment of Webb (1917). His results, shown in Table 16, indi-

TABLE 16

EFFECT OF PREVIOUS LEARNING ON PERFORMANCE OF NEW LEARNING TASK (FROM WEBB, 1917)

Experimental group	Previous Learning	Performance in Learning Maze B	
		Trials	Errors
Learn maze A		10.8	32.4
Control group	Rest	33.6	285.2
Improvement (difference between experimental and control groups)		22.8	252.8

cate a sizeable improvement in the learning of a second maze as a result of the learning of the first.

When one motor task is learned and transfer is subsequently tested on other types of motor performance, both positive and negative effects have been found. Woodward (1943) investigated the effect of learning to assemble a safety switch on learning to assemble a simple loom and found some positive transfer. But Cook (1941) found marked negative transfer from mirror tracing in one position to mirror tracing in another position. Which motor tasks yield positive and which yield negative transfer

is at the present time largely a matter for empirical determination.

Memory

The pioneer study of the effects of memory training is the oft-cited study of William James (1890). James first learned 158 lines of Hugo's *Satyr* and recorded his time. He then spent a month committing to memory Milton's *Paradise Lost*. When he had finished with this he returned to the *Satyr* and memorized another 158 lines. He found that this actually took longer than the first 158 lines. He concluded that there was no general improvement in memorizing ability. Later experimenters have repeated this type of study with more subjects and with the necessary controls. Sleight (1911) used a control group and three experimental groups equated on the basis of memory ability. One experimental group memorized poetry, another tables, and a third prose. No indication was found of any general improvement in memory.

On the other hand, experimenters have uniformly noted the improvement that comes from practice in learning successive lists of the same type. Ebert and Meumann (1904) attributed the improvement to better methods of memorizing, discovery of helpful aids, increased confidence, and reduction of anxiety about the learning. At least part of the discrepancy in the results of various experimenters is probably attributable to the stage of proficiency already attained in the task practiced in the experiment.

Woodrow (1927) reasoned that, if subjects were given systematic instruction in how to memorize, the improvement would be more marked. Accordingly he set up a study with two experimental groups and one control group. One group devoted itself to intensive memorizing of poetry and nonsense syllables. The second group spent the same amount of time but divided it between receiving instruction in good methods of memorizing and performing exercises using these methods. The group that spent all the time

in practice performed little better than the control group on subsequent memory tests, but the group given instruction in methods of efficient memorizing showed marked improvement: ". . . The experiment shows that in a case where one kind of training—undirected drill—produces amounts of transference which are sometimes positive and sometimes negative, but always small, another kind of training with the same drill material may result in a transference, the effects of which are uniformly large and positive" (p. 171).

Transfer of Principles

Many other experiments have supported the finding of Woodrow that transfer is facilitated when the initial learning can be formulated in terms of general principles applicable to new learning. Judd (1908) showed this in an experiment in which groups of boys practiced shooting targets under water. One group was first taught the principles of light refraction; the other was not. Both groups were then given practice in shooting at submerged targets. Both groups learned about equally well to adjust for refractive errors by trial and error. But when the depth of the target was changed the group previously taught about refraction quickly learned to correct their aim for the new conditions, whereas the other group required extensive further practice. Judd's results have since been confirmed by Hendrickson and Schroeder (1941). (Cf. also Cox, 1933.)

Without stress on principles, habits are often highly specific to the situation in which they are practiced. Bagley (1906) reported a study in which the arithmetic teacher constantly stressed neatness in the papers handed in by the students. A gradual improvement was noted in the neatness of these papers. But no transfer was found with respect to the neatness of papers turned in by these students in other subjects such as language and spelling. Ruediger (1908) repeated this experiment but had the teacher

who emphasized neatness also stress the general importance of neatness in dress, business, and the home. Under these conditions improvement was obtained not only in the subject taught by the teacher but in other subjects as well. The stress on generalization has been supported recently by a study of Swenson (1942) on transfer of training in arithmetic, where she found that stressing interrelations between facts produced better results than drilling on the task itself.

Further evidence relating to this topic is furnished by the experiments of Katona (1940). Geometric puzzles and card and match tricks were used as interesting learning material. Transfer was tested with other puzzles embodying the same general principles. One group was instructed to memorize the initial solution and was given practice through repetition. The second group was taught the principles involved. A control group received no practice. The test results demonstrated the advantage of learning principles (cf. Table 17).

TABLE 17

PERCENTAGE OF PERFECT SOLUTIONS TO NEW PUZZLES FOLLOWING VARIOUS TYPES OF INITIAL TRAINING (FROM KATONA, 1940)

	Control Group	Memorization Group	Example Group
Task A	6	21	34
Task B	9	8	46 *
Task C	6	42 *	21

* Subjects had previous experience on these tasks.

Katona attributed the differences in the amount of transfer to the superiority of "meaningful" over "senseless" learning. He concluded that, although meaningful learning transferred to new situations, senseless did not. The extent to which Katona's results are specific to tasks like puzzles that are "derivable" (i.e. where if part of the series is known the rest of the sequence can

be filled in without learning) remains a serious question.

Transfer in School Subjects

Traditionally, educators have relied upon what has been called the doctrine of "formal discipline," i.e. that training in such subject matter as classical studies and mathematics would improve understanding of other subjects. A good review of studies in this field is that of Kingsley (1946). By way of illustration the work of Thorndike (1924) may be mentioned. He studied the effect of a year's work in such high school studies as Latin, mathematics, and history. All students used in the study were first given a test of "selective and relational thinking." During the year some students took a program that included Latin, history, etc., while others took shopwork, bookkeeping, etc. At the end of the year another form of the general test was given. Only small effects attributable to the different subjects were obtained, and Thorndike concluded that no marked balance in favor of one rather than another subject was found. Many subsequent studies have confirmed his findings.

Summary

The foregoing brief review indicates the difficulty of generalizing adequately the conditions of transfer. When the conditions of cross-education obtain, positive transfer may be uniformly expected. But this form of transfer has extremely limited generality. When the material learned through practice results in discovery of a rule or theory, considerable transfer to new applications is possible. But the teaching of principles directly is more efficient than the discovery of it through trial and error. With motor learning, positive and negative transfer effects are both frequently obtained, and description of the task does not always enable us to predict which will occur. This difficulty may be due to the complex relations existing among various tasks whose transfer effects have been studied. Per-

haps more precise analysis of what is being transferred to what would clarify the picture.

ANALYSIS OF TRANSFER IN TERMS OF STIMULUS AND RESPONSE FACTORS

A simple type of transfer situation exists if we have the same response in the original and new task but vary the relation between the stimuli. This pattern could be represented diagrammatically as follows:

	PRIOR LEARNING	NEW LEARNING
Experimental group	Learn $S_1 \rightarrow R_1$	Learn $S_2 \rightarrow R_1$
Control group	Rest	Learn $S_2 \rightarrow R_1$
	(Do not learn $S_1 \rightarrow R_1$)	

This situation is similar to the type of set-up that produces stimulus generalization in conditioning experiments. Response is obtained to stimuli not originally used in the conditioning, and the response is greater to stimuli similar to the stimulus originally used than to those more remote.*

The relevance of the principle of generalization to problems of verbal learning has been pointed out by a series of experiments on "semantic conditioning" (also labeled

* Here as in conditioning experiments (see above) there is an inherent difficulty in defining the dimension of similarity. On the stimulus side this has often been done in terms of judgments concerning similarity (e.g. Yum, 1931) or in terms of discriminability (e.g. Hovland, 1936, spaced his stimuli by equal numbers of just noticeable differences in pitch). Both methods have severe limitations. In the first, there is no certainty that a unitary dimension is involved: different judges may be using different factors in scaling. In the second, irregularities in the dimension are common. A well-known example is the octave effect in pitch. A large number of just noticeable differences in pitch may, for example, exist between 400 and 775 cycles, whereas 400 and 800 cycles may be very difficult to discriminate because they are exactly an octave apart. The problem of units is even more difficult on the response side where we know too little about response organization to devise appropriate units to measure response similarity. Consequently it is particularly difficult to predict transfer in motor learning.

"mediated generalization"). Russian investigators, whose work is summarized by Keller (1943), found generalization from a verbal symbol to the object denoted by the word and to phonetically and meaningfully related words. Razran (1939a) used his conditioned salivary technique to study these relations, finding antonym, synonym, and homophonic gradients. Other studies related to this problem are those of Riess (1946) and Foley and Cofer (1943).

Results analogous to those in conditioning are obtained with verbal learning. This was first shown by Yum (1931). He had his subjects learn to give a four-letter word response to hyphenated nonsense syllables. For example, the subjects were taught to respond with the word "WOLF" to the stimulus "REB-QIM." In the recall series the same syllables, or variants with one or more letters changed, were employed as stimuli. He found that many subjects gave the originally learned response to stimuli that were similar but not identical to those initially used, but that the frequency of recall was less than to the original stimuli. This led him to experiment systematically with similarity of stimuli. He had raters classify words and figures used as stimuli into various degrees of similarity. After training with one set of stimuli, recall was tested to the stimuli used in training and to the stimuli rated as having varying degrees of similarity. His results are shown in Table 18 for both verbal and visual stimuli. Similar results have been obtained by Gibson (1939), who varied the similarity of tactual stimuli. The subjects were taught to respond to a vibratory stimulus with a verbal response. Other vibratory stimuli separated spatially from the one used in training evoked the verbal response, the frequency of response being progressively less, the farther apart the stimuli. See also Gulliksen (1932) and McKinney (1933).

Transfer based on the similarity of stimuli thus appears to be well established. In the field of verbal learning the generalization

TABLE 18

TRANSFER WITH VARYING DEGREES OF SIMILARITY BETWEEN STIMULI (FROM YUM, 1931)

	Percentage Recalled
Verbal Stimuli	
Identical word	50.154
Close similarity	32.562
Moderate similarity	11.266
Figures	
Identical	84.616
First degree of similarity	64.530
Second degree of similarity	49.146
Third degree of similarity	45.299
Fourth degree of similarity	36.324

about the relations between similarity of stimuli and the amount of response is covered by the *law of assimilation*, which

FIG. 37. Frequency of false ("generalized") verbal responses as a function of proximity of vibratory stimuli to initially practiced point. (From E. J. Gibson, 1939.)

states that "each new stimulating condition tends to elicit the response which has been connected with similar stimulating conditions in the past" (Carr, 1925).

The foregoing results are based on percentage of recall for different conditions. Bruce (1933) experimented with conditions even more closely approximating those used in conventional experiments on the transfer of training. He gave his subjects 12 training trials on paired nonsense syllables. Then, keeping the response words constant, he had his subjects learn lists in which the stimuli were either similar to or different from those used in training. His results can be expressed in terms of the per cent difference between the mean number of trials under these conditions compared with the number of trials required with no previous learning (Table 19). Greater positive transfer is

TABLE 19

AMOUNT OF TRANSFER AS FUNCTION OF SIMILARITY OF STIMULI (FROM BRUCE, 1933)

	Percentage of Trials Saved
<i>Similar</i> stimulus words, identical response words	56
<i>Different</i> stimulus words, identical response words	37

produced by similar stimuli than by those that are different.

Let us turn now to results obtained when transfer is studied with identical stimuli but with varying response. This situation may be diagrammed as follows:

	PRIOR LEARNING	NEW LEARNING
Group 1	Learn $S_1 \rightarrow R_1$	Learn $S_1 \rightarrow R_2$
Group 2	Rest (Do not learn $S_1 \rightarrow R_1$)	Learn $S_1 \rightarrow R_2$

At first glance this may seem to represent the conditions obtaining for bilateral transfer, where we have seen that marked positive transfer occurs. But, whereas in bilateral transfer the execution of the cross-member responses is not incompatible with the originally learned responses, under most learning conditions the execution of the new responses (R_2 in the paradigm) is incompatible with the response initially learned

(R_1). Under the latter circumstances negative transfer is usually obtained.

Although anecdotal evidence was available earlier (Münsterberg, 1889), the first systematic study of this problem was by Müller and Schumann (1894). Their generalization is that "when any two items, as *A* and *B*, have been associated, it is more difficult to form an association between either and a third item, *K*." Subsequent studies have provided many examples where prior association makes the new association easier. When the learning of a new association is made more difficult because of a prior association, the effect may be called *associative interference*; when it is made easier, the effect may be called *associative facilitation*.

Adequate data are not available on the amount of transfer as a function of the similarity of the two responses. Bruce (1933) presented data on only two conditions relevant to this analysis, one in which the responses were similar and one in which they were different. The stimuli were identical for the training and the transfer series. With 2 and 6 repetitions of the training lists negative transfer was obtained. The extent of negative transfer was less when the responses were similar. After 12 training trials on the original series, positive transfer (20 per cent) was obtained when the responses were similar, and slight negative transfer (9 per cent) when the responses were different. I. P. Robinson (1948) obtained greater transfer with similarity in responses. On the basis of the present scanty data the generalization would be that negative transfer is obtained when stimuli in the original and transfer situation are identical; i.e. the more similar the response, the less the negative transfer.

What is the effect upon transfer of varying both stimuli and responses? Gibson's (1941) results bear upon this question. She had her subjects learn paired-associate lists with visual forms as stimuli. After 5 trials with the original lists, the subjects learned new lists made up of entirely different re-

sponse syllables but with stimulus terms varying from identity to considerable dissimilarity. The results, presented in Fig. 38, show a clear tendency for the learning of new material to be increasingly difficult with greater similarity of stimuli, provided different responses are involved. I. P. Robinson (1948) stressed the fact that the effect

FIG. 38. Associative interference showing numbers of trials required to learn new list following initial list as a function of similarity between stimuli in initial and new lists. (Data from E. J. Gibson, 1941.)

of degree of stimulus similarity on amount of transfer is dependent on response conditions. "The amount of transfer is an increasing function of response similarity, rate of increase being a positive function of stimulus similarity" (p. 250).

In the light of these facts it is easy to see why it is so difficult to predict whether positive or negative effects will be obtained in transfer of training experiments without knowing the specific stimuli and responses involved. The generalization made by Wylie (1919) that "the transfer effect is positive when an old response can be transferred to a new stimulus, but negative when a new response is required to an old stimulus" still

appears valid, but it requires supplementation to cover the effects of varying similarity between stimulus and response. Osgood (1948) showed how the empirical relations could be integrated by representing stimulus similarity, response similarity, and degree of transfer on a three-dimensional graph.

OTHER FACTORS AFFECTING TRANSFER OF TRAINING

The literature on the effects of various factors on the amount of transfer obtained is so extensive that adequate summary is impossible; only a mention of the most significant variables will be made.

Degree of Learning

In the simple type of transfer represented by stimulus generalization in conditioning there is typically an initial increase in extent of generalization with increase in amount of training. Beyond a certain point there is sometimes a decrease in generalization with further training. The experiments of Hovland (1937*d*) and Razran (1940) on this point have already been mentioned. Analogous results were obtained in transposition experiments by Jackson et al. (1938), and by Gibson (1942) for verbal learning.

In more typical situations, such as those represented in Bruce's (1933) experiment, corresponding results were obtained. Where the initial and transfer tasks had identical responses and similar stimuli (the situation producing positive transfer), increase in training on the initial task increased the amount of positive transfer (Table 20).

Where negative transfer is typical (identical stimuli, different responses) Bruce's results indicate a reduction in the extent of negative transfer with increasing practice. Siipola and Israel (1933) found that with increasing amounts of initial training the negative transfer may even be followed by positive transfer.

A related problem is how the amount of transfer varies with varying amounts of

TABLE 20

AMOUNT OF TRANSFER AS A FUNCTION OF AMOUNT OF TRAINING ON INITIAL TASK (FROM BRUCE, 1933)

Number of Repetitions of Initial List	Percentage of Savings on Transfer List Compared with 0 Repetition
0	0
2	16
6	36
12	56

practice on the new activity, given a constant amount of training on the initial task. Müller and Schumann (1894) found negative transfer to be evident on only the first few trials of the new learning. Their results have been confirmed in the case of the maze learning of children by Yoshioka and Jones (1945), who found the transfer effect primarily on the first trial. Similarly Melton and Von Lackum (1941) found decreasing interference through the first five trials of the new learning.

It would be expected on theoretical grounds that if negative transfer is produced through competition the amount of practice on the original and the transfer tasks would be of less importance than the relative strengths of the two habits in competition. Consequently the amount of practice on the two tasks should be studied in combination. In line with this reasoning the experiments of Siipola and Israel (1933) and Melton and Irwin (1940) indicate that negative transfer is greatest when the degrees of learning of the initial and transfer activities are close to equality. This is the situation that produces maximum conflict in motor tasks (Sears and Hovland, 1941). There is, of course, an upper limit to this relation in transfer, since two extremely well-established habits of equal strength may suffer little interference.

Time Interval between Learning and Test

It would be expected that the time interval between the initial learning and the testing

for transfer would be critical, but the evidence on this point is not clear-cut. Time interval had no effect in the studies of Bunch (1936) and Bunch and McCraven (1938). Ray (1945), on the other hand, found that interference increased with moderate time intervals but then decreased with longer intervals. His time intervals were 14, 27, and 91 days. He tied his results to the theory that learning and forgetting are merely two aspects of the same phenomenon. It must again be emphasized, however, that the relative strength of the two habits, rather than the degree of learning or the time interval, may be the primary variable.

Successive Transfer

Some evidence is accumulating concerning successive transfer. So-called "practice curves" are relevant to this point. It is usually found that the rate of improvement through practice is high at first and then declines. In situations where negative transfer occurs through habit interference, successive shifts from habit to habit appear to reduce the extent of interference (A. J. Culler, 1912; Stroop, 1935). The reversals become easier, the greater the degree of original learning, according to the result of McClelland (1943*b*) for his "serial verbal discrimination" task.

An interesting series of studies on successive transfer conducted by Dr. Margaret Kuenne was reported by Harlow (1949) in connection with his own results on animals. Her results indicated an orderly progression in the performance of children on successive discrimination problems (Fig. 39). When a series of tasks is learned successively, the amount of transfer is affected by the number of prior tasks, although the relation is very complex, for reasons analyzed by Underwood (1944). He found that, the greater the number of prior tasks, the greater the extent of negative transfer. The amount of transfer in such successive tasks is also affected by the time interval between successive units. Bunch (1944) had one group

learn five problems consecutively; another group waited 24 hours between problems. His results indicated that the cumulative effects of transfer are more pronounced in the early stages under massed practice but that the cumulative transfer at the end of the series was approximately equal for the two conditions.

FIG. 39. Percentage of responses correct on trials 2 to 6 in successive groups of discrimination learning problems. (From Harlow, 1949.)

EFFECT OF INTERVENING LEARNING ON RETENTION (REPRODUCTIVE FACILITATION AND INTERFERENCE)

Learning activities not only influence the acquisition of new habits; they also affect the *retention* of habits learned earlier. The research design used to investigate these effects is of the following type:

Experimental group	Control group
Learn activity A	Learn activity A
Learn activity B	Rest (Do not learn activity B)
Recall activity A	Recall activity A

The experimental and control groups differ only in whether a particular learning activity B was interposed between the learning and recall of A. When the intervening learning interferes with the retention of the first learned task, the effect is called *reproductive*

interference (in contrast with *associative interference* discussed earlier). When the intervening learning increases the retention of the original material, we may speak of *reproductive facilitation*.

"Proactive" and "Retroactive" Effects

In the usual experiment on reproductive interference the interpolated material is inserted between the initial learning and the test of retention of the original material, as in the diagram above. Because the interference shows up on the retention of material learned earlier, the interference has been described as "retroactive." Strictly speaking, however, this is a poor term, since the effects do not operate backwards on the prior learning, but only in a forward direction on subsequent recall. Nevertheless the term "retroactive inhibition" is very frequently applied in this connection.

Interference in retention can also be produced by learning other material prior to the primary learning. In this case the interference is said to be "proactive" and the effects are often attributed to "proactive inhibition." The type of experimental design used to study this phenomena is diagrammed below:

Experimental group	Control group
Learn activity B	Rest (Do not learn activity B)
Learn activity A	Learn activity A
Recall activity A	Recall activity A

If the learning of *B* decreases the recall of *A*, the effect is described as "proactive interference"; if the learning of *B* increases the recall of *A*, the effect is called "proactive facilitation."

The existence of proactive effects on retention was first studied by Whitely (1927). A good review is to be found in Underwood (1945, 1948). Although most studies have measured the effects in terms of recall and relearning, proactive interference is also obtained when recognition methods are used (Peixotto, 1947).

Early Studies

The pioneer work on reproductive interference is that of Müller and Pilzecker (1900), who worked with verbal material. These investigators showed that learning new material (nonsense syllables) during the rest interval made the amount of original material recalled less than the amount retained when simple rest was interpolated. Müller and Pilzecker explained the phenomenon on the basis of a post-learning perseveration. They believed that the associative process perseverates for a period following learning and that associations are strengthened and consolidated during this period. Rest immediately after learning favors perseveration and allows a full consolidation of the traces, whereas intervening activity interferes with the setting-in process and leaves the traces less strong. Their explanation thus covers not only intervening learning but any type of intervening activity.

Starting with DeCamp (1915) attention has been focused primarily on the problem of how the retention of prior learning is affected by interpolated new learning. DeCamp found that little reproductive interference in nonsense syllable learning was produced by interpolated mental work. His failure to obtain much interference with divergent materials made him believe that similarity in material was a necessary condition and that "the effect of retroactive inhibition would vary directly as the relative identity of the neurological groups involved" (p. 62). Webb (1917), on the basis of his maze experiments, reformulated the transfer theory of DeCamp to eliminate neural connotations. His statement is as follows:

Transfer hypothesis. "The retroactive effect is regarded as a case of transfer. In the maze sequence A-B-A the term retroaction refers to the effect of the acquisition of the B habit upon the subsequent functioning, or relearning of the A habit. The transfer hypothesis assumes that this effect is medi-

ated by the simple transference of certain elements of the B habit to the succeeding maze A situation. Theoretically this transference may operate either in an advantageous or detrimental manner; in other words retroaction may be positive or negative."

Disruption hypothesis. "In the maze sequence of A-B-A, we know that transfer obtained in proceeding from A to B. Certain elements of the complex A habit have been transferred to and utilized in the maze B situation. The hypothesis assumes that this incorporation of certain components of the A habit into the subsequently acquired B habit must necessarily involve its partial disruption and disorganization." (P. 84.)

Webb specified how the transfer may cause disruption and disorganization of the habit under certain conditions but may result in facilitative effects under others.

Reproductive interference has been one of the most popular topics of study in learning (cf. reviews by Britt, 1935, and Swenson, 1941). There has been an increasing tendency to concentrate on the analysis of how new learning affects retention rather than on how retention is affected by non-learning activities such as physical and recreational activities, which are typically less interfering than learning activities (McGeoch, 1931; Irion, 1946). As a consequence it seems desirable to employ the terms "reproductive interference" and "reproductive facilitation" to cover the phenomena rather than the frequently used term "retroactive inhibition" (coined by Müller and Pilzecker), which usually covers intervening learning as only a special case of intervening activity. The way has been paved for this transition in terminology by the contributions of McGeoch (cf. especially McGeoch, McKinney, and Peters, 1937). If it is desired to specify whether the reproduction is interfered with by prior learning or by materials interposed between learning and retention, the terms "proactive" and "retroactive" may be applied.

Similarity between Original and Interpolated Learning

One of the most significant factors affecting the amount of interference or facilitation has been found to be the similarity between the interpolated learning and the original material. Robinson (1927) defined the problem clearly by analyzing certain a priori considerations. He reasoned that with identity of the original and interpolated materials there would have to be positive transfer. On the other hand, with no resemblance the ef-

FIG. 40. Hypothetical relation between similarity of original and interpolated material and amount of reproductive interference. (From E. S. Robinson, 1927.)

fect should approach zero. In between there should be varying amounts of inhibition. "As similarity between interpolation and original memorization is reduced from near identity, retention falls away to a minimum and then rises again, but with decreasing similarity it never reaches the level obtaining with maximum similarity" (pp. 298-299). This formulation would give the accompanying hypothetical curve (Fig. 40).

This type of analysis raises the question: what aspect of the interpolated activity is to be rated in terms of similarity to the original activity, and how can it be measured? Pending an answer, we are unable to know whether obtained results are relevant to the A-B or B-C portion of the curve.

Robinson used as his definition of similarity the proportion of interpolated units that were identical to the original. He used lists of 8 consonants for learning material in a memory-span setup. He regarded the learning of the first 4 in the list as the orig-

inal task and the learning of the last 4 as the interpolated task. These lists can be schematized as follows:

ELEMENTS IN COMMON	ORIGINAL	INTERPOLATED
None	a-b-c-d	e-f-g-h
One	a-b-c-d	a-f-g-h
Two	a-b-c-d	a-b-g-h
Three	a-b-c-d	a-b-c-h
Four	a-b-c-d	a-b-c-d

Sixteen different arrangements of elements were used in all. His experimental results are shown in Fig. 41. There is a continuous

FIG. 41. Reproductive interference as a function of varying amounts of similarity between original and interpolated material. Each curve is for a different cycle of the experiment. (From E. S. Robinson, 1927.)

drop in retention as predicted. There is no suggestion, however, of a rise with maximum difference between original and interpolated learning.

Harden (1929) contended that Robinson's procedure was appropriate only for testing the initial part of the curve. She used consonants in the first positions of the list and varying proportions of letters and numerals in the second half. Her most "similar" list consisted entirely of consonants, and her most "dissimilar" list contained consonants in the first half (original material) and all digits in the second half (interpolated ma-

terial). She found a sharp end rise in the second portion of the curve.

In the writer's opinion Harden confused the issue by introducing two dimensions of similarity. If similarity is to be defined as degree of identity of elements (as Robinson defined it), the extremes would be represented on the one hand by all elements in common and on the other by no common elements. Numerous other possible definitions of similarity exist, of which her factor of proportion of the list coming from the same class of material (consonants or digits) is but one example. Accordingly the Robinson and the Harden experiments cannot well be plotted on a unitary dimension of similarity.

Boring (1941) tried to formulate the identity (or communality) dimension more rigorously and to test some of its quantitative implications. He analyzed the original and interpolated learning into n terms. He let n_1 represent the number of terms used in A repeated in B . (This would represent various numbers of consonants in common in Robinson's study.)

n_1 = number of terms from A repeated in B .

n_2 = number of new terms in B .

n = number of terms in A and in B =
 $n_1 + n_2$.

He then distinguished between the kinds of relations existing between various pairs of terms. These may be of three kinds: repeated relations where both terms that make the relation are repeated from A in B , un-repeated relations where both terms are changed from A in B , and altered relations where one term is changed and the other is not. He then proposed the following designations:

r_1 = number of repeated relations between n_1 terms.

r_2 = number of entirely new relations between n_2 terms in B .

r_3 = number of altered relations, where one term is repeated and the other changed.
 r = number of paired relations between n terms = $r_1 + r_2 + r_3$.

If it is assumed that identical repetitions (r_1 relations) are facilitating, and those in which one term is changed and the other is not (r_3 relations) are interfering, the amount of facilitation (F) becomes

$$F = r_1 - r_3 = \frac{n_1(3n_1 - 2n - 1)}{2}$$

If we apply this formulation to Robinson's experimental design we would substitute

FIG. 42. Rationally derived relation between similarity and extent of reproductive facilitation or interference. (Based on formula of Boring, 1941.)

values of n_1 from 4 down to 0 (and let $n = 8$). The curve that would result is shown in Fig. 42.

The overall form of the curve is similar to that hypothesized by Robinson and has a more rigorously defined rationale. Boring doubted, however, that "the right end of the curve, $n_1 = 0$, could ever be found, since the evidence from transfer and retroaction is that no two comparable organizations could be completely disparate" (p. 282). Does he at this point depart from his original operational definition of similarity?

A systematic repetition of the experiments of Robinson and of Harden has been reported by Kennelly (1941). He confirmed the results obtained by Robinson but got data that were markedly divergent from those of Harden. He then set up an experiment that conformed more closely to the procedures of the typical "retroactive inhibition" study by having the subjects learn and

FIG. 43. Percentage of recall with varying degrees of similarity between items in original and interpolated materials. (From Kennelly, 1941.)

recall the original and interpolated materials as separate units. The subjects were given three repetitions of a list of 8 consonants or 8 numbers. After a 10-second pause the subjects were given three repetitions of interpolated material also consisting of 8 consonants and numbers with varying similarity to the original lists. His results are shown in Fig. 43. They do not confirm the results of Harden, but they look interestingly similar to the equation of Boring.

Another definition of similarity of material would be in terms of the similarity of the individual stimuli and responses. This definition leads to an analysis along lines exactly similar to those used above in analyzing transfer of training.

Using this approach, one might first analyze the effect of varying the stimulus but

keeping the response constant. This can be diagrammed as follows:

	ORIGINAL LEARNING	INTERPOLATED LEARNING	RECALL OF ORIGINAL LEARNING
Experimental group A	Learn $S_1 \rightarrow R_1$	Learn $S_{1a} \rightarrow R_1$	Recall $S_1 \rightarrow R_1$
Control group	Learn $S_1 \rightarrow R_1$	Rest (Do not learn $S_{1a} \rightarrow R_1$)	Recall $S_1 \rightarrow R_1$

S_{1a} designates a stimulus similar but not identical to that learned originally.

FIG. 44. Reproductive facilitation as related to degree of similarity between stimuli when responses are identical. (Index of similarity based on percentage of generalization found in prior experimentation.) (Data from Hamilton, 1943.)

Results under these conditions can also be compared with continuous practice on the same material (identity):

Experimental group B	Learn $S_1 \rightarrow R_1$	Learn $S_1 \rightarrow R_1$	Recall $S_1 \rightarrow R_1$
-------------------------	-----------------------------	-----------------------------	------------------------------

or with distinctly different material (where a different stimulus is designated S_2):

Experimental group C	Learn $S_1 \rightarrow R_1$	Learn $S_2 \rightarrow R_1$	Recall $S_1 \rightarrow R_1$
-------------------------	-----------------------------	-----------------------------	------------------------------

Hamilton (1943) showed that interpolated material having stimuli similar to the one used in the original learning have a *facilitating* effect which decreases with decreasing similarity of stimuli (Fig. 44) when identical responses are involved. This is analogous to the finding of stimulus generalization or "assimilation" in the case of transfer of training. Osgood (1946) obtained

reproductive interference rather than facilitation under these circumstances, but he did find that, the greater the similarity of stimuli, the less the interference.

If the response is varied but the stimuli are identical (analogous to the situation that produces associative interference in transfer of training), we have the following paradigm:

Learn $S_1 \rightarrow R_1$ Learn $S_1 \rightarrow R_{1a}$ Recall $S_1 \rightarrow R_1$

R_{1a} indicates a response similar to R_1 .

At the extreme where responses are actually identical, the interpolated material would constitute another practice trial, and hence high facilitation is expected. When

FIG. 45. Reproductive interference as related to similarity of stimuli in original and interpolated learning when responses are different. (Index of similarity based on percentage of generalization found in prior experimentation.) (From E. J. Gibson, 1941.)

R_{1a} is extremely different from R_1 , interference is customarily obtained. No systematic evidence is available on how the extent of interference is affected by the degree of similarity of responses.

When variation in both stimuli and responses is studied, it is found that the more similar the stimulus in the interpolated learn-

ing is to that used in the original learning, the greater the interference. This has been shown by Gibson (1941) for forms paired with nonsense syllables. The stimuli were chosen to represent various points on the gradient of generalization. Her results are shown in Fig. 45.

From the foregoing considerations it is clear that it is necessary to specify both the stimulus and the response dimensions rather than the single one of varying degrees of identity specified by Robinson (1927). A good analysis of this problem was made by Gibson (1940).

In addition to the two methods of defining similarity presented above there are many others. They include similarity of meaning (e.g. McGeoch and McDonald, 1931; Treverton, 1941), similarity in degree of association value (Sisson, 1938), similarity of task and operation (Gibson and Gibson, 1934), similarity of spelling (Cheng, 1929) and similarity of association (McClelland and Heath, 1943).

OTHER FACTORS AFFECTING REPRODUCTIVE INTERFERENCE

Degree of Learning

The higher the degree of original learning, the less is the amount of reproductive interference. This is illustrated in the results of McGeoch (1929) in which the interpolated learning was always given 11 trials but the number of trials of the original learning varied from 6 to 26 trials. See also Shaw (1942).

When, on the other hand, original learning is held constant, there is a curvilinear relation between degree of interpolated learning and interference. Initially, increases in degree of interpolated learning are accompanied by increases in the amount of interference, but later increases in interpolated learning are accompanied by a decline in the amount of interference (Melton and Irwin,

1940; Fig. 46). Thune and Underwood (1943) reported that reproductive interference increased up to 16 repetitions of the interpolated list, beyond which an additional 10 repetitions yielded no further increase in interference.

Other data reported by Melton and Irwin (1940) support the hypothesis that maximal retroaction occurs when original and interpolated activities have been learned to approximately equal degrees. This accords with the

FIG. 46. Reproductive interference with varying numbers of practice trials on an interpolated list. (Data from Melton and Irwin, 1940.)

results of Siipola and Israel (1933) and Sears and Hovland (1941), cited in connection with transfer of training: in a conflict situation the probability of blocking becomes greater as the strength of the competing responses approaches equality. As in transfer of training there may be an upper limit at which there is no interference when both habits are very strong.

Temporal Relations

Results to date do not give a clear picture of the relation between the amount of interference and the time when the interpolation occurs. Early studies have given conflicting results, and later experiments do not clarify the picture. Houlahan (1941) found the amount of reproductive interference to vary directly with the proximity of interpolated learning to recall. Bunch (1946) found that,

with a punchboard maze, interpolated learning of a similar maze immediately after learning produced interference, but, when the interpolated maze was learned 120 days after learning, the relearning that followed immediately showed facilitation rather than interference. Postman and Alper (1946) obtained the greatest relative loss 1 and 8 days after learning, and 1 day before retest. Svenson (1941), after reviewing the results available at the time of her survey, concluded that interpolation is more effective in producing interference when it is adjacent either to original learning or to recall of original learning than at other points.

Quantity of Material

Both the amount of original material and the amount of interpolated material have been varied experimentally. The early studies of Robinson and Heron (1922) and Robinson and Darrow (1924) found that longer lists produced less interference than shorter lists. Later work by Sand (1939) casts doubt on the generality of their findings. Sand used 7 pairs of associates as the interpolated material and 6, 8, 10, 12, and 15 pairs as the original material. All but the shortest list gave equivalent interference.

At least with verbal materials, it appears that, the greater the amount of interpolated material, the greater the interference. Twining (1940) taught subjects a list of 8 nonsense syllables. Then 1, 2, 3, 4, or 5 lists were interpolated. The more lists used, the more adversely affected were both recall and relearning. Twining's data on recall are presented in Fig. 47. Similar results were reported by Underwood (1945) when the criterion was recall, but reliable differences were not shown in the number of trials required for relearning to mastery.

"Unlearning" Factors in Reproductive Interference

The analysis presented above of the nature of reproductive interference stresses the conflict of responses attributable to the fact

that the same or similar stimuli have been attached to more than one response. Another important factor affecting retention is the fact that the stimulus-response connec-

FIG. 47. Reproductive interference with varying numbers of different interpolated lists. (Data from Twining, 1940.)

tion involved in retention may be specifically unlearned. Thus let us suppose that $A \rightarrow B$ is learned; then $A \rightarrow C$ is interposed and the retention of $A \rightarrow B$ is tested. During the $A \rightarrow C$ learning the conditions for unlearning of $A \rightarrow B$ are established (cf. Melton and Irwin, 1940). A good test of the relative importance of this factor as compared with the factor of direct conflict is to compare the

retroactive and proactive interference situations:

Retroactive interference paradigm	Proactive interference paradigm
Rest	Learn $A \rightarrow C$
Learn $A \rightarrow B$	Learn $A \rightarrow B$
Learn $A \rightarrow C$	Rest
Recall $A \rightarrow B$	Recall $A \rightarrow B$

These two designs differ primarily in whether the subject gets specific practice in dissociating the learning of A and B through practicing of $A \rightarrow C$ after learning $A \rightarrow B$.

The amount of interference with retention produced by these two designs was compared by Melton and Von Lackum (1941). Their subjects learned lists of ten 3-consonant syllables for 5 trials, some with the proactive design and some with the retroactive design. Greater interference was obtained in the recall of the first learned lists. In an experiment by McGeoch and Underwood (1943), consistent but not reliably greater amounts of retroactive than proactive effects were obtained.

In the foregoing studies retention was measured shortly after the learning (*ca.* 20 minutes). When a 48-hour interval was used by Underwood (1948), the first and second lists were equally well retained. These results, if confirmed, will require modification of the "unlearning" formulation. Underwood proposed that unlearning is analogous to the experimental extinction of a conditioned response. These unlearned verbal associations that have been "unlearned" would then be expected to recover in strength with the passage of time, like extinguished conditioned responses.

McGeoch (1942) was inclined to believe that the unlearning factor can ultimately be interpreted in terms of competition of response, and that the dual character of the theory is simply an acknowledgment of the double locus of the competition. Bugelski (1948) also believed this to be the case. He found that when a series of lists is learned in rapid succession the odd-numbered lists are learned better than the even-numbered lists. The "unlearning" theory would ex-

plain this as due to the fact that time spent in unlearning a former list would reduce the time available for learning the new list. But Bugelski pointed out that the results could be explained equally well by McGeoch's interference explanation since a well-learned list could interfere more strongly than one poorly learned. Only further experimentation can determine whether the "competition" factor and the "unlearning" factor are distinctive or are merely different aspects of the same process.

CAUSES OF FORGETTING

Throughout the preceding discussion there have been reported a number of factors whose effect is to reduce retention. A brief attempt will be made here to list more systematically the various factors producing loss in retention with the passage of time.

Disuse

In early discussions of forgetting the most common explanation was that forgetting was a decrease in recall due to lack of use of the material. Using the analogy that a muscle is strengthened through exercise and weakened through disuse, theorists stated that repeated practice strengthens connections and lack of use weakens connections. It is possible that some forgetting does occur owing to physiological changes associated with disuse. Such an explanation has been reiterated by Thorndike and his collaborators (Bregman, Thorndike and Woodyard, 1943) to explain the loss, with time, in the ability of blindfolded subjects to draw lines of appropriate length. The extent to which forgetting can be explained on a physiological basis, however, is much smaller than was earlier thought, and such *ad hoc* explanations should not be invoked when other factors can be isolated.

Reproductive Interference

The earlier discussion of the extent to which recall is affected by intervening learn-

ing points up the importance of this factor in accounting for much of forgetting. In our daily life we are commonly learning new responses to stimuli that formerly evoked other responses, the situation most productive of interference.

Research on this problem compares the amount of forgetting with varying interven-

tions as it is a matter of interference, inhibition, or obliteration of the old by the new" (p. 612). Similar results, although with smaller differences, were obtained by Van Ormer (1932). These experiments closely simulate the conditions of real life and indicate that intervening activity is a potent factor in producing forgetting.

FIG. 48. Retention curves for nonsense syllables following various time intervals of sleep and waking (two subjects). (From Jenkins and Dallenbach, 1924.)

ing activities. The most desirable control comparison would be with absolutely no intervening activity, but this is of course impossible. A close approximation is achieved if the intervening activity is sleep. Forgetting is less rapid when sleep intervenes between learning and recall than when the intervening interval is filled with waking activity. The best-known experiment on this point is that of Jenkins and Dallenbach (1924) on the retention of nonsense syllables during sleep and waking. From their results, presented in Fig. 48, they conclude: "The results of our study as a whole indicate that forgetting is not so much a matter of decay of old impressions and associa-

Unlearning

Distinguishable in theory but closely linked in actual situations is the factor of unlearning. In the time intervening between learning and recall we are often confronted with some of the relevant stimuli, but we do not make the response initially learned. Thus we practice not making the learned response. Melton and Irwin (1940) have given a clear exposition of the role of this factor and its relation to reproductive interference.

Changed Cues

A fourth important factor in forgetting is the alteration of the stimulating conditions from the time of learning to that of the measurement of retention. Forgetting occurs when some of the stimuli present during the original learning are no longer present during recall, or when new stimuli are present that evoke competing responses sufficiently strong to block those originally learned. Relevant stimuli are both external (like the furniture in the room in which we learn, the apparatus, the experimenter, etc.) and internal (resulting from posture, responses made during learning, etc.). Reduced recall has been shown when learning has been in one location and testing in another (Abernethy, 1940). The gradient of generalization discussed above operates in determining the amount of such transfer. Similarly, when words are learned with one color background, recall is reduced when the background is changed (Dulsky, 1935). Case studies have also shown that a language learned in one context is poorly retained in a different context but is quickly relearned when the original context is restored (Carr, 1925).

Changed Set

Forgetting is sometimes due to the fact that recall occurs with a different set from that operating during the original learning. If one learns material with the expectation that he will have to recall it at a particular later date, attempts to recall it either earlier or later will be less successful. When the method of testing retention is altered, retention is also adversely affected (Postman and Jenkins, 1948). To what extent the explanation of such results coincides with the explanation in terms of changed cues at the time of recall is a problem for further research. A good review of the role of set will be found in J. J. Gibson (1941).

A related aspect of set concerns the relative retention of completed and incompleting tasks. A task that has been finished is less well recalled than one still incomplete, according to Zeigarnik (1927), although there have been a number of failures to confirm the appearance of the phenomenon. Detailed discussion of the results is beyond the scope of the present chapter, but an excellent review is available in Prentice (1944).

The foregoing discussion suggests that a large number of factors influence forgetting. Some may wonder whether they do not "overexplain" the phenomenon of forgetting and raise the question of why we remember things at all. Others may ask whether we ever forget things completely, or whether there exists only temporary interference with recall that could be overcome under appropriate conditions of set, context, etc. These questions cannot be answered at present, not only because we do not know all the factors involved, but more particularly because we have inadequate data concerning the relative contribution of various factors. Here, as throughout the entire field of learning and retention, there is an urgent need and an important opportunity for the kind of theoretical systematization that not only will specify the relevant parameters but will provide quantitative weighting as well.

MATHEMATICAL FORMULATIONS OF LEARNING

Empirical Equations

It was a natural development that, when results from a number of different studies became available, attempts should be made to formulate relations between learning variables in quantitative form. The first attempts were empirical equations that were not based on theory but were merely found to fit the available data. The first proposed was

$$y = a + be^{-cx}$$

where y is a measure of attainment, x is a measure of practice, and a is the limit of attainment as practice increases without limit. This equation was developed by Schükarew (1907) on the analogy of a monomolecular chemical reaction.

A second form is based on the assumption that the rate of learning with respect to the amount of practice is proportional to the product of the amount already learned and the amount still to be learned (the difference between present attainment and the physiological limit; or between total amount to be learned and amount already learned).

$$y = \frac{be^{Ax}}{c + e^{Ax}}$$

where y is a measure of attainment, x is a measure of practice, a is a constant for learner and task, b is the limit of attainment, $A = ab$, and c is a constant of integration. This equation was developed by Robertson (1908) on the analogy of a monomolecular autocatalytic reaction. It was later used by Valentine (1931).

Foucault (1914) used the hyperbola to fit his learning data and later called it "the law of exercise." Thurstone (1917) also suggested using the hyperbola

$$y = \frac{a(x + c)}{(x + c) + b}$$

in which y represents attainment in terms of number of successful acts per unit of time, x is the total number of practice acts, c is previous practice, a is the physiological limit, and b is a number representing the rate of learning. Other empirical equations that have been proposed are discussed in the excellent review by Gulliksen (1934).

Rational Equations

Of greater significance has been the more recent formulation of "rational" equations based on hypotheses concerning the relations among the variables. These are particularly important because they not only summarize data but also permit us to test the agreement between data and theory. One of the earliest important formulations of a rational equation was made by Thurstone (1930*b*). He assumed that at any one moment "all the acts that the learner is at all likely to initiate in his effort toward a goal may then be arbitrarily divided into two categories, those that lead to success and those that lead either to overt or implicit error . . ." (p. 470).

On the basis of his theory Thurstone developed a rational equation (1933):

$$u = \frac{(\sqrt{m/ak})R}{R + (\sqrt{m/k})}$$

where u = cumulative errors, R = number of trials, m and k are constants dependent on the task and learner, respectively, and a is a factor to take care of possible differences in units.

Thurstone found that this equation provided a very good fit to the maze data of Lashley. Parenthetically it should be noted that this equation, derived rationally, is essentially the same as the one suggested earlier by Thurstone on empirical grounds.

An important extension of Thurstone's work has been made by Gulliksen (1934), based on explicit formulation of Thorndike's law of effect. He derives the following equation:

$$u = \frac{g}{c} \left[1 - \left(\frac{\frac{h}{k}}{w + \frac{h}{K}} \right)^{c/k} \right]$$

where u = cumulative errors, w = cumulative correct responses, g = initial strength of incorrect response, h = initial strength of correct response, c = constant amount deducted from the strength of the incorrect response each time it is repeated and punished, and k = the constant amount added to the strength of the correct response each time it is repeated and rewarded. When k approaches zero, the function becomes exponential similar to the empirical equation presented above. Subsequently Gulliksen and Wolfe (1938) extended this type of treatment to problems of discrimination.

One of the most ambitious attempts at a rational treatment of learning data was made by Hull in his book, *Principles of Behavior* (1943). In contrast to the preceding studies, many more variables are taken into account. The major variables considered are drive, reinforcement, and temporal factors. The relation between strength and habit and number of reinforcements is represented as a positive growth function:

$$sHr = M - Me^{-kN}$$

where sHr = habit strength, M = physiological maximum of habit strength, N = number of reinforcements, and k and e are constants. More detailed formulas take temporal factors and size of incentive more specifically into account (e.g. formula 16, p. 178).

Most of these formulations are of a general character and apply to all types of learning. The deductions from them have often been tested in animal experiments. The most extensive development of a mathematical systemization specifically for human learning is that of Hull et al. (1940) for verbal rote learning. Their deductions dealt with serial position effects, reminiscence, length of lists, massed and distributed prac-

tice, oscillations at the threshold of recall, and a variety of other learning phenomena. The experimental evidence bearing on the truth or falsity of each deduction is summarized by the authors.

A very general mathematical formulation of learning is found in various papers by Rashevsky (e.g. 1936). His interest was in basic phenomena of learning, and he made little attempt to relate his formulations to empirical results. Pitts (1943), on the other hand, presented a treatment that is highly relevant to present learning problems and systematically relates experimental results to his equations.

Theoretical Interpretations of Learning

KENNETH W. SPENCE
The State University of Iowa

A theory in science serves to bring order and meaning into a particular realm of events. The task of ordering a set of events consists in discovering relations among them, or, as we say, in finding empirical laws. In the initial phases of this search we employ the process of inductive generalization from observation and experiment. In the physical sciences this process is straightforward enough, for the scientist in this area is able to arrange for simple systems of observation that permit the isolation and control of a relatively small number of variables. Unfortunately the behavior of living organisms does not yield so readily to simplification and control. The greater complexity of psychological phenomena makes difficult, if not impossible, the experimental isolation and measurement of the relevant variables. Consequently psychologists have found it necessary to guess or theorize much more than physicists had to at this stage of development in their field of knowledge.

As a consequence of the very different stages thus far reached in their development, quite different conceptions of the meaning of the term theory exist in psychology and physics. A theory in present-day physics is a system of highly abstract constructs used to integrate sets of empirical laws that without the theory would appear to be quite unrelated. Examples of such integrating devices are the electromagnetic theory of radiation and the kinetic theory of gases. In contrast, what passes for theory in the be-

havior sciences serves primarily as a device to aid in the formulation of descriptive laws.

Theory in psychology, then, consists primarily in the introduction or postulation of hypothetical constructs to represent the unknown or uncontrolled factors in a situation under observation. The relations of these constructs to the experimental (measured) variables are, in effect, hypothetical guesses at psychological 'laws.' Tolman (1938a) has suggested the term "intervening variable" as a name for these theoretical constructs in psychology because they are assumed to *intervene* between the independent environmental variables on the one hand and the dependent response measures on the other.*

The Task of the Learning Theorist

The task confronting the theorist in the field of learning involves (1) the specification of the experimental variables, environmental and organic, that determine the observed behavioral changes that occur with practice, and (2) the formulation of the functional interrelations (laws) holding between these sets of variables. It is the second of these tasks that has required an extensive use of the intervening variable type of theoretical construct.

Indeed, learning itself is just such a hypothetical construct. This meaning of the term

*A more complete discussion of the various types of theorizing in science and the differences between theory in physics and in psychology may be found in Bergmann (1943), Spence (1945, 1948), and Stevens (1939).

is exemplified in the distinction made by many psychologists between the concepts "performance" and "learning." Performance has reference to the observable, measurable response, a purely empirical concept. Learning refers to a hypothetical factor which is assumed, on the one hand, to be the product of the past interactions of the indi-

Figure 1 shows the relations between this type of hypothetical learning construct L, other intervening variables, such as drive D, and the various experimental variables, e.g. present environmental events S, past environmental events, or antecedent conditions AC, and response R. As we shall see, various learning theorists have differed markedly in

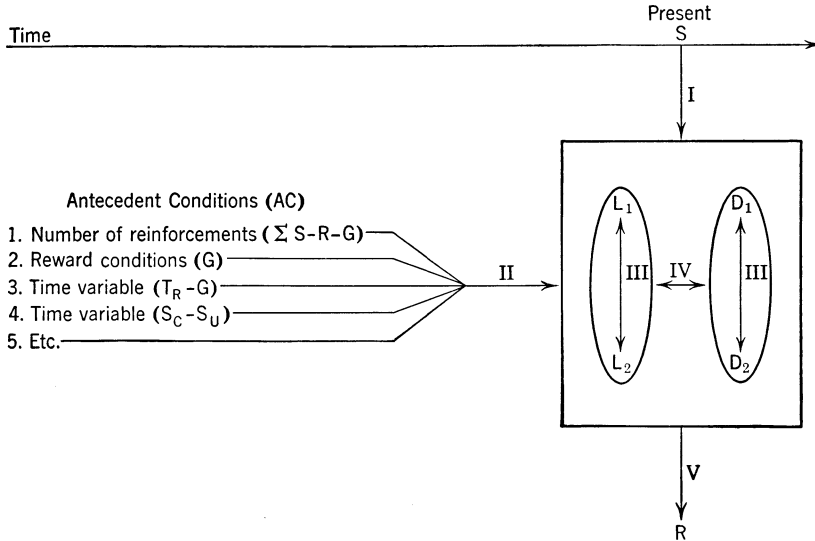

FIG. 1. The relations between intervening theoretical constructs and experimental variables, environmental and response. L and D represent two classes of intervening variables that are assumed to be defined in terms of the antecedent and present environmental variables. They are interrelated with each other and are related to an empirical response measure.

vidual with his environment, and, on the other, to be one of the conditions that determines his performance at any moment. In this sense learning is similar to other constructs representing hypothetical states of the organism, such as drive, fatigue, drug condition, etc., which are assumed to be among the determinants of performance. The learning theorist, in other words, ascribes the progressive changes in behavior that occur in a learning experiment to changes that develop in this hypothetical learning state as a result of previous experiences in the situation. This assumes, of course, that he has taken proper care to control all other factors that affect performance.

the way they have conceived their hypothetical constructs. Some have inferred them entirely from behavior changes or from phenomenological introspection, and have not attempted to tie them up with antecedent environmental conditions. Others have introduced them in terms of antecedent conditions (type II relation in Fig. 1) but have neglected to specify their relations to other nonlearning factors (e.g. drive state, type IV) or even to the response variable (type V). A few have concerned themselves primarily with an account of learning in terms of neurophysiological changes, or have emphasized primarily their intrinsic properties (type III relations). In addition to

these differences there have been disagreements as to the method of specifying operationally the antecedent conditions essential for the learning to take place. And last, but probably most confusing, rich and varied jargons have been employed, in which many terms appear to refer to essentially similar notions.

CLASSIFICATION OF LEARNING THEORIES

The Major Issues Dividing Learning Theorists

The classification of learning theories is a purely arbitrary matter. Depending upon the criteria chosen, quite different classificatory schemas may be developed (Dashiell, 1935; Tolman, 1934; Spence, 1942). The distinctions to be made in the present treatment are based upon what appear to be the two major issues dividing learning theorists today. (1) The first of these has to do with the nature of the fundamental concepts (intervening variables) employed to represent the hypothetical changes that take place in learning. (2) The second issue is concerned with the conditions assumed to be necessary for the hypothetical learning changes to occur.

If we designate the rival theories in terms of the type of theoretical construct they favor, we may divide them into perception or S-S (sign-significate) theories on the one hand, and S-R (stimulus-response) theories on the other. If we divide them according to "necessary conditions" we get three groups: (1) reinforcement or law-of-effect theories, (2) theories that do not hold reinforcement to be necessary for learning, and (3) two-factor theories, which assume that there are two basically different learning processes, one governed by the principle of reinforcement, and the other occurring independent of reinforcement.

When we consider the two issues together, we note that there is a marked tendency for those who adopt the same position on the

first issue to stick together on the second. Thus most S-S (perception) theorists support the nonreinforcement position, whereas the majority of S-R theorists believe in a law of reinforcement either as a universal law or as a law governing all learning except certain forms of the conditioned response. However, as we shall see, there are a number of exceptions to this tendency, and we find some psychologists who qualify as S-R nonreinforcement theorists and some who propose a theory of learning that is essentially an S-S reinforcement theory.

S-S versus S-R Learning Theories

The characteristics of the two main types of learning theory may be outlined briefly. One group of theorists (Köhler, 1929, 1940; Koffka, 1935; Lewin, 1936, 1942; Tolman, 1932, 1934; Adams, 1931; Zener, 1937) takes the position that learning is to be conceived in terms of the organization (or reorganization) into some kind of functional whole of the perceptual systems of the subject. In sharp contrast is the conception, held by a different group (Thorndike, 1935; Hull, 1943; Guthrie, 1930, 1935; Miller and Dollard, 1941; Spence, 1936) that learning is to be conceived in terms of alterations in the strengths of hypothetical intervening variables, variously referred to as S-R connections, associations, habits, or tendencies.

Learning as perceptual reorganization. The essential notion underlying the S-S theory is that learning is part of a larger problem of organization, including, as a most important aspect, perceptual organization. Instead of thinking of learning in terms of stimuli, responses, and modifiable associative connections, these theorists all agree on emphasizing its perceptual character. Referring to the simple type of learning involved in the conditioned-response situation, Zener writes:

According to the sign-urge conception [the name he applies to his variation of the theory], the essential structural modification consists in a reorganization into some kind

of functional whole of the perceptual systems (relatively afferent, if you will) corresponding to the conditioned and unconditioned stimuli; and in the functional relation of this organized system to the urge or tension system originally excited by the unconditioned stimulus. [1937, p. 386.]

Koffka (1935) describes learning as equivalent to a perceptual reorganization in which perceptual processes and their traces become organized into complex structures exhibiting field properties. Koffka's treatment of latent learning in the maze provides another good example of this emphasis. He writes:

What the animal has developed during its "latent learning" is a trace of the maze; this trace, being in communication with the present activity, regulates it more or less as the perception of the maze would. [1935, p. 588.]

Adams (1931), Tolman (1932, 1934, 1936, 1938a), and Lewin (1942) likewise emphasize that learning involves primarily the structuring of the cognitive field of the subject, i.e. the formation and modification of cognitive patterns corresponding to the stimulus relations in the environment. According to Tolman, the most active contributor among the S-S theorists, learning involves the development under the guidance of the principle of contiguity of what he calls a sign-Gestalt-expectation. This is one of his hypothetical intervening variables. It may be thought of as a cognitive pattern in which are organized the successive perceptual processes occurring in a behavior sequence.

As a final example of the perceptual approach to learning, let us consider the following paragraph from White's article (1943) in which he attempted to describe in everyday language the Tolman-Lewin interpretation of learning:

The perceptual-learning postulate implies the importance of *perceptual 'field' conditions at the time of the original perception*, rather than any subsequent reward or 'rein-

forcement.' This difference is both an affirmation and a denial. It affirms the importance in relation to learning, and not merely in relation to perception, of all those field conditions which have been experimentally shown to influence perceptual organization: temporal contiguity, spatial contiguity, visual continuity, common contrast, embeddedness, exploratory motivation, etc. All of these factors, except temporal contiguity, have been given less emphasis by S-R psychologists. [1943, p. 166.]

Learning as modification of S-R tendencies. The S-R theories formulate their account of learning in terms of stimulus-response connections (bonds, associations, habits, tendencies). Unfortunately these different terms have no clear-cut, single meaning. For some (Gates, 1942; Guthrie, 1942) they seem to refer to a purely empirical concept: the observed functional relation between a situation and a response. At times Thorndike (1940) seems also to have used the concept of S-R bond in this non-theoretical sense.

On the other hand, these terms sometimes refer to a hypothetical learning state (intervening variable). Hull (1943) and Thorndike (1913) have both employed one or another of these concepts in this sense. In effect, Thorndike's three major laws of learning provided definitions of his concept of S-R bond in terms of the experimental conditions, variation of which led to changes in the strength of this hypothetical learning factor. Later, in connection with his experimental studies with human subjects, Thorndike (1932) introduced six additional experimental variables that must, he believes, be taken into account in determining the strength of an S-R bond. These are belongingness, impressiveness, polarity, identifiability, availability, and mental systems (set). It is rather interesting to note that most of these variables are of the type emphasized by the perception-learning theorists, particularly the Gestalters. They refer to the content of the material learned

rather than to relations — e.g. temporal — between the contents.

Thorndike's major interest has been in the identification of the experimental conditions that are responsible for the occurrence of learning. In particular he has attempted to discover and describe the properties of a reinforcing state of affairs. He has not been particularly at pains to specify the nature of the functional relation between his hypothetical intervening variable, the S-R bond, and the antecedent experimental conditions. In sharp contrast is Hull's treatment of learning (1943). Hull's theoretical construct, *habit* (sH_R), is very precisely introduced by way of specific equations that relate it to the relevant antecedent experimental conditions — e.g. number of previous reinforcements, quantity of the goal object, time of delay of the reward. In addition, Hull specifies certain additional relations between *habit* and other similarly hypothesized intervening variables (drive, excitatory potential, inhibition, etc.), and he ends by relating all the latter to the several empirical response measures used in conditioning experiments.

So far as emphasis upon the association's being between stimulus and response is concerned, the most explicit of all theorists in this group is Guthrie. He writes:

Our position is that what is associated is a stimulus and a response. It would perhaps be more exact to say that what is associated is some stimulation of sense organs and a corresponding muscular contraction or glandular secretion. By calling them associated we mean that the stimulation has become the occasion for the response because of a past association of the two. [1942, p. 43.]

Guthrie here seems to use the word "association" in two senses. One refers to the condition of contiguity essential to the establishment of the relation. The other meaning appears to be comparable to the nontheoretical meaning of Thorndike's S-R bond — i.e. the observable relation between stimulus and response. At still other times Guthrie seems to have reference to a more theo-

retical notion — one roughly comparable to an afferent-efferent tie-up in the nervous system rather than an afferent-afferent connection. Guthrie himself avoided all reference to the nervous mechanisms underlying learning, but his writings imply that the functional tie-up is between sensory events and motor events rather than between the sensory events resulting from the conditioned and unconditioned stimuli.

The Reinforcement — Nonreinforcement (Contiguity) Issue

The second of the two major issues dividing learning theorists is concerned with the conditions deemed essential for the occurrence of the hypothetical learning changes, whether conceived in terms of variations of the strengths of S-R tendencies or as cognitive restructurings. Although the origins of the issue may be traced back to the earliest speculations of philosophers, its modern form dates from the beginning of laboratory investigations near the start of the present century. Out of the studies of Pavlov (1927), Thorndike (1898), and others, there have gradually developed three different positions with respect to the conditions that are essential for learning.

1. One point of view makes the assumption that learning requires some kind of motivating state, primary or secondary, and the occurrence of a reinforcing situation, variously described as drive reduction, satisfying after-effect, success, pleasure, and primary or secondary rewards. Although Thorndike's name has been most prominently associated with this *law-of-effect* type of theory, Thorndike did not himself hold strictly to the view that *all* learning involves the law of effect. Hull (1943), on the other hand, has attempted to develop a theory in which all instances of learning are subsumed under a common principle, the law of effect, or, as he prefers to designate it, the principle of reinforcement.

2. Diametrically opposed to this reinforcement theory may be grouped a number of

theorists whose views on the nature of learning are otherwise quite divergent (Tolman, 1937, 1938*b*; Lewin, 1942; Guthrie, 1935, 1942; Rexroad, 1932, 1933). They share the belief that reinforcement is not necessary for learning to occur. Although they recognize a number of conditions important for learning to occur — e.g. frequency, recency, and certain perceptual conditions — they emphasize in particular contiguity in experience. Those theorists in the group who consider themselves associationists look upon the law of association by contiguity (and not the law of effect) as the main principle of learning.

3. The third position taken on this theoretical issue represents something of a compromise between the first two. Learning theorists in this category (Thorndike, 1932, 1935; Schlosberg, 1937; Skinner, 1938; Razran, 1939*b*; Maier and Schneirla, 1942; Stephens, 1942; Tuttle, 1946; Mowrer, 1947) hold that there are two basically different learning processes. To one, the law of effect applies. To the other, reinforcement is unnecessary. Learning under this second process is assumed to be governed by the law of association by contiguity.

These different attitudes toward reinforcement will be discussed in more detail below. But first let us consider their relation to certain types of simple experimental situations.

Classical conditioning, instrumental conditioning, and selective learning (problem solving). Ever since laboratory investigation was first directed at understanding the fundamental nature of the learning process, two experimental techniques have predominated. One involves the so-called trial-and-error (problem-box) situation introduced into the psychological laboratory by Thorndike (1898, 1911), and the other is the classical conditioned-response experiment developed by the Russian physiologists, Pavlov (1902, 1927) and Bekhterev (1932). These two methods have been outstanding not only for the empirical data they have provided but,

more important still, for the extent to which they have influenced learning theory.

The early studies with the problem box gave rise to the law-of-effect interpretation of learning. In this type of situation a selection from among the subject's initial repertory of responses occurs. Thorndike's law of effect accounted for this selection in terms of the different effects or consequences of each response. Satisfying effects were assumed to strengthen the S-R bond or tendency of a response to occur; unsatisfactory or annoying consequences were supposed to have an opposite result. How the concepts of motivation and reward came to dominate the interpretations of the findings obtained with this experimental technique is easily understandable when we stop to consider the important role that each of these factors plays in the situation. The motivation of the subject is an obvious and important determiner of the initial responses made in the situation; variation of the drive produces marked changes in the hierarchy of strengths shown by the different responses. Similarly the environmental consequences of responses, particularly their goal or nongoal character, would seem to bear some kind of relation to the selection process, even if not that postulated by the reinforcement theorists.

In the classical conditioned-response experiment, on the other hand, the emphasis is not upon the effects of the responses and their relation to the motivating state. Instead, a single, measurable aspect of response, the occurrence of which is strictly under the control of the experimenter, is studied. Furthermore the administration of the new stimulus (conditioned) which is to acquire the property of eliciting this response is also under the exact control of the experimenter. The main interest here is in the temporal relation of the conditioned stimulus to the response. The simultaneous occurrence, or close temporal sequence of the events, CS, US, and UR, was regarded by the early experimenters employing this method as the most important factor operat-

ing in this situation. Although Pavlov appreciated the necessity for having his subjects motivated, he and other early students of the conditioned response did not stress this factor. The expression, "reinforcement by the unconditioned stimulus," had for Pavlov the physiologist's connotation of facilitation of action rather than that of retroactive strengthening of a response.

In introducing his new behavioristic doctrine, Watson (1914) seized upon the conditioned reflex as the basic unit of behavior. He proposed that the main principle of learning was revealed by this technique to be that of association by contiguity of stimulus and response. Watson claimed this principle held not only for conditioning but also for the more complex trial-and-error type of learning. For the latter he also made use of two subprinciples—frequency and recency. Thus he reasoned not only that the correct response was always the most recent one to occur but also that it would, on the average, occur more frequently than any other response because it takes place at least once on every trial. However, this interpretation assumed erroneously that an incorrect response would occur only once in a trial. In many instances of trial-and-error learning, incorrect responses occur much more frequently than the correct rewarded one, and yet the latter is finally selected and learned. It was primarily this kind of finding that led to the law-of-effect type of explanation of selective learning.

When American experimenters began to investigate CR learning, however, there soon appeared evidence to indicate that the role of motivation and reward had been sadly overlooked by the earlier experimenters. A large number of studies (e.g. Loucks, 1935; Loucks and Gantt, 1938; Culler, 1938; Brogden, 1939a; Brogden, Lipmann, and Culler, 1938) have clearly shown the importance of these factors in the establishment and maintenance of conditioned responses. With this recognition of the role of motivation and reward in the classical conditioning experi-

ment there developed a tendency to regard this type of learning as being essentially similar in nature to problem-solving learning. Following this line of thought, Hull (1937, 1943) reversed the direction of Watson's theorizing and attempted to extend the principle of reinforcement (his formulation of the law of effect) to account for the facts of classical conditioning.

Also helping to bring about this unification of conditioning and problem-box learning has been the development of a new type of experiment known as instrumental conditioning. As was described in a previous chapter, three different experimental arrangements—reward, escape, and avoidance—are usually included under this class of learning situation. The basis on which the three are subsumed under a single category is that, in each, the learned response is *instrumental* in bringing about the goal situation—reward, escape from pain, or avoidance of pain. Actually, the instrumental-avoidance experiment represents a modification of the classical conditioning setup in the direction of the trial-and-error situation. Instead of the noxious US always being administered by the experimenter at a fixed interval after the CS, the CR in this situation may be instrumental in avoiding the US, provided the CR occurs soon enough.

On the other hand, instrumental reward and escape are essentially limiting cases of trial-and-error learning. The selection phase of trial-and-error learning is eliminated, or at least minimized, by arranging for the correct, goal-attaining response to be the response most likely to occur from the beginning. This arrangement, like the classical conditioning setup, permits us to isolate the acquisition process from the complicating effects of the extinction and the spontaneous recovery of erroneous responses. In so far as we succeed in doing this, the situation approaches the classical conditioning setup in its simplicity. Indeed, Hilgard (1936a, b, 1937) has pointed out that the two procedures are essentially the same in terms of

the responses that take place. But different responses are measured in the two situations. In instrumental conditioning, the response R_1 that brings the reward — e.g. depressing the lever in the Skinner box — is measured, and the response R_2 to the goal object or US — e.g. chewing the food, salivating, etc. — is ignored. In Pavlov's classical situation, on the other hand, the response R_2 (salivation) to the US, food in the mouth, is measured, and the response R_1 (orienting to the food pan, etc.) is ignored. Theoretical opinion clashes on the issue: can the learning of the two different types of response be explained in terms of the same set of laws, or does it represent two entirely distinct processes governed by quite different laws?

CLASSICAL AND INSTRUMENTAL CONDITIONING

Reinforcement Theories of Conditioning

The stimulus-response interpretation (Hull). In his *Principles of Behavior*, Hull (1943) has offered a stimulus-response treatment of the findings obtained in the several types of conditioned-response experiments. On the constructs and principles put forward by Pavlov and Thorndike to interpret their original experimental findings, Hull builds a detailed explicit theoretical structure. He looks upon his formulation not only as an account of the phenomena of conditioning, themselves, but also as a theoretical basis for the integration and interpretation of more complex learning phenomena. The relatively simple and highly controlled nature of the conditioned response makes it, Hull believes, the ideal place to look for fundamental mechanisms and principles underlying behavior modification.

Hull sets up a series of postulates that introduce and define a number of intervening variables in terms of the experimental variables that have been shown to play a role in conditioning experiments. These intervening variables are then related to one

another and finally to empirical response measures by means of further postulates. One of his fundamental assumptions, the principle of reinforcement, makes explicit the role of motivation and reward in conditioning. In abbreviated form it may be stated as follows: *whenever a response of a motivated organism is followed by a reinforcing state of affairs, there results an increment in the habit strengths (sH_R) of the temporally coincident stimulus components (S_c) to evoke the response.*

A critical part of this formulation is, of course, the notion, "reinforcing state of affairs." A number of different interpretations of this concept have been offered in the past, including Thorndike's earlier hedonistic state of pleasure (1913) and his later definition in terms of objective behavioral criteria (1935). Hull's meaning requires that we first consider the concepts of need, drive, and drive stimulus.

In considering the meaning of Hull's theoretical constructs, we must keep in mind his proclivity for defining them in two different ways—first as an intervening variable introduced in terms of environmental events, and second in physiological terms. We shall for the most part stick to the first definition, adding the physiological meaning whenever it will add to the understanding. Defined in a general manner, need is a state of the organism that results from any deviation of the environment from the optimum biological conditions necessary for survival. More specific needs are defined in terms of specific antecedent conditions in the environment that are under the control of the experimenter — e.g. feeding schedule, administration of noxious stimulus, etc. The concepts, drive D and drive stimulus S_D , are, in turn, defined as hypothetical variables (states) functionally dependent upon the existing need states and hence indirectly upon the antecedent environmental conditions. Physiologically, drive is conceived as a general condition of the nervous system contributed to by all the specific needs of the moment.

Drive stimulus, on the other hand, refers to specific afferent neural impulses aroused by a particular need. There are, presumably, as many different types of drive stimuli as there are primary needs in the organism. The interrelations between these several concepts, with arrows indicating the direction of definition, are shown in Fig. 2.

As a tentative hypothesis Hull proposes to identify his "reinforcing state of affairs" with a reduction in the drive level D or possibly

forcing agents are the familiar appearance of a goal box or food cup, the sight and smell of food, etc.

Unlike Thorndike's law of effect, Hull's principle of reinforcement does not insist that the reinforcing state of affairs is necessarily an effect of a response. It merely states that stimulus-response events occurring in close temporal conjunction with a reinforcing event acquire an increment of habit strength. This, of course, is just what hap-

FIG. 2. The interrelations between Hull's constructs—need, drive D , drive stimulus S_D , and the antecedent conditions AC in the environment defining them.

with a diminution in the associated drive stimulus S_D . With each need, a response of the organism to some aspect of its environment initiates a sequence of events that culminates in a diminution of the drive. This, in turn, changes the habit strength s_{HR} . One of the clearest examples of such a primary reinforcing state of affairs is the cessation of a noxious stimulus—e.g. escaping from an electric shock. Supplementing this notion of primary reinforcement, Hull also suggests that there are secondary reinforcing states of affairs. Citing a number of different experiments—e.g. higher-order conditioning, delayed reward, etc.—Hull postulates that all those stimulus-receptor events that have regularly and consistently been associated in time with the reduction in a primary need (or any other stimulus previously so associated) themselves acquire the capacity of acting as reinforcing states of affairs. Examples of such secondary rein-

pens in the Pavlovian CR. The trace of the conditioned stimulus is present at the time the unconditioned response of salivation occurs, and the two are concurrent with the reinforcing event—the receipt of food. The difference between this situation and the typical instrumental and problem-box tasks is that the food produces both the response being learned (conditioned) and the reinforcing state of affairs. As Hull (1942, p. 68) has pointed out, theorists who have not accepted the view that the law of effect holds for Pavlovian conditioning have failed to realize that "food in the mouth" constitutes a reinforcing state of affairs, very possibly a secondary one, by virtue of the past association of this stimulation with primary hunger-drive reduction. According to this interpretation, the Pavlovian conditioned response is merely a special case of the principle of reinforcement.

Similarly Hull (1943, Chapter VI) has shown how the other types of classical and

instrumental conditioning are all special cases of learning under the principle of primary or secondary reinforcement. One difference between classical and instrumental conditioning is that in classical conditioning new stimulus-response associations sH_R are established, whereas in instrumental conditioning (also selective learning), already existent habits are merely strengthened further. As Hull concludes, "the differences between the

In formulating these postulates, Hull has been guided by the available experimental evidence.

The first postulate states how habit strength sH_R grows or develops with successive reinforced trials N . Hull assumes that the function is exponential: a growth curve in which the increments per trial ΔsH_R are always a constant fraction of the potential growth still possible. Figure 3

FIG. 3. Diagrammatic representation of the growth of habit strength. At the left are shown the successive increments of habit strength for successive reinforcements. The bars represent the accumulated habit strength at the successive reinforcements. (From Hull, 1943.)

two forms of learning are superficial in nature—i.e. they do not involve the action of fundamentally different principles or laws, but only differences in the *conditions* under which the principle operates" (1943, p. 78).

Hull's principle of reinforcement defines the necessary conditions (motivation and reward) that must hold for the hypothetical learning factor sH_R to develop. In an operational sense it defines one of the main variables of a learning experiment—the number of reinforcements or trials N . Hull then goes on to specify by means of four subprinciples the experimental variables that determine the strength of a habit or association. These subprinciples or postulates represent attempts on his part to guess at the "laws" or functional relations (type II) holding between the construct of habit sH_R and the independent experimental variables.

(taken from Hull, 1943, p. 116) provides a picture of this theoretical growth function. At the left of the graph are shown the successive increments of habit for successive reinforcements. The increasing columns to the right represent the amount of accumulated habit strength at the successive reinforcements. An imaginary smooth line joining the tops of each of these columns provides a picture of the hypothetical curve of habit growth that Hull postulates. The equation describing the function is

$$sH_R = M'(1 - e^{-iN}) \quad (1)$$

where M' = the limit to which the habit would grow under the particular conditions of the experiment, N = the number of reinforced trials, i = an empirical constant determining the rate of approach of the function to its maximum, and e = the logarithmic base.

The three remaining postulates have reference to experimental conditions that have been found to affect learning. They are: (1) the magnitude (quality) of the reward W —e.g. amount of food reward; (2) the time of delay of the reward T ; and (3) a time variable relating the onset of the conditioned stimulus to the occurrence of the response T' . Typically the last variable occurs only in classical conditioning: the time between the conditioned and unconditioned stimulus. The other time variable T has not been varied in conditioning experiments, although it conceivably could be.

On the basis of experimental studies, Hull assumes that each of these variables determines the limit to which the habit will grow with an unlimited number of reinforcements. The assumptions may be stated as follows:

1. Magnitude of the reinforcement. Other things being equal, the limit to which the habit will grow is a positive exponential function of the magnitude of the reinforcing agent.

$$M' = M_o(1 - e^{-kW}) \quad (2)$$

where M' = limit of habit growth under the particular conditions of the experiment, M_o = limit of habit growth under optimum conditions, W = some objective measurable property describing quantity or quality of goal object, and k = empirical constant.

2. Time of delay of reinforcement. Other things being equal, the limit to which the habit will grow is a negative exponential function of the time between the response and the subsequent occurrence of the reinforcement.

$$M' = M_o e^{-iT} \quad (3)$$

where T = the time of delay of the reinforcement, and j is an empirical constant. Hull suggests that there is a *primary gradient of reinforcement* of limited extent (from 20 to 40 seconds in the rat) beyond which learning would not occur if the influence of secondary reinforcement could be eliminated from the experimental situation. That is to say, the

effect of secondary reinforcement is to extend the actual period of delay in which learning can take place. This secondary extended gradient is Hull's old goal-gradient principle (1932). Spence (1947) has recently proposed that there is no primary gradient of reinforcement but that all learning involving a delay of reward occurs as the result of immediate secondary reinforcement which develops in the situation.

3. Time between the onset of the CS and the occurrence of the US. Other things being equal, the limit to which the habit will grow is a negative exponential function of the time between the onset of a continuously acting conditioned stimulus and the occurrence of the unconditioned stimulus.

$$M' = M_o e^{-u(T'-c)} \quad (4)$$

where T' = the time between the onset of the conditioned stimulus and the occurrence of the unconditioned stimulus, c = an empirical constant that determines the time interval at which conditioning is optimum (when T is less than c , the terms in the parentheses should be reversed $c - T'$), and u = an empirical constant.*

By substituting in equation 1 the several values for M' given in equations 2, 3, and 4, a single equation stating habit strength as a function of four variables may be obtained as follows:

$$sHR = M_o(1 - e^{-kW})e^{-iT}e^{-u(T'-c)}(1 - e^{-iN})$$

Hull does not, of course, consider that this equation is either complete or final. Recognizing that there are possibly other factors that enter into the determination of habit strength in simple conditioning, the present equation is offered merely as a point of departure for further experimental analysis.†

* In trace conditioning the time interval T'' is between the cessation of the conditioned stimulus and the onset of the unconditioned stimulus. The equation is $M' = M_o e^{-iT''}$.

† A number of other theorists have offered mathematical equations purporting to describe the hypothetical changes going on in learning or the resultant of these changes (Graham and

In addition to this hypothetical learning construct sH_R , Hull introduces certain other intervening variables in terms of experimental conditions that have been shown to affect the strength of the conditioned response. As these are nonlearning factors, we shall not treat them in detail but shall merely indicate in general terms their interrelations with the other hypothetical and experimental variables.

It is well known that the strength of the measured response is a function of the drive strength present at the moment (Warden, 1931; Perin, 1942). An instrumental or conditioned response may be greatly weakened, even eliminated, if the drive strength on which it is based is reduced. Hull has assumed that habit and drive interact in a multiplicative manner to determine the strength of a response, and he introduces another hypothetical construct, excitatory potential sE_R , to represent the combined action or effects of these two factors. That is,

$$sE_R = f(H \times D)$$

Note that this conception of Hull's does not ascribe any response-evoking properties to habits (associations) independent of the drive.

Motivation or need also enters into Hull's formulation in a second manner. It provides a component S_D of the stimulus complex which acquires sH_R to evoke the response. This particular motivational concept was emphasized in Hull's earlier theoretical articles (Hull, 1930b, 1931).

Another factor that may under certain conditions be an important determiner of response strength is identified by Hull under the concept of inhibitory potential I_r . This hypothetical state is assumed to result from the occurrence of the response itself, the amount of inhibition generated being a function of the amount of work involved in the act, the number of occurrences, and the degree of massing

Gagné, 1940; Thurstone, 1930; Gulliksen and Wolfe, 1938; Wiley and Wiley, 1937; Pitts, 1943; Spence, 1936).

or distribution of the trials. If the situation is one in which the response does not involve much work and the interval between trials is long, then this factor is relatively unimportant and can be ignored. When inhibitory potential is generated it is assumed to oppose excitatory potential, and their algebraic summation is designated by Hull as effective excitatory potential $s\bar{E}_R$. These relations may be stated as follows:

$$I_r = f(N, W, F)$$

$$s\bar{E}_R = sE_R - I_r$$

where N = the number of trials in which response has occurred, W = amount of work involved in performance of the act, and F = the frequency of occurrence of the response per unit of time, i.e. rate.

The two remaining theoretical constructs employed by Hull in his treatment of simple learning are behavioral oscillation sO_R and reaction threshold sL_R . Behavioral oscillation is introduced in order to take care of the well-known phenomenon that measures of response, even when showing no systematic change, nevertheless exhibit marked variability. From the fact that such measures tend to distribute themselves according to the normal probability function, Hull has ascribed normal variability to this construct. He further conceives of sO_R as an oscillating inhibitory potential, which acts against effective reaction potential $s\bar{E}_R$ to produce at any moment what he terms the momentary effective reaction potential, $s\bar{E}_R$. Thus

$$s\bar{E}_R = s\bar{E}_R - sO_R$$

The presence of such an uncontrolled oscillation factor in living organisms is a major perturbation that makes it difficult to discover laws concerning behavior. It precludes the possibility of predicting the exact momentary behavior of a single organism and necessitates the use of a number of subjects or a number of observations of a single subject.

The concept of threshold sL_R is defined as the minimal value of the momentary effective reaction potential $s\bar{E}_R$ that will evoke an ob-

servable response. The value of $s\bar{E}_R - sL_R$ must be greater than zero for a response to occur. This construct of sL_R , like that of sO_R , is not defined by Hull in terms of antecedent environmental conditions, but is rather to be regarded as a parameter characteristic of individual subjects. As yet Hull has not made clear whether sL_R is the same for all response systems in a subject or whether it varies from one response system to another.

With these intervening theoretical constructs, defined in the manner described above, Hull next completes his theory by relating them to the several empirical response measures employed in conditioning experiments, i.e. frequency of responses occurring in a block of trials, resistance to extinction in terms of number of trials to an extinction criterion, amplitude or magnitude of response, and latency of response. We shall consider only one of these measures as an example of Hull's procedure.

REACTION PROBABILITY (R_p) AS A FUNCTION OF THE EFFECTIVE REACTION POTENTIAL $s\bar{E}_R$. Other things being equal, the probability p of a response occurring to the conditioned stimulus is related by the normal probability integral to the extent to which the effective reaction $s\bar{E}_R$ exceeds the reaction threshold sL_R . This relation is not arbitrarily assumed at this point but follows from the earlier definitions of the oscillating inhibitory potential sO_R , the reaction threshold sL_R , and the effective reaction potential $s\bar{E}_R$. As $s\bar{E}_R$ increases above the value of sL_R , the percentage of momentary effective reaction potentials $s\bar{E}_R$ that remain above sL_R after the depressing effect of sO_R will increase. Moreover this increase will follow the normal probability integral, since the sO_R values are assumed to be distributed according to the bell-shaped normal probability function. The frequency (percentage) of occurrence of responses as a function of $s\bar{E}_R$ will be the same as that of the $s\bar{E}_R$'s, since a response occurs on each occasion that an $s\bar{E}_R$ is above the threshold value sL_R . A corollary of these relations is that the curve of frequency of conditioned responses, as a function of the number of reinforcement

trials [$R_p = f(N)$], will be either S-shaped or negatively accelerated, depending upon certain conditions which the theory is able to specify.

There are a number of other constructs and principles in Hull's treatment of conditioning, such as the principle of primary generalization, with its associated construct of effective habit strength $s\bar{H}_R$, the principle of afferent neural interaction, the principle governing the summation of excitatory tendencies, etc. By means of these various postulates Hull is able to account for most of the phenomena of conditioning. Indeed the whole system of related constructs is based on the findings in this relatively highly controlled type of experimental situation. It represents an attempt to guess at the main variables and laws governing changes in response. The value of the formulation may be measured not only in terms of its success in explaining the phenomena of conditioning but also in terms of the extent to which the same constructs and principles may be used to integrate the phenomena of more complex learning. Finally, Hull's system possesses the virtue that all learning is governed by a common fundamental principle—the principle of reinforcement—rather than by a number of exclusive principles.

S-S reinforcement theory (Woodworth). Although most S-S theorists do not stress the role of reinforcement, Woodworth (1947) offers an interpretation that emphasizes both the perceptual nature of learning and the principle of reinforcement. Applied to conditioning, Woodworth's view is that reinforcement is responsible for the hypothetical learning change, but that this change is not to be thought of in terms of the strengthening of the connection between the CS and the CR. Instead, Woodworth employs the concept of *expectancy* and states that the definiteness of the expectancy is what is reinforced. Expectancy is further described as involving a perception or registration of the sequence of stimulus events. As Woodworth writes, "The new learning, the conditioning, is sensory and not motor. The

change that takes place in him during the process of conditioning is a change in his way of receiving, or perceiving, the sequence of stimuli" (1947, p. 122).

In addition to recognizing the usual reinforcing role of goal objects for which the subject is motivated, Woodworth also postulates that simple perceptual learning is motivated by "a direct, inherent motive which might be called the will to perceive" (1947, p. 123). The attainment of a clear perception is itself a reinforcing event, according to Woodworth.

Contiguity Theories of Conditioning

S-R contiguity theory (Guthrie). One of the most persistent attempts to develop a theory of learning that has no recourse whatever to a reinforcement principle is that of Guthrie (1930, 1935, 1942). Relating his formulation to the earlier doctrines of the English associationists (Locke, Hume, Mill, etc.), Guthrie suggests that his version of associationism might best be described as "behavioristic associationism." For the older notion of association between subjective mentalistic events Guthrie substitutes the concept that the principle of association applies to observable stimulus and response events.

Starting with the phenomena of classical conditioning, Guthrie first carefully distinguishes between two concepts of response — movement and act. Movement refers to specific glandular and motor patterns of action such as salivary secretion, foreleg flexion, etc. An act, on the other hand, is a class of movements, defined in terms of its effects or end results, regardless of the particular pattern of effector activity involved. Examples of the latter are: opening a door, pulling at a loop, and depressing a lever. It is the latter concept of response, it will be observed, that is employed in instrumental and trial-and-error learning, whereas classical conditioning is concerned with movements. Guthrie begins his theoretical formulation with the phenomena of

classical conditioning because he believes that the basic laws of learning apply directly to movements and not to acts or accomplishments.

The main principle governing the development of associations between stimulus and response movements is *association by contiguity*. This principle states, "A stimulus pattern that is acting at the time of a response will, if it recurs, tend to produce that response" (1942, p. 23). The essential and sufficient condition for learning, according to this principle, is simultaneity of stimulus pattern and responses. Motivation, in the form of a drive state such as hunger, and the US serve merely to assure that the response to be conditioned will occur. Their function is that of a "forcer" of the response rather than that of a "reinforcer" of a connection.

Guthrie's principle of association, it will be observed, is an empirical generalization referring to observable stimulus and response events and relations between them. As such it is quite different from Hull's principle of reinforcement which introduces and defines a hypothetical learning factor — habit (sH_R). Although Guthrie is inclined to keep his theorizing at the level of "observable and namable items" as he describes it, he nevertheless goes on to speculate on how such secondary experimental variables as frequency and vividness operate to affect the strength (probability) of a tendency to respond. He offers this theory in place of the more traditional physiological hypothesis of variation of resistances at synaptic connections in the nervous system.

According to Guthrie's theory, association is established in a single trial. This means that all the stimulus cues (elements) present on the occasion of a particular response become associated in an all-or-none manner with this response. If exactly the same pattern of cues were present on the next occasion, the response would inevitably occur and conditioning would be said to have occurred in a single trial. Although conditioning may on occasion occur in a single trial, it more

typically develops only gradually. The explanation of this apparent contradiction is to be found in Guthrie's hypothetical construct, stimulus cues or elements. It is these elements, exteroceptive, proprioceptive, and interoceptive, that are assumed to become associated in an all-or-none manner with the response, and they remain so associated unless a different response is made to occur in their presence because of the activity of different stimulus elements. The gradual increase in the probability of occurrence of a conditioned response with successive trials results from the fact that more and more of the potential stimulus elements in the stimulating situation become associated with the response. In the classical situation the unflinching occurrence of the unconditioned response, due to the administration of the unconditioned stimulus, insures that eventually all or a sufficient majority of the cue elements will become associated with the response and insure its evocation.

Guthrie's concept of stimulus cue and his assumption of association between these cues and response movements are certainly not observable, point-at-able events. They are typical theoretical constructs put forward to account for the phenomena of behavior.*

The instrumental conditioned response and the successful response in trial-and-error learning are likewise acquired by the principle of association by contiguity. Unlike the setup in classical conditioning, however, there is no unconditioned stimulus in these situations to force the occurrence of the to-be-learned response from the beginning of the experiment. In the problem box the subject makes a series of trial responses. Each one, Guthrie assumes, becomes associated in all-or-none fashion to the particular pattern of concurrently acting stimulus cues and then becomes disassociated as another different response occurs and replaces it as the associated response. Finally the response

leading to success — i.e. the goal situation — occurs, and the sequence stops. In instrumental learning, as described previously, the trial sequence is minimized and the successful goal-attaining response occurs more promptly in the sequence, possibly even from the beginning. In either case the attainment of the goal ends the sequence, whereas the process continues after each nongoal-attaining response.

Recognizing that success, rewards, goal attainment, etc., play an important role in such learning, Guthrie nevertheless rejects the notion that these effects in any way act to establish the association between the situation and the appropriate response. The role of the after-effects of the successful response is to change the situation and make this response the last one to occur. Being the last to take place in the situation, this response will remain associated with it and will tend to recur when the situation occurs again. Reinforcing events thus serve to preserve one among the set of associations established by the principle of association.

There are a number of ways in which the successful response may change the stimulus complex. It might lead to escape from a distressing stimulus, such as getting out of a cage with a grid floor. The attainment of food in a problem box would likewise change the stimulus situation. Here Guthrie does not conceive of the food as immediately relieving the primary hunger drive but as eliminating a state of excited restlessness, annoyance, or conflict present before the food was reached.

Guthrie and Horton (1946) cite extensive experimental data to support this theory. Other experiments and discussions bearing on the theory are those of Seward (1942, 1943) and O'Connor (1946). The latter believes that the occurrence of learning when the reward is delayed is contradictory to Guthrie's theory and supports a reinforcement theory.*

* For a discussion of certain experimental data that tend to support Guthrie's hypothetical picture of classical conditioning, see Spence (1942, p. 303).

* Only one other writer, Rexroad (1932, 1933), has proposed an interpretation of learning along

The S-S contiguity interpretation (Tolman). Most S-S perception theorists emphasize contiguity and depreciate reinforcement. Tolman's extensive writings (1932, 1934, 1936, 1937, 1945) best exemplify this point of view. Tolman introduces explicitly a number of theoretical constructs to aid his formulation of the laws of behavior. His main construct is variously termed sign-Gestalt-expectation, cognition, hypothesis, or expectancy. It is described as a cognitive set or pattern within the subject which reflects relations in the experienced environment. In classical conditioning an expectation is built up to the effect that the first stimulus (called a sign) is going to be followed without further activity on the part of the subject by the second stimulus (called a significate). The expectation in the case of instrumental conditioning includes not only the knowledge of the sequence of the two stimulus events but also a further cognition relating to the behavior necessary to bring about the significate. Such a sign-Gestalt-expectation reveals itself by the fact that, given adequate motivation, the subject continues to exhibit the appropriate behavior as long as the particular arrangement of events in the environment actually obtains.

The experimental conditions assumed by Tolman to underly the acquisition of these expectancies constitute his definition of this theoretical construct. Recognizing that our knowledge is as yet incomplete, Tolman does not attempt the very specific type of postulate employed by Hull. Instead he discusses, in a very general fashion, three classes of variables and laws that he believes are important determiners of the formation of cognitions:

1. Gestalt laws relating to stimulus organization. These laws refer to conditions such as visual continuity, embeddedness, belongingness, fusibility, etc., which influence per-

ceptual organization and hence learning. Very little is known as yet about how these factors relate to conditioning.

2. Laws concerned with the sequence of sign, behavior and significate. Here Tolman mentions factors such as the frequency and recency with which the three components of a sign-Gestalt-expectation — sign, behavior, and significate — have been experienced in the past. Other variables included in this group are such temporal factors as the time between the conditioned and unconditioned stimulus in classical conditioning, and the delay of the reward in instrumental conditioning. Tolman's fundamental law of association should also be included here, for according to him these hypothetical expectancies are acquired because sign, behavior, and significate follow one another in experience. This sequence is a necessary condition for learning; other factors facilitate or inhibit the process.

3. Laws specifying motivational conditions. The findings of latent learning lead Tolman to reject the reinforcement principle. Accepting the observed fact that the reward value of the significate may affect performance, Tolman nevertheless denies that it plays a part in learning per se—i.e. in the formation of the sign-Gestalt-expectations. The law of effect, he believes, is a law of performance rather than a law of learning. Since the organism's performance B is a joint function of its cognitions C and its motivational states M — i.e. $B = f(C, M)$ — its performance varies with different significates, depending upon the extent to which they are "demanded." The "demand" value of a significate depends, in turn, upon the momentary needs of the subject. Thus a response that leads to a significate the subject needs will be stronger than a response leading to an indifferent significate.

A motivational variable that may affect the acquisition of sign-Gestalt-expectations is the vividness or emphatic character of the conditions accompanying either the sign or the significate, or both. Either pleasant or

painful experiences may accelerate learning, but it is because of their emphasizing or compelling character, not their attendant success or failure. Studies showing that learning speeds up when an electric shock follows the correct response provide a basis for the law of emphasis.

In addition to sign-Gestalt-expectation (the hypothetical learning change) Tolman introduces other intervening variables defined in terms of independent experimental conditions, including environmental and subject variables. Among these are the constructs of demand, appetite, differentiation, and biases. Presumably, when the theory is completed there will be further "second-line," "third-line," and possibly even more highly derived intervening variables. As Tolman writes: "These latter are further displaced toward the final behavior and they depend not only upon certain independent variables but also upon combinations of various of the preceding 'first-line' and 'second-line' variables" (1936, p. 99). Eventually the response measures are to be stated as functions of these intervening variables, thus completing the theorizing.

It should be realized that Tolman is not offering a finished theory of even simple learning phenomena, but only a blueprint outlining the formal structure of a theory. His treatment of the functions (definitions) specifying his second- and third-line intervening variables is even more vague than his description of such constructs as sign-Gestalt-expectation and demand. He is content to suggest that Lewin's topological and dynamic constructs indicate the most promising approach to an adequate formulation.

In this connection it is rather interesting to note that White (1943), in attempting to implement Tolman's theory with more specific postulates, suggested that cognitions and needs combine in a multiplicative manner to determine response strength. This assumption is precisely the same as Hull's (1943). It is the writer's opinion that, as Tolman's theory is developed, the essential similarity

of its formal structure to that of Hull's theory will become more and more apparent. The most fundamental difference between them at the moment is the question whether or not reinforcement is a necessary condition for the development of the hypothetical learning factor.

Two-Factor Theories of Conditioning

In contrast to the foregoing attempts to account for classical and instrumental conditioning by a single set of laws, a number of psychologists have stressed the differences between them and have held to the view that they cannot be reduced to a single system. Skinner (1935, 1938) was one of the first to distinguish carefully between the two types of conditioning. His earlier article implied, although not too explicitly, that one type of response (instrumental) is acquired on the basis of the law of effect, whereas the other type (classical) is acquired on the basis of the principle of conditioning (presumably) contiguity. In *The Behavior of Organisms* he definitely adopted this position (1938, p. 111). Referring to the two types of conditioned response as type R (instrumental) and type S (classical), Skinner made the further suggestion that a rough topographical distinction could be made between them: the type R responses are largely skeletal, whereas the type S responses involve primarily those types of effectors, smooth muscles and glands, that are controlled by the autonomic nervous system.

One of the most explicit early treatments of conditioning as involving two different kinds of learning is that of Schlosberg (1937). Certain experimental comparisons between classical (defense) conditioning and the avoidance type of conditioning led Schlosberg to propose two distinct types, governed by two quite different basic laws: (1) simple conditioning (classical) in which the principal law is temporal contiguity of the stimulus and response, and (2) 'effect' learning in which the success or satisfying consequences of the response determines the

learning. Schlosberg also differentiated between the types of response learned in the two kinds of conditioning. The type of CR governed by contiguity was described as diffuse, preparatory activity, and from the examples given (changes in electrical skin resistance, breathing rhythm, etc.) it is apparent that his conception was very close to Skinner's notion that they are autonomically controlled. Conditioned responses acquired on the basis of the law of effect — i.e. success — were described as involving the more precise skeletal musculature.

Schlosberg was not entirely sure, however, that the distinction he offered was basic. He looked upon it primarily as an aid to the present understanding of certain experimental findings in the field of conditioning, and he recognized the possibility that the instances of conditioning for which he invoked the law of effect might eventually be explainable by the principle of conditioning (contiguity).

This dual interpretation of conditioned response learning has been taken up again by Mowrer (1947), heretofore a vigorous supporter of the notion that all learning operates under the law of effect. In his earlier writings (1938, 1940, 1946) Mowrer attempted to show how all the various types of classical conditioning could be explained in terms of the same basic law (effect) that governs instrumental and problem-solving learning. In particular, his concepts of anxiety as a secondary drive and anxiety-reduction as reinforcement demonstrated how it was possible to bring the avoidance type of conditioned response — e.g. eyelid conditioning to air puff, finger and leg withdrawal from grid, etc. — within the realm of the law of effect. According to this conception the subject acquires during the early stages of practice a conditioned fear response (anxiety) to the conditioned stimulus as signal. During this period the overt defense response also occurs to the shock stimulus and becomes conditioned to the signal by reason of the primary reinforcement provided by

the cessation of the shock. When this latter response occurs prior to the onset of the shock, it leads, of course, to avoidance of the shock and the failure of primary reinforcement. The fact that such conditioning is benefited by this failure of primary reinforcement seemed to be unexplainable by a law-of-effect theory. The solution suggested by Mowrer was that it is the reduction of the secondary (anxiety) drive with the cessation of the conditioned stimulus that provides for the reinforcement.

Mowrer still believes that classical conditioned responses involving skeletal-muscle activity (eyelid response, leg flexion, etc.) are mediated by drive termination (satisfaction) but that emotional conditioning involving responses controlled by the autonomic nervous system is not. The conditioning of autonomic responses is governed, he believes, by contiguity. Accordingly the major differentiation should be between classical emotional conditioning on the one hand, and instrumental and classical conditioning involving skeletal responses on the other. The latter are merely special cases of problem solving and are acquired in the same way — i.e. through the action of the law of effect.

Other writers, Razran (1939*b*), Maier and Schneirla (1942), Stephens (1942), and Tuttle (1946), have also suggested some form of dual interpretation of conditioning. Finally, attention should be called to the fact that Thorndike (1931), for all his emphasis upon the law of effect, never held strictly to the belief that all learning occurs as a consequence of reinforcement. Even in his favorite experiments — trial-and-error learning — he recognized that mere repetition of an S-R connection might in time result in some small amount of strengthening, provided other conditions, such as belongingness, were adequate. On the basis of Thorndike's own experiments, however, it would appear that exercise without reinforcement has little or no strengthening effect on responses. Indeed, failure of rein-

forcement to occur seems to lead to an actual weakening (extinction) of a response tendency.

So far as the Pavlovian type of conditioned response is concerned, Thorndike has held to the view that it is a special instance of learning. He has not been convinced that this experiment would ever throw much light on the general principles governing learning. Conditioning was likened by Thorndike to a form of learning, *associative shifting*, in which the selective or trial-and-error process is eliminated. A simple instance of such associative shifting is the learning of a cat to approach at the call of "kitty, kitty" after these sounds have been combined on a number of occasions with the sight of a bowl of milk. However, both belongingness and satisfaction usually operate in ordinary associative shifting, whereas Thorndike claimed that Pavlov and his followers regarded the time relations alone as adequate for the establishment of conditioned reflexes. The following quotation from the Messinger Lectures sums up Thorndike's evaluation of the conditioned reflex studies:

If we observe the two sorts of learning side by side, we shall, I think, find that the trial-and-success learning is more important for learning in general than the acquisition of conditioned reflexes. Indeed, I venture, though somewhat timorously, the prophecy that the phenomena of the pure conditioned reflex will teach us more about excitability than about learning. [1932, p. 112.]

The Reinforcement-Contiguity Issue

Types of reinforcement theories and the empirical law of effect. Considerable confusion in discussions of the reinforcement theory has resulted from failure to differentiate clearly between the law of effect (1) as an empirical statement, (2) as a general theory of reinforcement, and (3) as special hypotheses concerning the nature of reinforcers and their mode of acting. Critics have often cited evidence to refute reinforcement theory, which was relevant, if at all,

only to one of the special hypotheses as to the nature of a reinforcing state of affairs. In this section we shall examine the distinction between the law of effect and the various types of reinforcement theories.

McGeoch gives the following statement of an empirical law of effect: "Acts are fixated and eliminated as functions of their effects" (1942, p. 574). This formulation may be elaborated to say that responses leading to certain types of environmental consequences (called "rewards") become stronger and are retained, whereas responses leading to certain other types of after-effects (named non-rewards) become weaker and eventually disappear.

Contrary to common claims, there is nothing circular about this statement. It merely states the observed fact that different things subsequently happen to responses that are followed by different environmental consequences. Two different classes of environmental after-effects can be identified and named. The terms applied (reward and non-reward) need not carry with them any implication whatsoever that the after-effects act in a retroactive manner on stimulus-response bonds. Thorndike has called attention to the fact that very similar, possibly the same set of stimulus events (rewards and nonrewards) may also be differentiated from one another by a behavior test that is independent of the learning experiment. Thus he points out that a reward situation (he called it a *satisfier*) is "one which the animal does nothing to avoid, often doing such things as to attain and preserve it." A nonreward, or annoying situation, to use Thorndike's term, "is one which the animal does nothing to preserve, often doing things which put an end to it." (Thorndike, 1913).

Such formulations are purely empirical. They state relations between observed response happenings and two different classes of observable environmental events. At this point a general theory of reinforcement may be introduced to account for these observa-

tions. The theory might make the assumption that the two different types of environmental after-effects of responses operate, in some unspecified manner, to change (strengthen or weaken) the functional connections of the responses with their stimuli. The assumption is also usually made that the action of the after-effect on the learning change (S-R connection, S-S cognition, etc.) is direct (Thorndike) and automatic (Hull). Thorndike's latest treatment of reinforcement theory (1935) comes closest to being just such a purely general theory of reinforcement. He makes no assumption about the nature of a satisfier (reward), specifically stating that it is independent of sensory pleasure. A satisfier is assumed by him to arouse an unknown confirming reaction called the OK reaction. The arousal of this reinforcing process strengthens the connection upon which it impinges. In contrast to such a general theory of reinforcement, supporters of a nonreinforcement (contiguity) theory would deny that the change, increment in the strength of the response, is contingent on the subsequent occurrence of the satisfier. Thus Guthrie would say that the occurrence of the response itself results in an increase in its strength (really an increase in the number of potential cues that are associated with the response). For Guthrie the satisfier serves only the function of protecting these associations by eliminating the maintaining stimuli.

Going beyond this general theory of reinforcement are special hypotheses that attempt to specify (1) the nature of the reinforcing state of affairs and/or (2) the manner in which they strengthen the connection or association. The earliest hedonistic theories contained a special hypothesis concerning the differential nature of after-affects. Pleasant experiences were assumed to strengthen responses they followed, whereas unpleasantness led to weakening. Troland (1928) worked out a hedonistic theory that involved not only the psychological factors of pleasantness and unpleasantness but also

a parallel physiological account. Different situations following action were assumed to stimulate one of three types of receptors: beneceptors, neutroceptors and nociceptors. Nociception was assumed to lead by retroflex action of the thalamus to a decrease in the conductance of the then-operating cortical adjustors (synapses). Beneceptor activity, on the other hand, was supposed to increase the conductance of the operating cortical adjustors. Finally, pleasantness was identified with increase of conductance and unpleasantness with decrease.

Another group of theorists (Kuo, 1921; Perrin and Klein, 1926) described the reinforcing situation in terms of the re-establishment of equilibrium or relief from drive. In his *Principles of Behavior* (1943) Hull adopted this type of hypothesis. A primary reinforcing state of affairs is identified by Hull with either the reduction in drive level D or a reduction in the intensity of the drive stimulus S_D . Whenever such a reduction occurs, it presumably sets off the reinforcing machinery (unspecified). According to Hull, secondary reinforcing agents consist of stimulus events that, having consistently and repeatedly occurred in conjunction with drive-stimulus-reduction in the past, apparently have acquired the capacity to activate the reinforcing machinery.

Because Hull's concept of secondary reinforcement does not involve drive reduction, it has been claimed that he is not a consistent reinforcement theorist. This criticism fails to note, however, that Hull does not abandon a reinforcement position in the case of secondary reinforcement, but only the special hypothesis that reinforcement always involves drive-stimulus reduction.

Miller and Dollard (1941) take a consistent stand on the question of the nature of reinforcement. They hypothesize that all reinforcement, both primary and secondary, involves drive-stimulus reduction. Secondary reinforcement, like that involved in anxiety reaction, is assumed to involve a reduction in the intensity of the response-produced

stimuli constituting the secondary drive. Like Hull, these writers do not speculate on the nature of the physiological mechanisms by which the increase in habit strength is brought about.

The essential point to note here is that the various interpretations of reinforcement vary greatly in the extent to which they make special hypotheses about the nature of a reinforcing state of affairs. Many of the criticisms of reinforcement theory are really directed at these special hypotheses and are not relevant to the more general theory.

Experimental evidence on the reinforcement-contiguity issue. A final decision on the issue of whether some form of reinforcement principle is required to account for learning must await further experimental investigation. There are, however, some data already available that support the interpretation that reinforcement is a necessary element, at least in the conditioning of skeletal responses. Loucks (1935) reported an experiment in which he failed to obtain conditioning, to a buzzer, of a leg flexion elicited by direct faradic stimulation of the motor cortex of a dog. When food (reinforcement) was given following the leg flexion, however, conditioning took place. Another study pointing in the same direction is that of Loucks and Gantt (1938). These investigators found that leg flexion, elicited by electrical stimulation in the region of the spinal cord carrying kinesthetic fibers, could not be conditioned to a buzzer signal. When the shock was applied to the posterior root ganglion, thus involving pain fibers, the conditioning did occur. This result seems to show that some kind of motivational condition must be provided. The reinforcement theorist — e.g. Hull — would say that the pain drive and its reduction (reinforcing state of affairs) were necessary for the learning to occur. These two experimental studies lend strong support, then, to the view that reinforcement plays a critical role in the acquisition of conditioned responses involving skeletal systems. They do not, how-

ever, bear on the question whether emotional conditioning is or is not dependent on reinforcement.*

One type of experimental evidence that has been cited as embarrassing for the reinforcement view, and as favoring a contiguity interpretation, is the phenomenon of sensory preconditioning. Brogden (1939b, 1947) and Karn (1947) have shown that, if prior to conditioning a stimulus (e.g. a tone) to evoke a response it is presented simultaneously for a number of trials with a second stimulus (e.g. a light), the latter will, in subsequent tests, also tend to evoke the conditioned response. Control conditions have ruled out the possibility that the phenomenon is one of sensory generalization, and it has been interpreted as evidence that some connection, some sensory conditioning, was established during the original combined presentation of the two stimuli. There is reason to question, however, whether this evidence is critical for the reinforcement view. In the first place the conditioning is very weak, and in the human experiments it is not entirely clear whether it represents genuine conditioning or whether the responses occur as the result of complex voluntary sets established in the subject. Brogden has explicitly recognized this possibility and has concluded: "The experimental conditions of the phenomenon of sensory preconditioning are not necessarily critical for any learning theory" (1947, p. 538). But even should it be shown that some form of sensory conditioning is established in this type of experiment, there remains the possibility that one or the other of the two stimuli is sufficiently intense to produce a mild drive state, and hence for its cessation to produce a reinforcing state of affairs. The employment of very weak forms of stimulation and the elimination of any tendency of the stimuli to produce startle responses are necessary conditions if the ex-

* These two studies have been conspicuous by their absence from discussions of this problem by psychologists unsympathetic toward the reinforcement view (Hilgard, 1948; Leeper, 1944; Postman, 1947).

periment is to be critical for reinforcement theories.

Another experimental finding that has been interpreted as contradictory to the view that the strength of a conditioned response is a function of the number of reinforcements is that obtained in studies in which partial or intermittent reinforcement has been employed. A number of investigations (Humphreys, 1939, 1940, 1943; Finger, 1942*a, b*; Mowrer and Jones, 1946; and others) have shown that partial (50 per cent) reinforcement may lead (1) to as much conditioning, and (2) to greater resistance to extinction than reinforcement on every trial. Such evidence has been interpreted by a number of writers (Humphreys, 1943; Postman, 1947; Hilgard, 1948) not only as refuting the reinforcement interpretation but also as evidence that the relevant variable determining response strength is the number of trials on which the response occurs.

Hull (1940-41) suggests that the greater resistance to extinction found in the experiments with human subjects is to be explained partly in terms of stimulus patterning. He points out that when the shift is made from conditioning to extinction there is less change in the stimulus pattern to which the response is conditioned in the 50-per-cent group than in the 100-per-cent group. With this lesser change in the stimulus pattern, the conditioned response is stronger and more resistant to extinction in the 50-per-cent group. The explanation for the greater change in the stimulus pattern of the 100-per-cent group is that the trace of the unconditioned stimulus is no longer present in the stimulus during the extinction period. In the partial reinforcement group, on the other hand, such a stimulus pattern (i.e. one lacking trace of the previous unconditioned stimulus) is present and is reinforced on some of the original conditioning trials.

Denny (1946) has also shown that such partial reinforcement experiments have another factor inherent in them which must be

taken into consideration. When care is taken to control (eliminate) secondary reinforcement in the learning of a T-maze by a group of subjects receiving 50-per-cent reinforcement, learning is definitely slower than in the case of the 100-per-cent group. In fact, the 50-per-cent group required exactly twice as many trials (and hence the same number of reinforcements) to learn the T-maze as did the 100-per-cent group. Denny's experiment clearly shows the defect of the earlier studies and supports the view that learning is a function of the number of reinforcements rather than the number of practice trials.

Finally, passing mention should be made of the so-called latent learning studies (Blodgett, 1929; Tolman and Honzik, 1930; etc.) although they have involved a more complex learning situation than the conditioned response. Tolman's assumption of the contiguity principle is based primarily on these studies, which show that, when reward is introduced after a number of unrewarded trials in a maze, the error curve typically exhibits a sudden, marked drop greatly exceeding the usual effects of a single reward. Tolman explains the sudden improvement on the basis of the learning or acquisition of sign-Gestalt-expectations during the earlier unrewarded trials. These cognitions are utilized, according to his view, only when a reward is introduced into the goal box, thereby setting up a differential demand. Granting the genuineness of the latent learning phenomenon, there still remains to be explained the rather remarkable speed with which the critical cognition, "that food is in this particular locus," i.e. the goal box, was acquired. That more evidence is needed in order to settle the reinforcement-contiguity issue is shown by the findings of Reynolds (1945), Karn and Porter (1946), Spence and Lippitt (1946), and Kendler (1947). All these studies appear to be in conflict with Tolman's contiguity interpretation and even with some of the earlier experimental findings.

Theories of Response Elimination (Inhibition)

Internal inhibition theory (Pavlov). In addition to what they tell us about the acquisition process, conditioning experiments tell us a lot about how responses are weakened or eliminated. Pavlov aimed much of his experimentation at this phenomenon, and on the basis of his findings he elaborated his theory of *internal inhibition*. According to this conception, experimental extinction, or the weakening of a conditioned response with failure of reinforcement by the unconditioned stimulus, and other related inhibitory phenomena result from an active, independent, inhibitory state I. This state of inhibition counteracts (negates) the excitatory process E established by conditioning; the algebraic resultant of the two processes determines the strength of the tendency to make the response at a given moment.

Although inhibition, like excitation, was regarded by Pavlov as some kind of neural process, he defined its properties primarily in terms of certain experimental operations. In the first part of his book (Pavlov, 1927) he seems to have assumed that the essential condition for the development of inhibition is failure of occurrence of the unconditioned stimulus. However, on the basis of other studies, particularly the occurrence of a decrement in the strength of the response during conditioning with massed trials, Pavlov later (1927, p. 234) suggested that inhibition develops with each presentation of the conditioned stimulus. During conditioning trials, inhibition is more than offset by the developing excitatory state resulting from reinforcement, but with cessation of the unconditioned stimulus and continued presentation of the conditioned stimulus the inhibitory state becomes stronger and stronger. Eventually it offsets completely the excitatory state, and response ceases.

Pavlov assumed further that the inhibitory state is weaker and more labile than excitation, and that it dissipates with the passage of time. On the basis of these assumptions he was able to account for a great variety

of inhibitory phenomena — e.g. differential inhibition, conditioned inhibition, disinhibition, inhibition of delay, inhibitory after-effect, etc.

The success of Pavlov's theory in explaining his experimental findings is due largely to the fact that the theory was tailored to fit — i.e. he inferred the hypothetical properties of his construct of inhibition from his data. This is, of course, no criticism of the theory, for all scientific theories begin with the data they are to explain. The initial *ad hoc* character of a theory is lost when it develops new experimental implications that are verified by test. Pavlov's theory of internal inhibition has been very successful in this regard. Not only has it served to integrate (explain) a wide range of experimental data, but it has also been successful in accounting for new experimental findings.

Interference or counterconditioning theories of inhibition. A number of psychologists (Wendt, 1936; Guthrie, 1930, 1935; Culler, 1938) have objected to the Pavlovian theory of inhibition on the grounds that it is unnecessary to postulate the concept of inhibition I. Differing in details, these theorists all reject Pavlov's concept of internal inhibition and attempt to account for the decrement and elimination of a learned response in terms of the development of a competing response. Figure 4 contrasts these two views. The upper diagram represents the Pavlovian view with its conception of two different processes, excitation E and inhibition I, jointly determining the response. The lower figure gives the interference interpretation. The inhibitory factor depressing the original conditioned response R_1 , in this instance, is conceived of as a competing excitatory process leading to another, incompatible response R_2 . The latter is assumed to act in a more or less algebraic manner to depress the strength of the first response. This theory views experimental extinction and other forms of inhibition as the learning of a new, incompatible response or,

as it has been aptly described, as counter-conditioning.

Major difficulties with these interference theories of inhibition are the problems: what makes the competing response occur initially, and how does it eventually become stronger than the originally learned response? When the extinction procedure involves the introduction of some new stimulus that evokes the new, competing response, this difficulty does not arise. Thus Culler's example (1938)

FIG. 4. The upper diagram represents the Pavlovian conception of excitation (+) and internal inhibition (-). The lower figure gives the interference interpretation of inhibition.

of the extinction of a child's fear response to a rabbit by presenting the child with food while the rabbit is kept at a sufficient distance to prevent the fear response from being elicited is easy to understand as a simple instance of counter or redirected conditioning. The feeding responses in the presence of the rabbit, reinforced by the presentation of food, gradually become stronger and supplant the fear response. The extinction of an approaching response to some stimulus object by the introduction of shock (punishment) is another example of the elimination of a response by means of a stronger, competing response elicited by a new stimulus.

In the typical experiment on extinction, however, the unconditioned (reinforcing) stimulus is merely withheld and no new stimulus is introduced. Recognizing the need for some auxiliary postulate to account for the initial occurrence of the competing response, Guthrie at first pointed out that

Pavlovian experimental extinction was a special phenomenon and that most inhibitory conditioning involved the type of counter-conditioning described above. In attempting to account for the Pavlovian phenomenon itself, Guthrie (1935) first postulated that with the withholding of the unconditioned stimulus there is a change of set or attitude on the part of the subject, and the response decreases or ceases altogether. Subsequently this temporary set or postural pattern becomes conditioned to "not responding"—i.e. stopping salivation. In a later discussion Guthrie (1937) modified his theory to accord with a suggestion made by Winsor (1930), namely, that the absence of the food (unconditioned stimulus) leads to irritation and excitement. Such activation of the sympathetic branch of the autonomic nervous system reciprocally inhibits the salivary response, which is under the control of the parasympathetic system. Such an explanation serves only, of course, for responses under the control of the parasympathetic system and is not satisfactory for conditioned defense reactions such as the eyelid reflex.

Apart from these difficulties there are other experimental facts incompatible with the theory that extinction results only from the conditioning of a new, competing response. One of the most embarrassing findings is the fact that the massing of trials has opposite effects on conditioning and extinction. Whereas conditioning is superior under spaced trials (Hilgard and Marquis, 1940), extinction is faster (or as fast) under massed trials (Reynolds, 1945; Reyna, 1946; Rohrer, 1947). If extinction is fundamentally identical with conditioning, no such difference should be found. Other experimental findings embarrassing to the interference type of theory are the absence of positive correlations between conditioning and extinction measures (Hilgard and Marquis, 1940), the differential effects of an extra stimulus on responses extinguished to different degrees (Razran, 1939c), the different

types of extinction curves following massed and distributed conditioning (Hilgard and Marquis, 1940), the extinction of a conditioned pupillary response in a curarized cat (Harlow and Stagner, 1933), and even the phenomenon of spontaneous recovery. Still other difficulties confronting this type of inhibition theory may be found in Razran's (1939a) thorough discussion of the problem.

Mention should be made of the fact that, although Tolman and other believers in cognition learning do not have an explicit theory of inhibition, their position falls implicitly in line with the interference or counterlearning type of interpretation. Just as Tolman does not conceive of conditioning as the strengthening of a response but as the acquiring of a cognitive structure concerning the sequence of psychological events, so he does not conceive of experimental extinction as the weakening of a response. Instead, when the unconditioned stimulus stops, a new environmental sequence (conditioned stimulus followed by no stimulus) occurs, and, corresponding to it, a new, different cognition develops. Presumably this new cognition interferes or is confused with the first for a period of time, and then finally becomes clear as the representative of the new environmental situation.

Compound work-inhibition — interference theory. An interpretation of inhibitory phenomena that combines some of the properties of Pavlov's concept of internal inhibition I with the interference theory has been offered by Beritoff (1927) and by Hull (1943). According to Hull's version, experimental extinction of a conditioned response involves the development of inhibitory potential \dot{I}_R . The latter, in turn, is composed of two components: reactive inhibition I_R and conditioned inhibition ${}_S I_R$. Reactive inhibition is a hypothetical condition or state that is assumed to develop in a response system upon its activation. In the properties assigned it, this concept is very similar to Pavlov's concept of internal inhibition. Reactive inhibition is assumed to accumulate with the

occurrence of each response and to dissipate during intervals between responding. The amount of work (energy consumption) involved in the response also plays an important role in determining the rate of development of reactive inhibition. As with his other hypothetical constructs, Hull has made mathematical guesses about the functions relating reactive inhibition to the determining experimental variables.*

It is by means of this construct I_R that Hull is able to account for the phenomenon of spontaneous recovery and for the dissimilar effects, on conditioning and extinction, of the time interval between trials. Reactive inhibition occurs with every response and hence is present in conditioning as well as in extinction. Distributed practice aids conditioning because longer intervals between trials provide more time for dissipation of the inhibition. On the other hand, experimental extinction should be hastened by the massing of trials, because the inhibition then has less opportunity to dissipate.

The second part of Hull's theory of inhibition is like the interference or incompatible-response hypothesis. He assumes that reactive inhibition acts as a primary negative motivational state (need for rest) comparable to pain or tissue injury. Cessation of the activity — i.e. ceasing to make the response — results in alleviation of this motivational state and thereby provides a reinforcing state of affairs that leads to a conditioning of the competing (cessation) response to the stimulus complex. This conditioned tendency of "not responding" is Hull's conditioned inhibition ${}_S I_R$. It is really an excitatory phenomenon involving a habit structure and a drive, and it could be designated as ${}_S E_R = ({}_S H_R \times D)$, in which R represents

* Physiologically, the two concepts are quite differently conceived. Pavlov regards his internal inhibition as a state or condition of the sensory analyzers (cortex), whereas for Hull the locus of the inhibition is in the effector mechanism. Actually neither makes much use of these topographical speculations.

a response that is antagonistic to the original response.

By means of this second component of his theory, Hull is able to account for such phenomena as generalization of inhibition to other stimuli, incompleteness of spontaneous recovery, the finding that recovery becomes less and less with successive extinction, external inhibition of the conditioned response, etc. His theory fails, however, to account satisfactorily for disinhibition unless he assigns different properties to the habit sH_R involved in sI_R from those he ascribes to it in connection with his other uses of this construct.

More experimental work on the various problems of inhibition is needed before the issues between these rival theories can be settled. Research is especially difficult in this area and the results so far obtained have been complicated by the fact that the conditions under which the original learning occurred have not always been taken into consideration. An example of the importance of this factor is Reynold's finding (1945) that the effect of the time interval between trials upon the rate of extinction depends upon the time interval employed in the original conditioning.

THEORETICAL ISSUES IN COMPLEX LEARNING

The types of conditioned responses that we have been considering all consist of a simple response tendency that is acquired or lost (experimental extinction). From the study of conditioned responses have come laws and guesses at laws (hypotheses), and it is the belief of most students of conditioning that these same laws, along with others, apply to the more complex types of learning. Examples of more complex learning are (1) the process of discovery of the adaptive response in the problem box and in discrimination experiments, (2) the integration of a series of responses in maze and rote learning; and

(3) the processes by which new patterns of motor coordination (skills) are acquired.

Although there exists a considerable body of experimental data concerning these more complex processes, we shall confine our discussion to a few of the more important theoretical issues.

Insight versus Trial and Error in Problem Solving

One of the major concerns of theorists interested in the more complex learning problems has been the process known as *discovery*. The problem has to do with the factors responsible for the first occurrence of the adequate response in a novel situation, and its subsequent dominant status in the response repertory of the subject. One group of theorists believes that the correct goal-attaining response is arrived at through a process known as *insight*; another group thinks it is attained by a process of *trial and error*.

The issue gets itself confused by the fact that the term 'insight' has been used in two quite different senses: (1) as a descriptive term referring to a kind of behavior sometimes observed in problem-solving situations, and (2) as the name of a hypothetical process that is assumed to control behavior and to result in a different kind of problem solution when it is present than when it is absent. The criteria that are said to distinguish insightful from noninsightful solutions are: (1) the suddenness with which the successful response is adopted — e.g. sudden drops in error curves; (2) the readiness with which the correct response is repeated — e.g. the absence of further erroneous responses; and (3) the resistance of the response to forgetting (Yerkes, 1927). There can, of course, be no question that these phenomena occur in certain kinds of learning. They contrast with learning in which the errors are only gradually eliminated and the correct response only gradually adopted. Actually, however, problem solutions vary all the way between these two extremes. As Melton (1941) has

pointed out, all three of the criteria for insight refer to behavior characteristics that vary in a continuous manner. Consequently, they do not imply a dichotomy of modes of problem solution—blind trial-and-error solutions as against intelligent insightful solutions.

Turning to the theoretical notion of insight, one finds little to help him understand the different varieties of problem solution. The hypothetical properties ascribed to the concept are either inferred from the observed behavior itself or are arrived at through introspective reports of the subject at the time of the problem solution. In either event one has only a response-inferred construct which, until its hypothetical relations to environmental events, past and present, are specified, is of no great theoretical value. To say that the subject suddenly responds correctly because he suddenly, and for the first time, perceives the situation in a new way (reorganizes his perceptual field) does not provide a satisfactory answer for the learning theorist, although it may be quite true that the change in behavior is the result of such a change in the perceptual response to the situation. This answer, however, merely pushes the problem of explaining the learning back a step, for the theorist must now answer the question: what made the subject perceive it in the new way? What are the factors (variables) that are responsible for the perceptual reorganization? This, it will be seen, is merely a restatement of the problem of learning.

Furthermore, although it may be true for human subjects that sudden drops in the error curve are at times accompanied by introspective reports of suddenly "seeing into" the relevant relations, it does not necessarily follow that sudden changes in animal learning curves involve comparable experiences of insight. Indeed, Spence (1939) has reported an experiment involving multiple choice in which the subjects (chimpanzees) often adopted erroneous responses suddenly and persisted in making them for some time.

If suddenness and persistence indicate the presence of a process of insight, or intelligent "seeing into," in the case of the correct response, it must mean that these subjects were also having intelligent insights when they adopted and persisted in the erroneous responses. It need hardly be pointed out that this latter interpretation does not agree with our usual understanding of the meaning of intelligent behavior.

Although the explanatory concept of insight has not, in the opinion of the writer, been a particularly fruitful concept, the perception theorists, particularly the Gestalt group, have, nevertheless, made a notable contribution to our knowledge of the type of learning known as problem solving. This contribution has consisted primarily in the design and use of new types of problem situations which differed markedly from those that had been employed by most other learning psychologists. The basic plan of these problems involves the presentation to the subject of a novel situation in which the direct approach to the lure is blocked but an indirect route is left open. The problem is arranged in such a manner that its various parts, and the relations among them, are clearly visible to the subject. It is thus possible to perceive the relation of any part of the situation to the lure. Examples of this type of experimental arrangement are the roundabout or *umweg* problems involving the fabrication of implements, and problem situations in which the subject employs some object, for example, sticks, boxes, etc., as an implement to obtain the lure. In these situations it is found that solutions are not always gradual and do not always involve a long, persistent series of erroneous responses. Sudden solutions (insight) and solutions with few or no erroneous trials are, then, genuine-enough phenomena in problem solving. Furthermore they require explanation just as do the instances of learning in which the presolution period is marked by the repeated occurrence of a number of erroneous

responses and the gradual adoption of the correct response.

When we turn to the stimulus-response theorists' discussions of problem solving or selective learning, we find that their earlier treatments (Thorndike, 1913; Watson, 1914) were primarily concerned with explaining the gradual type of trial-and-error learning that occurred in the kind of problem box they employed. Quite contrary to the statements of some writers (Krechevsky, 1932), however, these early interpretations of this kind of learning did not view the presolution period as a blind, random, undirected affair. Moreover later theoretical treatments of the discovery process in selective learning by Hull (1930*a*, 1937) and in discrimination learning by Spence (1936) have explicitly assumed that the genesis, the range, and the order of occurrence of the trial responses are strictly determined, lawful, systematic processes. These theorists have assumed that the subject exhibits an initial hierarchy of responses, the individual strengths of which vary (1) with innate factors such as preference for dark over white alleys, etc., (2) with the past reinforcement experiences of the subjects with similar environmental situations (principle of generalization or transfer), and (3) with the particular motivational state of the moment, coupled with the past relations between various responses and the satisfaction of particular drives. Experimental confirmation of the genesis of these trial responses in the past experience of individual subjects has been experimentally demonstrated in selective learning by Hull (1939) and in discrimination learning by Spence (1937*b*).

In the typical problem box the subject, motivated toward a goal object, is confronted with a situation to which a variety of responses to various parts or aspects of it can be made. One of these responses is 'successful' in the sense that it leads to the goal object. When this 'correct' response is low in the response hierarchy of the subject, so-called trial-and-error activity ensues.

That is to say, the subject typically makes a number of different responses, often repeating the same one a number of times, until the successful one occurs. On subsequent occasions the number of erroneous responses decreases, until finally the correct response is made at the very start of the trial. No further erroneous responses occur, and the problem is said to be solved.

The explanation offered by the stimulus-response psychologist of this type of trial-and-error learning is that the subject's initial responses are those that are strongest by virtue of his past experience in similar situations. With failure of reinforcement the incorrect responses are gradually weakened until their strength is below that of the correct response, which is strengthened on its occurrence. The recurrence of incorrect acts after the correct response has been 'discovered' is accounted for in terms of 'spontaneous recovery' from the effects of non-reinforcement. Eventually the correct response, as the result of the reinforcements it receives each time it occurs, reaches a level of strength above that to which the weakened erroneous responses recover. This, of course, represents only the most schematic outline of a very complex set of events. Other factors that play a role in the variability of the behavior in the presolution period are refractory phase, punishment, variable stimulation resulting from the responses of the subject, etc. Experimental studies bearing on this theoretical interpretation of simple trial-and-error learning may be found in Hull (1939) and in Hull and Spence (1938).*

*Maier, (1939, 1940) has proposed that the variability of responses exhibited in the presolution period of trial-and-error learning results from a need or tendency to vary for the sake of variation. He also refers to an ability to vary. Subjects showing a lesser tendency to vary their responses are said to have a weaker need to vary or a poorer ability in this respect. Such circular reasoning is to be contrasted with the interpretation given above in which variability of behavior is recognized as a behavioral phenomenon to be explained in terms of principles (inhibition, spontaneous recovery, and reinforcement)

A good part of the issue of gradual versus sudden solution in problem solving is thus seen to be based upon differences in method. Undoubtedly both types of solution occur in learning. In the kind of problem employed by the early S-R psychologists the consequences of a response—i.e. whether correct or incorrect—could not be ascertained except by actual trial. The situation may in this sense be described as blind. In contrast, the 'insight' proponents used an 'open' situation, one in which the consequences of the alternative acts could be anticipated without actual carrying out of the act. The two kinds of situations have led to different kinds of behavioral phenomena, gradual solutions predominating in the 'blind' situation and sudden solutions occurring more frequently in the 'open' situation. It should be clearly understood, however, that considerable trial-and-error activity may occur in the 'insight' type of problem and that there are many instances of sudden learning in the supposedly 'blind' problems. Spence (1938, 1939) has shown that it is quite possible to explain, in terms of the type of theoretical schema outlined above, the sudden instances of learning in 'blind' problems as discrimination and multiple-choice learning. The greater frequency of 'insightful' solutions in the 'open' problem would seem to be explainable by this theory in terms of the fact that the occurrence of the correct response in open situations probably depends on the subject's making a particular receptor-exposure adjustment. That is, once this particular orientation of the sense organs (particularly eyes) occurs, the subject will, because of past learning, make the appropriate perceptual response that leads directly to the correct overt act. Much of the learning in this situation, then, probably consists in trial-and-error sense-organ adjustments which the experimenter usually fails to observe and record. Attention should also be called to

discovered in an entirely different type of experimental situation (i.e. the conditioned response experiment).

the fact that with human subjects there is probably considerable implicit (symbolic) trial-and-error activity that is not recordable. It still remains highly questionable, however, whether some new higher-order process (insight?) must be invoked to explain such instances of sudden learning in animal subjects.

In concluding this discussion, it should be pointed out that there are certain, still more-complicated types of problem solution that stimulus-response theorists like Hull would agree differ from trial-and-error learning. Thus the reasoning experiments of Maier (1929) and the Tolman-Honzik 'insight' maze (1930) probably involve mechanisms different from those involved in the ordinary problem box, maze, and discrimination setups. Hull's treatment (1935) of these problems in terms of stimulus-response principles is to be contrasted with those of Maier (1940) and Tolman (1932, 1937).

Continuity versus Noncontinuity Theories of Discrimination Learning

Experimental studies of discrimination learning have shown that the period prior to the attainment of solution is an organized lawful process, marked by the occurrence of systematic response tendencies or, as they have been termed by one investigator (Krechevsky, 1932), 'hypotheses.' Two sharply contrasting interpretations of these systematic behavior tendencies have developed. One, referred to as the noncontinuity theory, had its origins in a suggestion of Lashley (1929), to the effect that these systematic responses (consistent response to the left, simple alternation, etc.) represent more or less insightful attempts at solution on the part of the subject. According to this view (Krechevsky, 1932, 1938; Lashley, 1942) the animal selects and responds, in turn, to certain aspects of the situation and does not acquire any differential response tendencies to the relevant cue until just at or just preceding the time of solution. That is, during the occurrence of the incorrect hypotheses

the subject may be learning something concerning the particular discriminanda involved in these hypotheses, but he is not learning anything about the relevant set of discriminanda.

In contrast to this conception, the continuity interpretation (Spence, 1936, 1937a, 1940, 1945; McCulloch, 1939; McCulloch and Pratt, 1934) insists that, so long as the subject is receiving discriminably different stimulation from the positive and negative discriminanda during the presolution period, differential associative tendencies will be developed with respect to them. According to this theory, discrimination learning is conceived as a cumulative process of building up the excitatory strength (habit, associative strength) of the positive cue as compared with the competing excitatory strength of the negative cue. This process is assumed to continue until the difference between the excitatory strengths of the two cues is sufficiently great to offset any other differences in excitatory strength that may exist between the stimulus complexes of which the cues are members. Thus, according to this conception, when an animal is responding always with a left-going hypothesis, it receives reinforcement every time the positive cue (e.g. white stimulus) is on the left side, but it is not reinforced when the negative cue (e.g. black stimulus) is on the left. As a result of this differential reinforcement the white cue gradually acquires a greater excitatory strength than the black, but the subject continues to choose the left side predominantly because the difference in excitatory strengths between the left and right positional cues is greater than the difference in the excitatory strengths of the cue stimuli. Eventually, with continued differential reinforcement, this latter difference becomes greater than that between the positional cues, and the subject gives up the left-going hypothesis and adopts the correct white-going hypothesis.

As a critical test of the two opposed theories an experimental design has been em-

ployed in which the significance of the stimulus cues during a preliminary period of trials, in which the subject is responding with some irrelevant hypothesis, is the reverse of that used in the subsequent learning problem (i.e. the positive cue is made negative, and vice versa). According to the noncontinuity theory this preliminary training should have no effect on the subsequent learning of the reverse problem. In contrast the implication of the continuity theory is that the learning of such a reversed group would be retarded as compared with a control group that did not have such initial reversed training but instead was given 50-per-cent reinforcement on each of the relevant cues for the same period of trials.

Three experimental studies employing this design have been reported. Two of them (McCulloch and Pratt, 1934; Spence, 1945) obtained results that confirmed the continuity theory; the third (Krechevsky, 1938) found that one group (40 preliminary trials) supported the continuity theory and another (20 preliminary trials) the noncontinuity theory.

Krechevsky employed pattern discrimination, whereas the more simple brightness discrimination was employed in Spence's study (1945). The latter has the advantage that no special receptor-exposure adjustments must first be learned in order to provide discriminably different proximal stimulations from the two stimulus cards. In the case of the black-white discrimination the animals cannot help but receive discriminably different retinal stimulation from the very first trial, and, because of the differential reinforcement, differential associative strengths with respect to the two stimulus cards develop from the beginning. Such is not necessarily the case, Spence contends, in pattern discrimination, particularly in the Lashley type of jumping apparatus. In the preliminary training with this apparatus the subject learns to jump to an open window, and it acquires the habit of fixating the lower ledge to which it must jump. Although

this fixation undoubtedly brings the stimulus cards into the visual field of the subject, it does not guarantee that discriminably different retinal patterns of stimulation will be received from the stimulus cards. Under such conditions no differential learning with respect to the two cards would take place. The subject must first learn to make the appropriate receptor-orienting acts that will lead to the reception of retinal stimulus patterns that are discriminable. Krechevsky's subjects presumably failed to do this in the 20 preliminary trials but did so in 40 trials. Hence the former group showed no retardation, whereas the latter did.

Experimental confirmation of the foregoing analysis has been obtained by Ehrenfreund (1948). When the jumping platform of a Lashley type discrimination apparatus was placed (as is customary) at the same level as the bottom of the stimulus window, and the stimulus forms (upright and inverted triangles) were placed slightly above the center of the stimulus card, Ehrenfreund obtained results comparable to Krechevsky's 20-trial group. That is to say, the preliminary reversal of the reward value of the cues led to no retardation in the subsequent learning of the reversed problems. However, in a strictly parallel experiment, except that the jumping platform was raised so that the rats jumped directly to the stimulus card at the level of the forms rather than to the bottom of it, the experimental results were just the opposite. Under this condition, in which coincidence of the initial fixation point and the cue was approximated from the first, the reversed group showed significant retardation in the learning test as compared with the control group.

The experimental findings of this and earlier studies clearly show, then, that differential learning with respect to the relevant cues can occur, as the continuity theory states, while the subject is responding on the basis of an irrelevant 'hypothesis.' Beyond the level of the simplest perceptual situations, however, there is no guarantee

that differentiation will develop with respect to all the cue differences present in the stimulus situation. Such complex pattern discrimination apparently involves, as an important component, the preliminary acquisition of receptor-exposure adjustments that provide the discriminably different retinal stimulation necessary for learning. Perceptual factors obviously play a very important role in this type of learning.

Cognitive versus Response Theories of Simple Maze Learning

For the learning of problems that offer alternative pathways and demand the making of a choice (e.g. the maze), two radically opposed theoretical analyses of the underlying mechanisms have been proposed. One, favored by the S-S or perception theorists (Woodworth, 1947; Tolman, 1932, 1934; Leeper, 1935, etc.), conceives of the learning in terms of the development of cognitions that are representative of the stimulus relations in the environment. Thus maze learning is described as the acquisition of knowledge about the various parts and aspects of the maze, including the sequences and relations among the paths. In the simple T-maze, involving a single choice-point, the subject is assumed to learn the difference between the two alternative alleys in terms of what they signify, if entered. Thus one alley entrance comes to be a sign for a dead end, whereas the other comes to signify food or some other goal object. In terms of Tolman's concepts, sign-Gestalt-expectations or cognitions are built up to the effect that one alley (e.g. left) leads to the significate, food C_{L-F} , whereas the other alley leads to nothing C_{R-0} . Tolman, of course, assumes that these cognitions develop as the result of mere sequence in experience of the stimulus events, whereas Woodworth believes that reinforcement also is an important factor.

The development of a differential response — e.g. preference for the alley leading to food over that leading to a dead end — is not to be accounted for, according to

the cognitive theory, in terms of a stronger cognition of the left response than of the right. Rather it is due to the greater demand value of the food than of the empty alley. Given sufficiently clear cognitions or 'significate-expectations' with respect to the two alternative alleys, the one leading to the significate that has the higher demand value will be taken. The demand value of the significates will depend, in turn, upon the motivational state of the subject. This theory may be stated briefly, as follows:

$B_F > B_0$, if C_{L-F} and C_{R-0} exist, and $\Delta F > \Delta_0$

In contrast to this interpretation, the typical S-R associationistic theory accounts for the development of the preference for the rewarded (food) alley in terms of a building up of the associative connection to the left response, whereas no such association is developed to the response of going to the nonrewarded alley. Thus, if we were to extend to selective learning the constructs and principles that Hull has developed for classical and instrumental conditioning, we might say that the habit strength of the left-alley response becomes greater than that of the right-alley response. As both habit strengths are multiplied by the same existing D (drive) strength, this leads to the implication that the excitatory potential for the left-going response will be greater than that for the right-going response ($sE_{R \text{ left}} > sE_{R \text{ right}}$). The learning criterion (e.g. 100 per cent) is attained, according to this view, when the difference between the competing excitatory potentials reaches a value that is greater than the range of oscillation of the excitatory potentials.

Although this treatment in terms of Hull's constructs is adequate as far as it goes, it is not complete, for consideration must still be given to a theoretical mechanism that Hull does not treat in his *Principles of Behavior*, but one that figured prominently in his earlier theoretical articles on maze learning (1930b, 1931, 1932). Reference is made here to the fractional anticipatory goal reaction r_g

and its proprioceptive cues s_g which Hull has hypothesized as playing an important role in the integration of the various responses in the maze sequence.

In a symposium paper on simple maze learning, Spence (1941) attempted to show how, under certain conditions, this fractional anticipatory goal mechanism would play a decisive role in selective learning. An experiment carried out by Kendler (1946) will serve to explain this function. Employing a single T-maze, with food at the end of one alley (e.g. left) and water at the end of the other, Kendler gave white rats, motivated for *both* goal objects, a total of 14 trials to each side. Test trials were then given in which the subjects were *either* hungry or thirsty. It was found that the animals were able to respond appropriately (85-per-cent correct) on these test trials. When hungry they tended to go to the food side, and when thirsty they chose the alley leading to water. Now, whether we assume that the habit strengths of the two responses were built up equally, or that they were more strongly built up on one side, it is not possible, on the basis of the theoretical S-R analysis given above, to account for the successful differential responses on the different test trials.

The explanation suggested by Spence (1941) was as follows: During the training series the stimuli in the water box and in the water alley become conditioned to anticipatory drinking acts r_w and, in turn, the proprioceptive components s_w resulting from these anticipatory acts themselves become conditioned to the response of entering and continuing locomotion in this alley. In a similar manner, anticipatory eating responses r_f develop and their cues s_f become conditioned to the response of entering the alley leading to food. During the test series when only one drive is operative, the anticipatory act related to the goal for which the subject is motivated is much stronger than the other and hence produces stronger proprioceptive cues. Thus, when the subject is hungry, pro-

prioceptive cues from anticipatory eating responses are stronger than those for drinking. As these cues become conditioned to the response of entering the food alley, they tend to throw the balance of habit strength to the food-alley response. According to this view, the relative excitatory strengths are a function of the strength of this fractional anticipatory goal reaction and its habit relations, as well as a function of the other intervening variables assumed by Hull in his *Principles of Behavior*. Thus the functions for the sE_R values would be as follows:

$$sE_{Rf} = f(sH_{Rf}, D, r_f \rightarrow s_f H_{Rf})$$

$$sE_{Rw} = f(sH_{Rw}, D, r_w \rightarrow s_w H_{Rw})$$

Strictly conceived, the role ascribed here to the fractional anticipatory goal reaction ($r_g - s_g$) should also apply to instrumental conditioning. The writer believes that it does so operate, and he would employ it to explain the fact that stronger instrumental responses occur when the goal object is increased in amount (Crespi, 1944). This hypothesis is to be contrasted with Hull's interpretation (1943) that magnitude of the reward determines the strength of response through determination of the limit to which sH_R grows (postulate 1, p. 699). Finally, the possible motivational role of this $r_g - s_g$ mechanism should not be overlooked. It is conceivable that the occurrence of these fractional goal responses, in the sequence leading up to the goal, results in a certain amount of conflict, and hence in tension. It is entirely possible that heightened tension contributes to an increase in the existing state of generalized drive D .

In concluding this discussion, attention should be called to the possibility that the $r_g - s_g$ mechanism as proposed above is essentially the same thing as Tolman's sign-Gestalt-expectation (cognition). The present treatment has attempted to show the manner in which such expectations might operate to produce differences in response. As such it escapes the criticism that Guthrie

(1935) and Thorndike (1946) have made of Tolman's conception, namely, that it does not specify how expectations are related to action.

Summary and Evaluation of S-S versus S-R issues

The preceding discussion of representative theoretical issues in problem solving, discrimination learning, and maze learning has tried to show the extent to which disagreement centers around the issue of S-S versus S-R. Perceptual learning theorists like Koffka, Köhler, Lewin, Maier, and even Tolman have emphasized at one time or another the concept of insight in their attempts to explain problem solving, although all have not meant the same thing by the term. In contrast, the stimulus-response psychologists have consistently rejected an insight hypothesis and have offered in its place some variant of the trial-and-error interpretation. Similarly the disagreements concerning discrimination and maze learning stem primarily from these two opposed theoretical positions. A few further comments on these two theories will be given in order to summarize some of the basic issues involved.

In addition to picturing the hypothetical learning modifications as changes in the perceptual or cognitive states of the subject, the S-S theorists vigorously reject the concept of association. There are, it is true, a few conspicuous exceptions. Thus Tolman (1937) and Maier (1939) explicitly accept a principle of association although they postulate that the functional relations established by sequence in experience (principle of contiguity) are not between S's and R's but between the successive stimulus-aroused events. As Tolman (1938b) has acknowledged, his associationism is essentially a return to the eighteenth century concept of "association of ideas."

The main opposition to association theory comes from the original Gestalt group (Köhler and Koffka) and from Lewin.

Köhler and Koffka emphasize that learned cognitive fields (trace systems, etc.) do not consist of separate items merely coupled or joined together by bonds. Rather they are conceived as organized dynamic structures in which the relations between the terms are determined only in part by contiguity. Much more important are differences in the *intrinsic* qualities of the items being organized. Field properties also exert their special effects in the process of organization and in the process of reproduction. Most of the criticisms by this group, however, are directed against the associationistic doctrines of the German school (Mueller, 1924) and are not always relevant to current associationistic theories in America. For example, Lewin has offered the criticism that an association should not be interpreted as a force that can produce responses. It must only be thought of as providing for the organization of cognitions which must in turn be energized by the motivational systems of the individual before action. As we have seen, Hull's concept of habit (associative) strength essentially complies with Lewin's view; the habit strength alone cannot produce a response but must be combined with the co-existing drive state in order to do so.

Reference by these psychologists to the intrinsic properties of the hypothetical psychological fields brings us to another characteristic exhibited by many of the theories falling in this class. The learning theories of the Gestalt group, in particular, are marked by an extensive discussion of the intrinsic nature of their hypothetical intervening variables. Thus Koffka treats at length the various kinds of hypothetical factors he assumes — e.g. processes, traces, trace systems, behavioral environment, ego systems, etc. He theorizes about the possible nature of the interactions (interrelations) among them and, more important, between them, and the behavior they determine. Lewin's theorizing shows this same tendency. Indeed he has emphasized the need for psychological theorists to concentrate more on

what he calls the conceptual properties of their theoretical constructs as distinguished from their operational definitions (1940). Finally, Zener seems to imply that this is the only task of the learning theorist. In introducing his theory he states: "We are concerned with the conception of the permanent structural change produced, not with the process of acquisition" (1937, p. 386).

Our diagram (Fig. 1) showing the various types of relations between the theoretical and experimental concepts in psychology may help to clarify this last point. Of the functional relations shown in this figure, the Gestalt discussions of learning theory consist primarily of types III, IV, and, to a lesser extent, of type V. Conspicuous by their complete absence in Lewin's treatment, and by their sparsity in Koffka's and Köhler's theorizing, are relations of type II. Koffka, it is true, mentions some of the experimental variables that he believes to be important in determining the properties of his hypothetical learning variables. For the most part, however, his treatment consists in references to the experimental variables in the present stimulus situation that play an important part in the perceptual processes (type I relations). The implication is usually given that analogous relations (laws) will be found to hold for traces, and hence for learning. The belief on the part of the Gestalt psychologist that learning is merely a part of the larger problem of perceptual organization provides much of the rationale for this appeal to the laws of perception.

A criticism persistently directed at the Gestalt theorists' concern with the *inherent* dynamics of hypothetical learning organizations is that their treatments are speculations with no empirical reference. This criticism is not entirely justified, however, for their constructs are derived from experience, from the observed behavior changes in the learning experiment, and particularly from the phenomenological introspection of their sub-

jects.* Together these sources provide an empirical basis for making guesses as to the nature of hypothetical learning processes.

From the point of view of learning theory, however, an important problem is usually left untackled by the S-S, particularly the Gestalt, theorists. This is the specification of the relations between the hypothetical learning factors of the *present* and the experimental conditions of the *past*. The formulation of such historical laws constitutes the peculiar task of the learning psychologist, for it is these laws that provide the means of controlling behavior changes.

The approach of the Gestalt psychologists to the problem of learning theory probably reflects their preference for the mediational type of explanation of psychological events. For Köhler, in particular, explanation of psychological events is to be sought in the underlying neurophysiological processes. Köhler attempts to indicate the isomorphic relations of his hypothetical trace fields to electrical brain fields. In contrast, the more behavioristic-minded psychologists tend to direct their interests toward explanations that refer to events in the physical and social environment, past and present.

An outstanding exception to this tendency on the part of S-S theorists to concern themselves with the intrinsic properties of their theoretical fields is Tolman's sign-Gestalt formulation. One of the first psychologists to enlist the aid of the intervening variable in the formulation of laws in psychology, Tolman has always insisted that these theoretical constructs must be defined in terms of the independent (environmental) variables and in terms of the resulting behavior. Tolman's theorizing is almost completely free of physiological speculation.

* Snygg (1941) has proposed a theoretical system of learning that is based exclusively on phenomenological introspection. He believes that attempts like those of the Gestaltists to develop theoretical systems based both upon an objective frame of reference and upon the phenomenological approach lead only to confusion.

Likewise, it should be observed that, so far as the meaning of their defining equations is concerned, Hull's theoretical constructs are not concerned with the intrinsic properties (physiological or introspective) of the hypothetical learning changes. As a matter of fact the mathematical equation defining the construct of habit sH_R does not identify it as either an S-S or an S-R concept. Coupled with this purely mathematical definition of habit, however, is a further treatment of learning in neurophysiological terms. Here Hull refers to 'receptor-effector connections' (sC_R) being strengthened by reinforcement, and he identifies (coordinates) this concept with his mathematical concept of habit sH_R . It is only by virtue of this additional neurophysiological theorizing, then, that Hull falls into the S-R group. Actually he makes little or no use of the physiological properties he ascribes to his theoretical constructs.

Attention should also be called to the fact that Thorndike likewise invokes a physiological hypothesis concerning the nature of his concept, the S-R bond. He identifies the change in strength of a bond with changing synaptic conduction between neurons. Interestingly enough, it is primarily these superfluous physiological interpretations of Hull and Thorndike that the cognitive-field theorists object to as being mechanistic and elementaristic. Apparently there has been a failure to appreciate the fact that little or no use is made of the physiological aspects of these constructs by the S-R theorists in their actual attempts to explain learning data.

So far as the experimental evidence is concerned, there is little data bearing on the question whether the functional tie-up is between sensory-motor events or between successive sensory events. It would seem entirely possible that certain kinds of learning, particularly simple perceptual learning, might well involve sensory-sensory associations or combinations, whereas other more complex learning, such as problem solving, might involve primarily the development of sensory-

motor integrations. In this connection, Maier and Schneirla (1942) have cited the experiment of Loucks (1935) as support for the view that learning involves sensory-sensory connections. Loucks, it will be recalled, reported finding that a dog could not be conditioned to a buzzer when the unconditioned response of flexing the hind leg was produced by faradic shock applied directly to the motor area of the cortex. This procedure, of course, by-passed the usual sensory system (pain from shock to the limb) involved in normal conditioning. The association between the sensory event resulting from the sounding of the buzzer and the sensory event aroused by the shock could not occur since the latter did not occur.

That conditioning could and did take place when the sensory process corresponding to the unconditioned pain stimulus was absent was, nevertheless, demonstrated by a variation on the experiment. When reinforcement in the form of food was given the subject each time the leg flexion occurred, conditioning followed. An S-R theorist would interpret this to mean that the association was between afferent-efferent events. The connection or association did not occur in the first part of the experiment because of the absence of reinforcement. With the introduction of reward, the association was established. The results of the two experiments taken together are thus seen to favor the S-R interpretation rather than the S-S. Girden (1943) has provided further evidence in favor of the assumption that a response must occur during the training series in order for learning to take place. Girden found that, when complete striated muscle paralysis was induced by injection of the drug erythroidine, no conditioning involving these muscular responses took place. On the other hand, changes in blood pressure and pulse rate, autonomically controlled responses occurring in the drug state, did become conditioned.

In the opinion of the present writer, too much attention has been given to this issue

of S-S versus S-R. If we employ constructs introduced by mathematical definition, in the manner of Hull, the problem of the nature of the intrinsic physiological properties of the changes underlying learning does not, for the present at least, even arise. We should be able to work out the laws governing behavioral changes without having to stop and consider such physiological matters. What is needed most at the present time in the study of learning is the continued and persistent pursuit of the type of integration of theory and experiment that will lead to the discovery and formulation of laws of learning in terms of environmental and behavioral variables. When such a body of knowledge is available we shall be in a better position to evaluate the adequacy of competing physiological hypotheses. Perhaps by that time, also, the physiologically oriented psychologists will have at hand independent hypothetical physiological mechanisms whose properties are not themselves inferred from the learning phenomena they purport to explain.

Cognitive Processes

ROBERT LEEPER

University of Oregon

Although the psychology of cognitive processes — their nature and their role in human behavior — raises many problems of definition, it seems best to start our discussion, not directly with a set of definitions, but with a description of the experiments that must ultimately set the bounds of meaning on the terms we use. When we start in this way we are assuming, of course, that useful definitions are those that enable us to classify phenomena on the basis of empirical evidence of functional similarities.

To some extent, cognitive processes have always been defined partly in this functional manner. But they have also been defined as though it were possible to identify cognitive processes as such — to discern their qualitative characteristics as conscious experiences. It was thought by some that the two modes of definition are compatible, but this assumption did not stand up under experimental investigation.

For example, it was thought that cognitive processes, as *conscious* processes, are used to compare the pitch of two tones heard in succession or to compare the weights of two objects lifted successively. The theory was that, on the second stimulation, the person experiences a conscious image of the first stimulus and makes a comparison between this conscious image and the perception of the second stimulus. But, as early as the experiments by Schumann in 1898 and Marbe in 1901, this hypothetical process was not confirmed by careful introspective observa-

tion (see, for example, the review of this work by Needham, 1934). There was, in truth, some process that yielded rather accurate comparisons. But the subjects could typically detect no images or conscious representations of the first stimulus at the time the second was given. They reported merely that, as an immediately experienced fact, the second tone, say, was heard as higher or lower in pitch than the first. If cognitive processes were responsible for the judgments, those cognitive processes were not in themselves conscious, even though they yielded a conscious end product.

The same finding resulted from experiments that sought to investigate more complex cognitive processes. Ach (1905) presented to his subjects pairs of digits such as 7, 3; 9, 2. Sometimes the subjects were told to add the numbers; at other times, they were told to multiply or to subtract. The subjects at first had some conscious representation of each new task, but the consciousness of the task faded as the work on each series continued. And yet the subjects responded appropriately. Watt (1905) found similar results. He used single words as stimuli. In different series he asked his subjects, given a word like "tree," to name a larger class, a subclass, or a coordinate class. Or the subject was asked to name a whole when given the name of a part, to name a part when given the whole, or to name another part when given the name of a part.

What he found, as Woodworth summarized the study, was:

When the same task had continued for a series of stimulus words, the conscious awareness of the task faded out even from the foreperiod and was reduced to a mere feeling of readiness. The preparation lost its specificity as a conscious state, but not as an adjustment, for it still insured correctness of response according to the task. With practice the set became at once less conscious and more efficient. [1938, p. 791.]

There were, of course, conscious experiences in the intervals before the response words appeared: the subjects might note a feeling of fatigue, an odor in the room, or what not. But there were no distinctive and relevant conscious processes to which the final response could plausibly be attributed.

Woodworth noted the same phenomenon in his early experiment on voluntary movement (1906). His subjects developed their specifications for such movements by a series of conscious perceptions and thoughts, but these specifications were carried over and used without any clear consciousness of the set thus employed.

Since Ach and Watt were members of the "Würzburg school," which is known chiefly for its concept of "imageless thought," and since Titchener questioned so vigorously the evidence for this concept, it is apt to be forgotten that he heartily agreed with their contribution that conscious processes are often determined by not-conscious processes. In fact, Titchener's views on imageless thought led him to emphasize this finding in unequivocal terms:

But is meaning always conscious meaning? Surely not: meaning may be carried in purely physiological terms. In . . . the rendering of a musical composition, without hesitation or reflection, in a particular key . . . ; in these and similar cases meaning has, time and time again, no discoverable representation in consciousness. . . . This predetermination of consciousness by influences that, during the course of conscious-

ness, are not themselves conscious, is a fact of extreme psychological importance. . . . [1910, pp. 369-370.]

In later experiments on "concept formation" an even more drastic conclusion was demonstrated. This conclusion was not reached in the early experiments on concept formation, because in these experiments the subjects were told that they were to search for common elements and to report introspectively how they developed generalizations (Grünbaum, 1908; Moore, 1910; Fisher, 1916). In experiments by Hull (1920) and later workers, however, a different procedure has typically been used. The subjects are given no instructions to form concepts. They are told merely that they are to learn the names of a series of Chinese characters that will be shown them, or of a series of geometrical designs, or whatever. Actually, however, the materials fall into classes that contain common features, and the same name is given as each member of a class is presented to the subjects. Many of the subjects in these experiments soon recognize that they can best handle their task by searching for such common features and by associating the names with them. Some of the subjects, however, develop the ability to name new examples without being able to say how they do it, even when the necessary formulations lie well within the limits of their vocabularies. Hull gives only a meager report of the introspective observations of his subjects, so it is impossible to say to what extent this effect occurred in his study. In later work, however, as in the studies of Heidebreder (1924, 1946, 1947), Smoke (1932), Rees and Israel (1935), Snygg (1935), Heidebreder, Bensley, and Ivy (1948), and Bouthilet (1948), this unconscious process is abundantly demonstrated. The conclusion from these studies, in other words, goes even beyond the findings of Ach, Watt, and Woodworth. For these studies indicate not merely that responses may be governed by sets or determining tendencies, initially

established by conscious processes and later dropped from consciousness, but also that complex guiding processes can be formed, retained, and used without the person's being aware of the process at any step. The subject is aware, of course, of the concrete materials and of his efforts to link names with concrete configurations. But he forms more generalized means of naming the figures without realizing that he is doing it.

All these experiments show that unconscious processes are often the means of accomplishing results that were formerly attributed just to conscious cognitive processes. These experiments show that definitions of cognitive processes in terms of the functional properties of psychological processes would not coincide with definitions of cognitive processes as conscious states.

There was also another outcome of the early introspective experiments that cast doubt on the value of definitions of cognitive processes in terms of conscious experience. This was the discovery that it is exceedingly difficult to describe conscious experiences as such.

For example, one of Titchener's students (Perky, 1910) tried to determine the differences between images and sensory perceptions. She instructed her subjects to construct conscious images, projecting them, as it were, on a ground-glass screen in front of them, and then to describe introspectively the nature of the images. At some points, however, without telling her subjects, she caused faint pictures actually to be projected onto the screen from the other side. These stimulations were faint, but not subliminal. Her subjects, however, could not distinguish between these sensory experiences and the images that they themselves projected. They remarked with surprise, sometimes, that their "images" were not what they would have expected. Thus, the banana that was being "imaged" was placed vertically, whereas they said it would seem more natural for the image of this object to lie horizontally. But

they could not distinguish introspectively between images and sensory perceptions.

Perky's results have often been regarded as evidence that there is no useful distinction between perceptual and imaginal processes. This conclusion does not follow. Her results suggest, however, that the distinction must be made in terms of functional relations—particularly in terms of the different origins of the two types of processes—and that it cannot be made by introspective observations of the two processes as such.

Much the same conclusion was suggested by the long controversy regarding "imageless thought." The studies by Watt and Ach did not reach merely the one conclusion that some of the controlling processes are unconscious. The introspective reports indicated also that the conscious experiences are not always describable in terms of images, feelings, and sensations but include also "conscious attitudes" of readiness, hesitation, certainty or uncertainty, and the like. This suggestion was carried further in studies with still more complex thought processes by Binet (1903), Bühler (1907), and others. For example, Bühler first read a series of proverbs to a subject to give him a body of material he could use. Then, to provide the process to be described introspectively, he read another proverb similar in sense to one of these, but different otherwise. The subject was asked to recall the related proverb and then to describe the conscious processes involved in this recall. The subjects reported that they often recalled the "meaning" or sense of the required proverb before they could recall its words or before they had any imagery related to it. They claimed they had conscious "thoughts" in terms that were neither sensory nor imaginal.

Moore (1919) supported the same conclusion in a series of reaction-time studies of different sorts of conscious processes. For instance, he flashed single printed words before his subjects and asked them in some cases to react as soon as they were conscious of the "meaning" of the word, in other cases

to respond as soon as some conscious visual image appeared. Visual images, on the average, took about twice as long to appear as did a consciousness of the meaning of the word. The differences were not so great in another study with simple pictures as stimuli and with instructions to respond to conscious meaning in one case and to the consciousness of some word association (such as the name of the object) in the other case. But, here again, meaning was reported more quickly.

In his *Lectures on the Experimental Psychology of the Thought Processes*, however, Titchener (1909) said that the alleged "imageless thoughts," in so far as they were actually conscious processes, were reducible to sensory and imaginal materials (often slight kinesthetic sensations) which the advocates of imageless thought had failed to discern. He did not deny that "meanings" were aroused in thought experiments like Bühler's. But, he said, Bühler's subjects failed to distinguish between the actual content of their conscious experience and the content they inferred it must have in view of their recall, e.g. of the appropriate proverb. In other words Titchener insisted that conscious experience is much more meager, much more sketchy and senseless in character, than we would have suspected from everyday observation. Meaning, he said, was carried in great part "physiologically" (by processes that were not conscious) rather than by conscious experience.

To this argument the advocates of imageless thought (see Woodworth, 1915, and 1938, pp. 783-800) replied that their subjects actually were describing their conscious experiences. They claimed that the structuralists were deciding the outcome of their observations in an a priori manner by refusing to allow their subjects to report conscious meanings that existed only as such.

Pratt (1928) claimed that the introspective studies on this problem had led to a general acceptance of the view that conscious thought contains such "impalpable"

materials as imageless thoughts. This possibly has been the general tenor of opinion. But another lesson was suggested even more forcibly — namely, that it is apparently much harder to describe cognitive processes as such than to study them in terms of their functional relations. For neither Titchener nor his opponents doubted the existence of processes that carry an elaborate meaning. What they could not agree on was the extent and character of the conscious experience involved in this process.

During this period in which the controversy raged over imageless thought, two new types of psychological research were demonstrating that cognitive phenomena may be studied without reference to considerations of consciousness. One was the work with intelligence tests, starting with Binet and Simon in 1905. This work indicated that it is possible to explore intellectual activity by a procedure that does not concern itself with the conscious aspects of the thought processes involved.

The other development was derived from the evolutionary-biological research in England. Thus the English biologist, Hobhouse (1901), using problems analogous to many of those later employed by Yerkes and Köhler, reported an ingenious array of studies with monkeys. He found that monkeys seem to "think," because they solve many problems with a relative independence of overt trial and error. Although most of the animal psychologists in the United States followed the example set by Thorndike (1898), who emphasized that animals do not use "representative" processes, a number of experiments supported the evidence of Hobhouse's work. Thus Hunter (1913) used a "delayed-reaction experiment" with several species of animals. The animals were trained to go from a restraining cage to whichever door was designated by a brief illumination. Then, during the test trials, the animals were restrained for several seconds or minutes after the light was turned off, and the animal had to remember which

door had been designated. Hunter found that rats and dogs could respond successfully only when, during the delay, they preserved their bodily orientation toward the exit to be used. On the other hand, raccoons handled delays up to about 20 seconds, even though they moved around restlessly in the restraint compartment.

Tinklepaugh carried this work further with monkeys and chimpanzees. He allowed a chimpanzee to watch him hide a bit of food under one of a pair of containers in one room and then to watch the same process in a second room, a third room, etc. Under these conditions Tinklepaugh found that chimpanzees could respond without error after having watched as many as 10 placements on one "trial." What is more, with both monkeys (1928) and chimpanzees (1932), he showed that, if the animals had seen a preferred food hidden, they reacted with strong frustration when this had been secretly replaced with a less-preferred food before the moment of choice. In other words, without going through the overt process of choosing a container and without experiencing directly the reward associated with it, these animals were able to establish some guiding process that represented both the nature and the location of the food.

Furthermore elaborations of the experimental methods favored by Thorndike showed that, even with mazes and latch boxes, the habits that are learned cannot be described in terms of connections between the stimuli and the overt movements present during the learning. Rats can traverse a maze accurately by swimming after they have been able only to wade through the maze during training (Macfarlane, 1930). They can negotiate a maze when they have been badly crippled by cerebellar injuries after the learning (Lashley and McCarthy, 1926) or by spinal-cord injuries (Lashley and Ball, 1929). Muenzinger (1928) demonstrated that normal guinea pigs show a lot of variability in the means by which they move a lever that gives them access to food.

These studies indicate that maze habits and problem-box habits are comparable to the variable adaptive responses of human beings that we explain by saying that the person "knows" what effect has to be attained.

Furthermore these experiments emphasize that the controlling processes involved ought to be studied primarily in terms of their functional properties and only incidentally, if at all, in terms of whether they are conscious processes.

HOW ARE COGNITIVE PROCESSES TO BE DEFINED?

The problem here is broader than the problem of defining the one term "cognitive processes." It is a problem also of the conception and definition of an important group of subordinate terms like perception, concept, thinking, expectation, and mental activity.

The older view in psychology, derived from everyday experience, was that almost all mental processes are conscious and may be observed introspectively. Thus G. F. Stout's *Manual of Psychology* says:

. . . there are three ultimate modes of being conscious of an object: knowing, feeling, and striving; the cognitive attitude, the feeling attitude, and the conative attitude. . . . The word *cognition* . . . covers all modes and degrees of being aware of or cognizant of an object. [1899, p. 56.]

Stout recognized, of course, that there are "psychological facts" or processes that are not "psychical facts" or conscious processes. He was familiar with the stereoscope and knew that there must be some process, even though it is not introspectively observable, whereby the disparate stimulations of the two retinas are combined to produce the three-dimensional experience. But, in spite of such examples, Stout regarded conscious mental activity as encompassing most of the processes by which we adapt, and he regarded introspection as the key to the observation of these processes.

This emphasis on consciousness in the definition of cognitive processes is seen in Warren's *Dictionary of Psychology* (1934):

Cognition = a generic term used to designate all processes involved in knowing. It begins with immediate awareness of objects in perception and extends to all forms of reasoning.

Even more clear is this tendency in the definition of perception:

1. the awareness of external objects, qualities, or relations which ensues directly upon sensory processes, as distinguished from memory or other central processes; 2. a mental complex or integration which has sensory experiences as its core; 3. awareness of present data . . .

The same emphasis is placed on consciousness by Humphrey (1948). He emphasizes some of the same experiments we have discussed above and says that there is often an interval of "organic processes" between the presentation of a problem and the solving of it. But, he then says (and he apparently intends this as his own definition too): "By 'directed thinking' or reasoning is usually understood the *conscious* side of these intervening processes" (p. 12, italics added). The same slant appears in his brief description of methods of research on thinking (pp. 6-7). Humphrey speaks as though the only available methods are variations of introspective techniques: such methods as the recording of (1) the spontaneous remarks of children as they work on problems, and (2) the retrospective reports of thinking after it has been completed.

These definitions of cognitive processes in terms of consciousness are not, however, an outgrowth of experimental studies on cognitive processes. They can be traced back, instead, to the time before such studies had been made. They are based on the assumption that our responses and our conscious processes are accounted for by previous conscious processes in a much fuller measure than has proved experimentally to be the

case. They are based on the assumption that the nature of conscious experiences can be described introspectively with much more certainty and facility than has proved possible in practice. And they are derived from definitions that were formulated before new methods of research had demonstrated the possibility of fruitful study of cognitive processes in children, animals, and other subjects incapable of adequate introspective reports.

In a situation like this we have to make a choice. Either we must devise new terms to reflect the fruits of experimental work or we must redefine the old terms. A few new terms have, in fact, been proposed and used, such as "set" and "determining tendency." But not much progress has been made in this way.

The chief problem arises from the fact that, as Woodworth says, it seems possible for the same process to become "at once less conscious and more efficient." In other words the functional properties of many processes (aside from the one property of being conscious) seem to be the same even though the process is conscious in one case and unconscious in another. The question is, therefore, whether we should define cognitive processes, perception, thinking, concept formation, and the like in terms of *conscious* processes exclusively, or whether we should say that consciousness may be present or absent, as the case may be, and that all these processes are to be defined in terms of their other functional relations.

This latter alternative has been rejected by some psychologists on the grounds that to speak of "unconscious concepts" or "unconscious perceptions" is equivalent to speaking of "unconscious consciousness." But this does not necessarily follow. Although the concept of consciousness emphasizes a property antithetical to "unconsciousness," such concepts as thinking and perception need not refer at all to conscious properties but merely to the origins and to the effects of the processes in question.

For the purposes of this chapter we will follow the suggestion that cognitive processes must be redefined without mention of consciousness. This is apparently the procedure that has appealed to experimenters on pragmatic grounds. Thus it has become typical for experimenters on concept formation to use a criterion of "correct naming of new examples" as the criterion of the attainment of concepts even when the subjects could not say why the name fitted that new stimulus.

In adopting this point of view we are not rejecting introspective observation as having no place in the picture. We use it whenever it seems valuable. It remains true, furthermore, that one of our key problems concerns the difference it makes whether a cognitive process is conscious or not. Another question is why cognitive processes are conscious in some cases and not in others. But it does not seem helpful to include the characteristic of consciousness in the definition of cognitive processes.

A few of the workers who have reintroduced the term "cognitive process" into psychology have defined it as the process whereby there is created, for the individual, a "psychological environment" (Lewin, 1946) or a "behavioral environment" (Koffka, 1935), to which the individual responds. The same notion is embodied in the suggestion of a number of writers that the individual should be thought of as responding to his "phenomenological field" (see Snygg, 1941; MacLeod, 1947; Krech and Crutchfield, 1948). This conception has led to a fruitful attack on certain problems, but it has not proved relevant to all the problems of cognitive processes. It seems better, therefore, to avoid narrow definitions and to say that cognitive processes include all the means whereby the individual represents anything to himself or uses these representations as a means of guiding his behavior. It is in this broader sense that the term "cognitive processes," after virtually disappearing from the vocabulary of psychology, has been re-

appearing in the writings of such psychologists as Adams (1931), Tolman (1932), Heidebreder (1945), and Hilgard (1948).

METHODS FOR THE STUDY OF COGNITIVE PROCESSES

As we have said, the view prevailed originally that cognitive processes could be studied only by the method of introspection. Other methods have since been developed, but it still remains true that introspection has considerable value. In the experiments on concept formation, for example, introspective reports have disclosed that the subjects typically engage in an extremely active exploratory process, often formulating, testing, and discarding hypotheses within single trials. Thus Heidebreder described some of the means that her subjects used to help them link the nonsense-syllable names with the drawings she presented:

Mnemonic devices . . . were very frequent. . . . For example, several definitions of *ling* . . . which was represented in the first series by a drawing of two stockings, reported that the word was remembered as the sound of Christmas bells and associated with Christmas stockings. . . . a definition of *silm* (bird) . . . contained the comment: "This seemed a queer word. I first learned it by associating it with slim and thinking of the bird's slim legs." . . .

Many definitions of *fard* (circle), which in none of the three experiments was represented in the first series by a pictured object, included such comments as: . . . "The first one made me think of the perfectly round moon in a picture of Welch poets and *bards*, bard rhyming with *fard*." [1947, pp. 112-113.]

Conceivably, by means of large and elaborate tests given after each trial, an experimenter might determine *objectively* just what processes had gone on within his subject, but, as a practical matter, this is not possible. The verbal reports provide evidence that can hardly be gotten in any other way.

Actually many studies of cognitive processes in recent decades have suffered because the experimenter neglected to collect verbal reports to show how the subjects understood their task and how they worked on it. Thus, even though Hull (1920) tried to have his subjects think of his experiment with Chinese characters as a memory experiment rather than as an experiment on concept formation, his comments indicate that many of the subjects came to realize that concepts could be formed and used. But no information is given as to how many subjects came to realize this, or at what points, or with what influence on their behavior.

As was brought out above, however, the introspective method cannot be the sole approach to the study of cognitive processes. There are too many processes that, even though once conscious, fade out of consciousness and yet continue to function effectively. And there are too many cases, as in the concept-formation experiments, in which concepts are formed and used without ever having been conscious.

Another limitation on introspective observation is suggested by Maier (1931) who found that perceptions themselves may sometimes elude introspection. His subjects were brought into a room in which two cords hung from the ceiling, so far apart that, while holding to one cord, the subject could not reach the other one. A few other things were present in the room, such as a chair, a piece of wire, and a pair of pliers. The subjects usually were able to get two possible solutions—reaching for the second cord by means of the wire, and tying the one cord to the chair to bring it closer while they approached it with the other cord. But, when told to search for still a third solution, most of them failed. It required that they tie an object to one string and set it swinging like a pendulum so that it would swing within their reach while they held the other cord. Maier gave them a clue by walking past the second string and brushing against it so as to set it swinging.

Of the 38 subjects who had been unable to solve the problem up to that point, 23 got the solution in an average of 42 seconds. However, only 7 of these 23 were able to report, even after specific questioning, that the movement of the string had given them the clue. As Maier says, retrospective accounts obviously did not indicate the clue that had helped them solve the problem, even though there must usually have been a conscious perception or conscious representation of the swinging string.

It would seem, then, that there is no one method for the investigation of cognitive processes. There are several methods, and their essential feature is the observation of behavior *as precisely and completely as possible and under as great a diversity of conditions as possible*. It is only in this way that we can get dependable and worthwhile information about the cognitive processes that lie back of behavior.

Many studies of learning are unsatisfactory as studies of cognitive processes because the observations are secured under such a small range of conditions that we are left in ignorance of the cognitive processes involved. For example, it has long been observed that, in many discrimination situations, the "error curve" drops more rapidly on successive trials if the animals are "rewarded for correct responses and punished for wrong responses" than when no extra punishment, such as shock, is added to the wrong responses. From this observation it was concluded that punishment "stamps out" the nervous connections leading to the punished responses. But Muenzinger raised the question of what would happen if the grid were placed in a T-maze right after the choice point, *but in the correct alley rather than in the wrong one*. When the rats were given both punishment and reward for right responses, the error curve dropped even more rapidly than when they were punished for wrong responses (Muenzinger, Bernstone, and Richards, 1938).

An experimental example from Spence (1939) illustrates both the great possibilities for cognitive study that come from precise observation and also the uncertainties of interpretation that come from insufficient variation of conditions. In a multiple-choice

Not only did Spence report precisely the behavior exhibited, but he tested the animals under new conditions and related the observations to the previous findings. That is, he tried the animals on the other three possible settings of 5 boxes. The 5 chim-

FIG. 1. Error curves for one of the 10 chimpanzees that learned *separately* each of the four original settings on a multiple-choice problem. (Spence, 1939, p. 22.)

experiment, Spence found that his chimpanzees had considerable difficulty in learning to select the *middle* box from different groups of 5 adjacent boxes. The apparatus had 11 boxes that could be lifted into position, and Spence used four different settings in the original training. Correspondingly, he drew, for each chimpanzee, a curve of its errors on *each* of the four settings. The result was that he found two distinctly different outcomes. With 10 of his 15 subjects, the curve for each setting came down separately, as in Fig. 1. With 5 of the chimpanzees, however, the error curves are typified by the graph shown in Fig. 2. That is, 10 subjects had learned each setting separately. The other 5 subjects apparently learned some more generalized habit. From observing the latter animals, moreover, Spence noted that they "... usually went to the far side of the cage between trials and thus approached the apparatus from a distance. . . . also . . . , as these subjects approached, they gave the appearance of attempting to place themselves equidistant from the two ends of the setting" (1939, p. 47).

panzees that had learning curves like those in Fig. 2 were still able to select the correct (middle) box with more than 80-per-cent accuracy. None of the other animals made more than 55-per-cent correct choices with the new settings.

FIG. 2. Error curves for one of the 5 chimpanzees that learned *simultaneously* the four original settings on a multiple-choice problem. (Spence, 1939, p. 22.)

This experiment provides a striking example of the fact that different subjects may learn either more particular or more generalized habits in the same objective situation, and it shows how significant this fact may be in tests of transfer.

The study also indicates how we are often left with uncertainties that can be resolved only if the conditions are varied even further. Thus Spence suggests that the more generalized habit was perhaps dependent on the motor pattern of withdrawing to the opposite end of the cage and approaching from a distance. This suggestion might have been tested by forcing the five "generalizers" to choose from a position as close to the boxes as that usually assumed by the "particularizers."

Not only do we need good methods for the study of cognitive processes, we also need to develop a constructive theory. Too much of the work in this field has been done at random, as it were, or just on *negative* problems. Thus a lot of research and discussion has been devoted to the propositions that not all conscious thought is carried by images, that not all thought is accomplished by words, that not all problem solving is accomplished by trial and error, that not all problem solving is accomplished by insight. This work has value, of course. But it would be still more valuable if we could hypothesize the factors that are responsible and plan our experiments in relation to them. Thus Heidbreder, in a survey of methods, concludes:

It would be misleading, however, to close this account without stating explicitly that these methods, however effective in specified conditions, have led to little knowledge of thinking that is at once broadly significant, solidly grounded in fact, and unequivocal in meaning. It would be misleading, too, to omit the suggestion that this state of affairs may be due, not so much to a lack of suitable procedures, as to failure to ask effective questions. . . . scientific research . . . is basically an inquiry into significant problems. [1948, pp. 121-122.]

Similarly, Gibson and McGarvey end their review with the statement:

There have been amazingly few attempts to formulate an hypothesis and test it in carefully planned experiments. There should

be a great revival of interest in the psychology of thinking when investigations in the field become truly critical experiments. [1937, p. 345.]

Not all the research on cognitive processes needs to be aimed at theoretical issues, however. There has been a scarcity, also, of what might be called adequate *ecological* studies. For example, there has been discussion, for centuries, of the various types of errors that conceivably can be made in deductive arguments. But there have been few, if any, studies to determine to what extent each of the logically possible errors is actually found in human thinking. Piaget (1929, 1930) has made some noteworthy studies of this ecological sort with reference to the thinking of children, and some anthropologists have gathered such material with reference to primitive people (e.g. Paul Radin, 1927). But there is need of much more extensive material of this sort.

COGNITIVE PROCESSES AS MEANS OF LEARNING

Earlier in this chapter various incidental references have been made to cognitive processes as means of learning or acquisition. We now turn to the task of pulling these strands together and of indicating more adequately how cognitive processes figure in the phenomena of learning. We will confine ourselves to three matters: inductive concept formation, deductive concept formation, and inventive concept formation. These three processes do not cover all of learning. They do not cover the phenomena of memorizing, the acquisition of sensory-organization habits, or the acquisition of motor-coordination habits. They do cover, however, a great portion of the field of learning.

INDUCTIVE CONCEPT FORMATION

Most of the experiments that are commonly thought of as experiments on in-

ductive concept formation have been experiments on classification. The subject learns that certain stimuli should be classed together on the basis of some common property and that all these stimuli have the same name. Actually, however, inductive concept formation is a very broad and common psychological process, and its nature is indicated only partially by these experiments on class concepts.

What then do we mean by inductive concept formation? Partly we mean a process that is defined by what it produces—namely, concepts. It is the process of developing a habit or a cognitive mechanism that permits a person to respond to an object or event in terms of some property of which he may or may not be immediately aware. Furthermore, we cannot say that a concept is present unless there is some *generality* of application of the habit, and some *differentiation* of those cases to which the concept applies. In general, the experimental psychologist has always found it necessary to study concepts in the sense of “propositions” and not in the sense merely of single terms.*

* It may be well to note that this is not the old philosophical definition of “concepts.” In the older philosophical literature the idea was that a conceptual process is a cognition or apprehension of a quality or characteristic *as such*. To have a concept of *red* a person would have to think of “redness” apart from any red objects. This philosophical usage, however, has not been useful to experimental psychology, because it has not been apparent how to measure “apprehension of universals as such.” But it has been possible to distinguish between the knowledge of an attribute that is linked specifically to some one object and the knowledge of an attribute that is readily recognized in new specimens that possess it. Thus a small child can learn to say correctly that he has a “red wagon.” But, even at 3 or 4 years of age, he is not likely to be able to employ the word “red” appropriately when he is shown rubber balls of different colors. We know, from his inability to apply the word in new situations, that he did not “know what is meant by *red*.” He did not have the concept of *red*. This is a simple example, but it illustrates the definition of “concepts” or “conceptual processes” that has been employed, pragmatically at least, by virtually all the experiments on concept formation.

By inductive concept formation we also mean the *process* by which concepts are formed. Inductively formed concepts originate in experiences and observations that provide the organism with a wealth of perceptual materials. Inductive concept formation is the process of recognizing, from this material, that certain features of the material are related to certain other features.

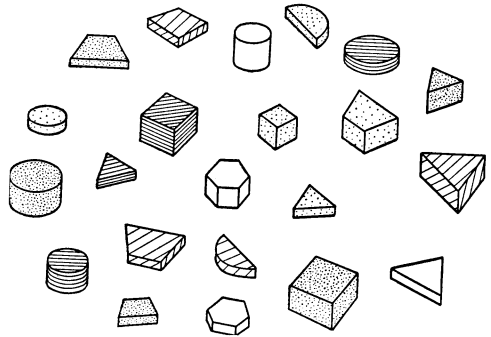

FIG. 3. The blocks used in the Vigotsky or Hanfmann-Kasanin test of concept formation. Colors of the blocks are indicated thus: unmarked = white; light stippling = yellow; heavy stippling = orange; light crosshatching = green; heavy crosshatching = blue. (Adapted from Hanfmann and Kasanin, 1937.)

This process of inductive concept formation may end in a verbal formulation of the concept, but not necessarily. Furthermore, even when some verbal formulation is achieved, it is not always true that the concept is acquired by verbal means. This is demonstrated especially well in a study by Hanfmann (1941) with the test that has come to be known as the Vigotsky or Hanfmann-Kasanin test, which uses the blocks shown in Fig. 3. The subject is told to sort the blocks into four groups that will match names printed on the hidden or bottom sides of the blocks. Hanfmann found that some of her subjects worked out their groupings primarily by moving the objects around and by observing them. Thus she tells of one subject:

The subject noticed two small blocks that happened to lie close to each other, started

adding other small blocks to them, all the while saying in an astonished tone of voice: "I really do not know why, but I just feel like putting this one with them, and this one, and this one." Only after she had grouped all the blocks correctly, she said, as if discovering something: "Oh, I see. Of course it is size!" This sequence of events — grouping first and formulating the principle after, or at least during, the process — is typical of the approach that is guided by perception . . . [1941, p. 318.]

The process of inductive concept formation, then, is the experiencing of one thing after another and the selective perception of certain aspects of the material as common to several objects.

As was mentioned above, most of the experimental studies of inductive concept formation have studied the formation of class concepts. These experiments correspond, therefore, to the analysis of thinking given by the older or formal logic. According to traditional logic, deduction is concerned primarily with matters of inclusion and exclusion — as though all deductive thinking had a form like this:

Mr. J lives in Boston

All of Boston is included within Massachusetts.

Therefore Mr. J lives in Massachusetts.

Actually, however, most of our deductive thinking takes one or the other of these forms:

(1)

Calcium-deficient diets produce rickets.

This diet is deficient in calcium.

Therefore this diet will produce rickets.

(2)

Yellow fruits and vegetables are rich in vitamin A.

These peaches are yellow.

Therefore these peaches are rich in vitamin A.

The second proposition in each example is a class concept. But the first proposition in

(1) is a concept of cause and effect, and in (2) it is a sign-significate relation. And, indeed, since our definitions and classifications, both in science and in everyday life, depend primarily on our knowledge of functional properties, it follows that most of our class concepts are acquired from the observation of cause-and-effect and sign-significate relations. Accordingly it is true enough that inductive concept formation ought to be studied and interpreted as a process that is related to deductive thinking. But the typical content of deductive thinking suggests a broader territory than has usually been conceived as the field for studies of inductive concept formation.

How widely, then, does inductive concept formation occur? Is it restricted just to cases of technically sophisticated thinking? The answer is that inductive concept formation is found in a much vaster area. It is a great part of the learning of everyday life, as when a person "learns what another individual is like." It is found in small children as well as in adults (witness the fact that the small child typically uses a host of regularly formed words that he has never heard others use, such as "eated," "drinked," "goodest," and "unfavorite"). Furthermore it is not found solely in human beings. Some experiments by Harlow (1949) will later be described that give a fine demonstration of this sort of learning in monkeys. Even on less complex matters than those Harlow has explored, however, it also appears that many aspects of animal learning are examples of inductive concept formation. Specifically this seems to be the case in conditioning, discrimination learning, and much of so-called "trial-and-error learning." For example, a dog in a conditioning experiment faces a complex and confusing situation. He receives a welter of stimulation from the walls of the room, from noises, from pressures of the harness, from odors, etc. And then, without any special factor that distinguishes the "signal" from other stimuli, he is given the signal and, perhaps 2 seconds

later, receives a shock. As both Klüver (1933, pp. 344-349) and Mowrer (1947) have pointed out, the dog "learns" something immediately. He does not make merely an isolated foot withdrawal while the shock continues. When the shock ceases he still acts as though he had learned that the whole situation is threatening. He whines, struggles to escape from the harness, etc. As Mowrer says:

These latter responses are commonly referred to as "spontaneous," or "interval," responses, and are usually regarded as an uninteresting nuisance, to be minimized if possible and, if not, ignored. [1947, p. 110.]

The dog finally quiets down and waits. Then, once more, without any special warning so far as he is concerned, he gets the shock. As both Klüver and Mowrer go on to explain, the learning task for the dog is not primarily a task of building up a habit of fear in response to the grosser aspects of the situation. That is acquired immediately. The "conditioning," so-called, is a matter, instead, of acquiring a finer differentiation between two constellations of stimulation — the one that heralds the reinforcement, and the other that exists between trials. The dog has to learn the property common to the shock situations and absent from the others. We diagram such learning as though merely two stimuli were involved. But actually the dog's problem is comparable to the problem that confronts a human subject in an experiment on inductive concept formation. In both cases the learning depends upon the differentiation of some aspect of the situation, and in both cases the learning has some generality of application to new instances.

It might be asked, of course, what advantages we would gain if we considered discrimination learning, conditioning, and some "trial-and-error learning" as examples of inductive concept formation that should be grouped with the traditional concept-formation experiments. One advantage is economy.

Science aims to group together those things that have similar properties. A second advantage is that, when we thus group tentatively those phenomena that seem to have properties in common, we are more likely to generate fruitful research questions about one of the phenomena because we know something already about the others. Thus the traditional studies of concept formation indicate that human subjects are exceedingly active in forming, testing, and revising hypotheses, and that this is partly the process whereby the concepts are formed. Introspective reports are the chief source of evidence for this conclusion, but nonverbal evidence confirms it at a number of points. The studies of conditioning and discrimination learning in animals, however, have not yielded the same conclusion. But — and this point is vital — it is not that this conclusion has been tested and ruled out empirically in animal learning. The issue has not been clearly faced and checked.

Another reason why the territory of inductive concept formation is broad is that it properly includes many cases in which it seems that the concept is acquired on "one trial" or "one experience." Thus, in some of Piaget's research on the thinking of children, he presented some simple situation and asked the child to explain the effect observed. Piaget found that there is a tendency to seize upon some more or less obvious quality of the object to "explain" what has been seen. A chip of wood floats "because it is light"; a battleship floats "because it is big and strong." But even here the concept is not really formed from the single perceptual experience. In selecting the property that he emphasizes, the child draws upon his past observations. This is seen especially clearly in animistic responses given to such questions as: "Why does the wind blow?" The property of purpose, or "wanting to go somewhere," that the child cites as the explanation is not a directly perceived property of the wind. Here the child integrates his present perception

with past experiences of his own reactions, and perhaps of those of other persons.

The difference between the "explanations" of children and of scientifically trained adults, therefore, is not that the child uses only present perceptual material. Both of them go back to past experiences as well. The difference is partly that the adult has more memory materials to draw upon and partly that he has learned to search with more diligence for a wider variety of past observations out of which he can distill some satisfactory proposition.

In defining inductive concept formation, we might finally ask whether this process is simply the "paring away" or "omitting" of unnecessary features. It seems better to say, as Smoke (1946) suggests, that concept formation can also involve the enrichment of concepts. For example, a person can learn additional properties of some main class of things such as "dogs." Or he may acquire more knowledge about "subclasses" within a larger class and learn to know more of the particular properties of each subclass. Or a person may extend the range of cases that he can identify as instances of the main class.

Experimental Findings in Inductive Concept Formation

The results of several studies in this area have already been mentioned, but we will now try to summarize the experimental findings more systematically:

1. Several experiments show that concepts may be formed, retained, and used "unconsciously." This statement does not imply that the subjects are not conscious of the perceptual materials before them. It implies merely that sometimes the subjects do not consciously recognize what properties they use to group or classify the materials. An experiment by Rees and Israel (1935) might be added to those already cited. In one of their series the subjects were asked to rearrange into words a set of 30 anagrams. The first 15 were anagrams like *nelin*, *nedoz*,

and *sdlen*. Each of these had one possible solution and a uniform letter order (5, 4, 1, 2, 3). The last 15 were anagrams like *klsta*, *nolem*, and *dlsco*. Each of these had two possible solutions. However, the subjects who had worked first on the "5, 4, 1, 2, 3" anagrams gave corresponding solutions in 95 per cent of the cases; whereas control subjects gave only 47 per cent of such solutions. But 6 of the 10 experimental subjects had no conscious idea that a uniform arrangement was involved. And yet 91 per cent of their solutions for the ambiguous anagrams were of the determined sort. Another group of subjects was originally given anagrams that represented phenomena of "nature," such as *nirsa* (rains), *sargs* (grass), *metss* (stems). They were then given anagrams that might be solved either by "nature" words or by other words. About two-thirds of the 34 subjects did not realize that any such selection was involved, and yet their responses showed that they had adopted a definite set.

Indeed, even when the subject comes to realize that there is a "system" involved, it appears that he frequently develops the generalization and uses it for a while before he is able to recognize consciously what he is doing. For instance, the subject notices that the anagrams are getting "easier." If he seeks the reason for this he may come to realize that he has been using a particular pattern, or a certain area of association, or whatever.

2. The introspective reports of the subjects commonly disclose an exceedingly active process: they form hypotheses, test them against present perceptions and against memory, and revise them. The process often occurs so rapidly that it would be practically impossible to discover, except by verbal reports, the successive concepts that the person explores.

3. Some of the difficulties encountered in concept formation occur because the perceptual processes of the subject have the same highly selective character that we ac-

cept as characteristic of conceptual reactions. That is to say, the subject does not respond to a drawing, for example, in terms of all its easily discriminable aspects, but only in terms of a few of its aspects. He fails to form some concepts that he might form, and the reason, so he is likely to report, is that he "just didn't notice those other features of the stimulus." Lashley has expressed this principle by saying:

The mechanism of nervous integration is such that when any complex of stimuli arouses nervous activity, that activity is immediately organized and certain elements or components become dominant for reaction while others become ineffective. This constitutes a "set" to react to certain elements. . . .

In any trial of a training series, only those components of the stimulating situation which are dominant in the organization are associated. [1942, p. 242.]

This statement is good, but it is too restrictive to fit all the evidence from concept-formation experiments. For, even though the subjects do not retain an impression of many aspects of the stimuli, they do retain and later use more than just the "components . . . dominant for reaction" at that time. This is indicated especially well in an experiment by Heiddreder (1924) in which some rather full verbal reports are quoted from her subjects. These reports often indicate that the subjects were able to "think back" and to say, for example, "Come to think of it, I believe all the ones that have been correct had curved lines in them" (even though the subject, on the earlier trials, had guided his reactions by the hypothesis that some other property was the crucial one).

There is, therefore, some greater *retained* richness of perceptual processes than is involved in the main perceptual reactions of the moment. It is often out of this extra margin of richness that new perceptual and conceptual reactions can be developed. But this extra margin is meager indeed in comparison with what we might expect when we

consider the large number of aspects of the stimulus materials and the large number of habits of the person that are relevant to these different aspects.

4. The concepts that are developed and used do not depend upon any simple quantitative effects of reinforcements. This has been shown most strikingly by some *insoluble* problems used by Krechevsky (1932) and Spence (1939), and by some problems in which, conversely, it was impossible for the subjects to make errors (Witkin, 1940, 1941). Krechevsky trained rats in a 4-unit discrimination apparatus. In the 12 trials of each day, the position and illumination of the correct side at each choice-point were so randomly shifted that, no matter what "hypothesis" the rat adopted, it could not be successful in more than 50 per cent of its choices. With equal amounts of reinforcement and punishment for each possible systematic mode of response, it was nevertheless found that each rat would typically try two or even three systematic modes of response in succession. At the beginning the choices had no general character, but within a few days the rat would begin to choose the right or the left side, or perhaps the dark tunnel. Sometimes all the choices for several days would be of one sort. Then that type of response would die out, and a second would gradually appear. Spence (1939) demonstrated the same phenomenon with chimpanzees when he presented them with an insoluble problem on the multiple-choice apparatus.

Witkin used an apparatus much like Krechevsky's, except that the rats were free at each choice-point to choose either side to progress toward the goal. The rats soon learned to run swiftly and unhesitatingly. They did not run at random, however, but, as in Krechevsky's experiment, they soon developed a systematic mode of responding. What is more noteworthy, though, is the fact that, just as in Krechevsky's experiment, they typically shifted to a second or even to a third pattern of response. The shifts that

Krechevsky and Spence observed, therefore, cannot be attributed solely to the frustrations attendant upon the "wrong" choices.

5. Different persons, or the same person at different times, may form concepts by basically different methods in the same objective situation. We have already mentioned Hanfmann's observations with the Vigotsky test of concept formation (1941). In her control group of 64 college graduates, she found that about half the subjects went at the problem of classifying the blocks by formulating verbal hypotheses, with little resort to manipulation of the objects. Such subjects typically counted the number of colors on the blocks, and, since there were five colors, they said that color could not be the basis for the required fourfold classification. The subjects might then work with aspects of shape. When they finally discovered the correct solution, they usually expressed dissatisfaction with it as having a rather arbitrary and unnatural character. In contrast with these subjects who relied mainly on abstract thinking and verbalizations, the other subjects relied more on perceptual and situational factors and helped themselves more with tentative overt groupings of the material. This approach seemed to favor an emphasis on different qualities from those most naturally stressed by the "thinking" group. When these subjects discovered the solution they were typically pleased by it and regarded it as very appropriate. The scores for these subjects were about twice as good as for the subjects who used the more abstract or verbal approach. Hanfmann points out, however, that this result is presumably due to the nature of the imposed problem. If the test had called for a classification on the basis of shapes, rather than on the basis of a combination of height-plus-area, the "abstract thinkers" would have made the better scores. Hanfmann noted further, however, that the most effective work was done by those subjects who were apparently able to employ both modes of approach, alternating between them.

In her original experiment on thinking, Heidbreder (1924) noted a similar effect when the subjects had to figure out the rules for marking different geometrical designs. When the problems were difficult, the subjects sometimes shifted over to what she called "spectator behavior." The subject would say, for instance, "I'm just lost. I'm just marking at random, because I've tried everything I could think of and I can't imagine what the rule would be here." And yet, out of such responses, seemingly just passively made, the subjects were usually able to reach solutions.

Bouthilet (1948) has also demonstrated this effect. She had her subjects try to learn paired associates like:

elephant—path
recognize—zero

After the presentation of 30 pairs she gave a multiple-choice test like this:

elephant—(1) been, (2) front, (3) very,
(4) felt, (5) path.
recognize—(1) goat, (2) ruin, (3) zero,
(4) dime, (5) frail.

Among these multiple-choice items were 30 new pairs not included within the learning series. The subjects were told to guess, if necessary, but to try to determine the correct item in each case. The results fell into two distinct categories. Some subjects explored one abstract hypothesis after another. Their successes tended to remain at the chance level until they hit upon the correct hypothesis (that the associated word always was formed from letters included within the stimulus word), and then rose sharply to about 100-per-cent correct. Some of the subjects, however, improved gradually over a longer period of trials. These subjects typically said that they "felt" that such and such response words were correct, but that they didn't know why.

Apparently, therefore, there are fundamentally different ways in which inductive concept formation may occur. It would be

interesting to know the advantages of each of these procedures for different tasks and the reasons why different individuals use one or the other.

6. Concept formation is sometimes helped by starting with materials that reveal the principle in an extremely clear form. Hull (1920) made this point when he worked with Chinese characters drawn with the root character in red as contrasted with the black of the other strokes. The same phenomenon has been extensively demonstrated in conditioning experiments. Thus "differentiation training" is rapid if it begins with a to-be-distinguished stimulus that is markedly different from the stimulus that is to remain the positive stimulus. It is also well known that long "trace conditioned responses" can be formed only if the animal is first permitted to learn, with a small time interval, to respond to the particular stimulus. Similarly, with the jumping apparatus, Lashley (1938) has demonstrated that rats may require more than 150 trials, say, to learn a discrimination between a lighter and a darker gray. But if trained first to discriminate black from white, which they learn in perhaps 10 trials, they are then able to transfer without further training to the difficult pair of grays. In other words, out of clearly different materials the animals can learn something in a few trials that then can be applied to a more difficult problem on which more training would have been required.

7. Inductive concept formation may be made either easier or more difficult by previous training on related problems. And which of these opposite effects will occur may be predicted from the relation between the present task and the perceptual-conceptual emphasis acquired in the earlier learning.

An excellent illustration of how previous learning facilitates later concept formation is reported by Harlow (1949). His monkeys were required to discriminate small everyday objects like oilcans, matchboxes, and padlocks. On each trial an opaque screen was

lifted at the front of the cage, a board was slid within reach of the monkey, and the monkey was permitted to reach out and lift one or the other of the pair of objects to try to secure the food hidden in a small depression under one of them. After a series of trials on one pair of stimulus objects, a second series was given with another new pair of objects, and so on until the monkey had learned more than 300 different discriminations.

FIG. 4. Showing how monkeys learn to discriminate simple objects on the first six trials of successive series of problems. After the first hundred problems the monkeys almost mastered the discrimination completely on the first trial of the series. (After Harlow, 1949, p. 53.)

Even at the beginning of training, the problem was not difficult. But the remarkable thing is that, as the training continued, the monkeys improved more and more until their learning became almost instantaneous. As is shown in Fig. 4, after the first hundred problems, the monkeys were able to learn new discriminations on the first trial with each new set of objects. A fact that makes this more remarkable, but that is not mentioned in Harlow's article, is that all the studies used a noncorrection method. Even though the monkeys were necessarily wrong on about 50 per cent of their first choices, and even though they were not allowed to lift more than one of the objects on each trial, they were able to learn the object-

discriminations from both their failures and their successes. Thus, as is shown in Fig. 4, about 97 per cent of the second trials were correct after the 256th series. Harlow says: "In the final phase of our discrimination series with monkeys there were subjects that solved from 20 to 30 consecutive problems with no errors whatsoever following the first blind trial . . ." (1949, p. 56).

FIG. 5. The responses of monkeys on the "discrimination reversal problem." From the first or "informing" trial on the later series of problems the monkeys achieved almost complete mastery. (Harlow, 1949, p. 57.)

Eight monkeys, trained as described above, were then given a "discrimination reversal problem." With each new pair of objects, the monkey was first given 7 to 11 trials. Then the previously correct object was made the wrong choice, and vice versa; and training continued for 8 trials. On the first reversed trials, of course, almost all the responses were wrong. But, as is shown in Fig. 5, the monkeys gradually built up a generalized "learning set," as Harlow calls it. With increasing training, they made fewer and fewer errors and finally practically no errors after the first "informing" trial.

A set to utilize a special aspect of the stimulus materials, however, will interfere with the learning of sign-significate relations of other aspects of the situation. Lashley (1942) showed this interference in rats. On the jumping apparatus his rats

first learned, in an average of 95 trials, to choose a circle 10 centimeters in diameter and to avoid a 6-centimeter circle. Then they were given 210 trials with the same small circle versus a triangle 10 centimeters on each side. They transferred so readily to these new stimuli that there were only 1.5 errors, on the average, in the 210 trials. Lashley then tested them with an 8-centimeter circle versus a triangle of equal area. All four rats reverted to the use of position habits. Tested with a large circle versus a small triangle, they all chose the circle. In other words, the original training had taught them to look for relative largeness. As long as a basis for size discrimination was present, its use prevented the development of shape discrimination.

In such a case, of course, there would probably be a shift to a new basis of discrimination if circumstances made it hard to continue on the former basis, especially if there were a very ready cue that the subjects could use instead. Lashley had a case of this sort. He says:

In the one instance where a suggestion of association with the new aspect of the stimulus appeared, the patterns added to the original size difference were conspicuously different and of such a character as to obscure somewhat the difference in size; a six-pointed star with long points vs. a triangle of larger surface area but smaller linear dimensions. [1942, p. 259.]

Other Factors Affecting Inductive Concept Formation

The history of science and of culture in general shows striking differences in the speed with which various concepts have been achieved. Perhaps it would be worth while to explore these cases of unequal cultural advance and to try to define the governing factors that operate. We tend to say, for instance, that the slow development of some parts of knowledge, such as the social sciences, is due to institutional resistance or to the fact that they concern emotionally laden

problems. These may well be real factors. But when we note how much time had to pass before the concept of vitamins was clearly established, we are warned against accepting too easy explanations.

From an examination of cultural development it appears that the following are some of the factors that impede the discovery of cause-and-effect relations:

1. A separation in time between cause and effect (as between mosquito bites and malaria).

2. Perceptual incongruities between the cause and effect (as the difference between flies and maggots, in the case of the old theory of "spontaneous generation").

3. Already existing habits that cause a misleading organization of the items in the situation (as the knowledge that led early workers on beri-beri to search persistently for the transmission of bacteria from one affected person to another).

4. Relative intangibility of either the cause, or the effect, or both (as the elusiveness of wind resistance as a factor in the inefficiency of trains at high speed).

5. The existence of interdependent causes (as the fact that neither sufficient calcium nor sufficient vitamin D can prevent rickets by itself, but that both must be present).

6. Motivational factors that work against acceptance of a conclusion (as when Semmelweiss's fellow obstetricians in the 1840's refused to accept his demonstration that puerperal or child-bed fever was due to the transmission of some material from one woman to another by the obstetricians themselves).

DEDUCTIVE CONCEPT FORMATION

Deductive thinking, or deductive concept formation, is a very common process. We often fail to appreciate this fact because we conceive of deductive thinking solely in terms of the fully stated syllogism. Actually it occurs most often in everyday life as the

enthymeme. Thus a child says, "I don't want to eat that because it's burned." The major premise is assumed, rather than stated. But psychologically it is playing its role as truly as though it were stated. When we recognize the deductive process in cases like this, we can readily see that it is characteristic of small children as well as of adults, and that it is a typical mode of thinking of people of all social and educational levels.

To study deductive thinking we need the help of both logic and psychology. Each field has its distinct contribution to make. Logic, for instance, is like mathematics (see Chapter 1). It describes the transformations by which the conclusion may be secured from the premises. It identifies and describes the types of errors that can be made in such transformations, and it describes the rules by which sound transformations can be made.

From the rules of logic, however, we get no adequate comprehension of the psychological processes involved in deductive thinking nor of the many psychological factors that affect these processes. What is more, we get an inadequate idea of the functions served by deductive thinking. The concepts of logic tend to suggest that deductive thinking is legitimate and profitable only when both premises have been adequately established. But this in turn leads to the discouraging conclusion that deductive thinking must generally be tautological. Thus, consider the syllogism: "All communicable diseases are caused by bacteria; this is a communicable disease; therefore it must be caused by bacteria." This conclusion cannot be drawn unless we already know, from prior study, that this particular communicable disease, as well as all others, is caused by bacteria. Most of our deductive thinking in real life, however, occurs in cases in which, to tell the truth, we have only very sketchy evidence for the propositions from which the conclusion is drawn. The premises are hypotheses, in short. And the conclusions drawn from them are also hypotheses, al-

though we often fail, in ordinary life, to appreciate their tentative status.

Why do we use deductive thinking if it is as uncertain as all this? From a psychological point of view, several reasons may be suggested:

1. It is often true that we need to act in practical matters on conclusions that have not been reached by an adequate process of inductive concept formation. Thus a psychologist may be asked by a parent for advice regarding the toilet training of his baby. The psychologist tells him there are no good studies of what effects occur from what methods of dealing with this problem. "But," the parent insists, "I must do something. What should I do?" Accordingly, the psychologist might reason that "maturation makes learning problems easier; toilet training is a matter of learning; therefore it would be well to postpone such training till a later age than is usually done." In so reasoning, he has to go beyond his knowledge. He does not know whether all things are learned more easily at 2 years, say, than at 1, or whether this is one of the exceptions to such a general rule. Nevertheless it is by deductions such as this that most of the practical decisions in politics, business, religion, child care, and many other practical matters have to be made.

2. Deductive thinking is often a means of formulating fruitful scientific questions. Thus Hill and his co-workers reasoned: "All physiological processes seem to involve heat production; the conduction of nerve impulses is a physiological process; therefore it probably involves heat production." Their work that grew out of this deduction is a classical example of how a deductive argument, persistently followed up, led to the final establishment of the conclusion even though the initial research yielded only negative results.

3. Deductive arguments are used in many situations because our knowledge can be put more economically into the form of ab-

stract statements. It is difficult to learn and remember many specific items of information. It is more economical, instead, to learn, say, that all cases of levers obey such and such laws and then to learn that such and such cases may be thought of as levers even though, superficially, they seem to be quite different.

4. Deductive arguments are also used because strong motivational values get established with reference to general propositions, and, by deductive argument, these motivational values are carried over to specific cases. Thus people build up emotionalized attitudes with reference to such propositions as "Democratic procedures are better than autocratic procedures," or "Gambling is wrong." Then, when it is argued that a given concrete case is an instance of such a broad class, there tends to be a carry-over of the motivational value to the specific case.

Unfortunately the number of experimental investigations of deductive thinking is small (see Woodworth, 1938, pp. 807-817). The neglect of this type of cognitive process may be partly due to its entanglement with logic and to the consequent belief that deductive thinking is more a logical than a psychological problem. Actually, however, there are many purely psychological issues that could well be approached, as suggested above, by methods other than logical analysis. Not much is gained by the mere logical analysis of possible sources of error in deductive thinking. Our greatest need, perhaps, is to start with an empirical investigation of the kinds of deductive thinking people use in actual life, and the kinds of logical mistakes they are likely to make, and under what circumstances. Such "ecological" studies of deductive thinking may not seem to be part of experimental psychology in a narrow sense, but it is probably safe to predict that investigations of this sort would soon lead to really significant experimental problems.

INVENTIVE CONCEPT FORMATION

The process that occurs in problem solving or in trial-and-error situations may or may not be inventive concept formation. For in such situations either of the two means of concept formation may occur that we have discussed above. Thus deductive thinking is often used in an effort to solve baffling problems, as when the research workers on beri-beri argued that, since the symptoms were comparable to those of bacterial origin, probably bacteria were to blame for beri-beri also. In other instances the problem solving may be mainly a matter of inductive concept formation, as when it was noticed that chickens fed on table scraps developed symptoms like those of beri-beri, but that these symptoms cleared up when the chickens happened to be fed on brown rice. The only way to solve some problems is to follow this vague rule: observe and try various things and try to determine, from the perceptual experiences, what factors are related to what other factors.

In some problem situations, however, another type of process is possible. The subject can draw upon his stock of knowledge and on his present perceptual experiences to construct a representation of the solution, or at least an anticipation or representation of *part* of the solution. When the evidence indicates that the subject does this before actually trying out a new technique or a new arrangement of the materials, we say that the subject has engaged in inventive thinking or inventive concept formation.

It is possibly true that there is no fundamental difference between inductive and inventive concept formation. The inductive process often requires a high order of discernment to determine what common properties run through a series of situations. Especially when he tries to "explain" an event (which we grouped under inductive concept formation), the subject has to draw on related knowledge in a way that is highly

reminiscent of what he does in inventive thinking. Because of these similarities, much of what has been said about inductive concept formation applies also to inventive concept formation. On the other hand, there may well prove to be at least some principles peculiar to the behavior of the subject who has to think of how to use familiar materials in new ways, or even has to construct new tools not previously in existence. The wiser procedure seems to be to classify these cases as a distinct group.

It is customary, in studies of inventive thinking, to employ problems that the subject is at first unable to solve, because we often have to rely on this initial failure as evidence that the problem is new to the person. However, it is a mistake to insist that there must be this initial blockage. For sometimes the evidence is fairly definite that the individual did not learn his specific response previously and yet is able to produce it almost instantaneously, as when one small child spoke unhesitatingly of a museum as a "dead zoo" and another child spoke of shavings as "carpenter peelings." And, conversely, the initial inability to respond is not always evidence that there was no past learning. Thus we frequently hesitate over a name but recall it after an interval. We surely would not say that we get the name by inventive thinking rather than by past learning. In the same way, it sometimes happens that a subject believes he is doing original inventive thinking when, as it turns out later, he has recalled a solution learned previously.

A lot of interest has been focused on the problem of whether new solutions, or at least new part-solutions, can be achieved by a process of "insight." Usually this has been understood in the sense of "foresight"—i.e. in the sense of a process that yields a representation of a more or less complete solution before the actual manipulation of materials could facilitate the representation perceptually. However, as some writers like Woodworth (1938) have pointed out, a subject

often gets a solution by chance but does not discern what happened. So, Woodworth says, "insight" may sometimes be a matter of "hindsight" and yet be a considerable cognitive accomplishment at that. It seems doubtful that these cases should be called inventive thinking. But, if not, they certainly emphasize once more the continuity between inventive thinking and other sorts of concept formation.

A number of careful studies have demonstrated that the taking of new steps in inventive problem solving is often dependent on prior learning. Thus Cleveland (1907) demonstrated that learning to play chess depends on getting a mastery of successively more complex configurations. Guanella (1934) made a careful study of how small children learn to build with blocks and showed what a gradual development of constructive ability is manifested here. Durkin (1937) used puzzles in which flat pieces had to be fitted together to make larger geometrical designs and showed how the solution of more complex problems was facilitated by prior experience with simpler problems. For that matter, Köhler (1925) recognized this phenomenon in chimpanzees. Not until after they had learned to rake in food with one stick could they solve the problem of using a short stick to rake in a longer stick that might, in turn, be used to secure food. In the box-stacking problem, where the chimpanzee had to pile one box on another in order to reach some food hanging high in the air, Köhler recognized a series of steps. First the chimpanzees learned to use a single box. Then they got the notion of employing a second box, but they did no more than to bring it near the first box that had been placed under the food or to hold it up in the air toward the suspended food. Later they learned to place the second box on the first. Even after that, however, the animals still had to learn to adjust the second box well enough to make it usable — and their progress on this last task was so irregular and fumbling that Köhler believed it was

learned by trial and error rather than by insight.

Many studies give evidence that the development of solutions, or the steps of inventive thinking, often depends upon some favorable constellation of physical stimuli or upon some chance exploratory activity that *almost* gives the solution. When one of Köhler's chimpanzees solved the problem of fitting one stick into the end of the other to make a longer one with which to reach, he did so partly as a result of the fact that, when fumbling with the sticks, he seemingly by chance got them in a straight line with each other and almost touching.

Although inventive processes may rest in part on previous learning and in part on favorable external conditions, it is also true that subjects are able to transcend, to some extent, what is given by past experience and by external stimulation. There is some process that is contributed by the organism, some process that runs ahead of what is given by past experience or present environmental stimulation.

The problem of inventive concept formation, however, is not disposed of by the mere demonstration that there are steps or developments that run beyond what is given environmentally and by past experience. The main question is: what factors permit such steps to occur and permit them to be larger in some cases than in others, and what factors tend to impede inventive concept formation?

A number of factors have been shown to *help* inventive thinking:

1. Some species are clearly more capable of inventive thinking than are others. Klüver (1933) showed that Cebus monkeys considerably surpass Rhesus monkeys, even though the two species do not differ greatly in their manipulatory equipment. Yerkes (1927) found that the gorilla is not so gifted as the chimpanzee.

2. Inventive thinking depends strongly on motivation. Indeed, without motivation there often "is no problem" so far as the

subject is concerned. Rossman (1931) found that men who were known as inventors typically attributed part of their progress to their strong desires to accomplish one thing or another. It is likely, however, that this contribution of motivation to inventive thinking can be analyzed more specifically. Thus it is now accepted that motivation helps not solely in the acquisition of habits but also in governing the use or reinstatement of what was learned previously (Tolman, 1932; Hull, 1943). Strong motivation also tends to inhibit responses to factors in the situation that would otherwise distract the problem solver.

3. Inventive thinking often requires long-continued effort. It is not true that solutions come either quickly or not at all. This factor too, however, invites further study, because it would be important to know the factors that are introduced by such long-continued efforts, but that are not present in briefer attempts. It is obvious, of course, that long periods give more time for the occurrence of favorable chance constellations of physical stimulation or of memories and associations. The longer periods also give more time for the mastery of subordinate aspects of the problem, so that the thinker is better able to attempt larger integrations. It may be, however, that long-continued effort causes readjustments of the nervous processes even aside from these influences, just as long-continued viewing of the same stimuli permits an individual to get binocular-rivalry effects and reversible-illusion effects that he would not otherwise see.

4. Inventive thinking is helped by a background of relevant knowledge and skills. A rather striking indication of this fact has been given by the sociologist, Ogburn (1922), who has listed a long series of instances that show that identical inventions and scientific discoveries frequently have been made independently within a few years of one another.

5. An analysis of the nature and function of the solution of a problem may help to solve it. Duncker (1926) reported that, when

his subjects were first presented with new problems, they typically tried to find a concrete solution immediately and directly. But when they found themselves blocked they tended to resort to intermediate processes: a closer diagnosis of the source of the difficulty, and, even more important, a "definition of the functional value that the solution would have to serve."

It is noteworthy that at least one field of practical inventive thinking (architecture) has come to rely explicitly on this intermediate process (see Cooper, 1946). The student of architecture is taught not to strive for a concrete design immediately but to study first what the house is for, the purpose of each room, and the kind of family for whom it is intended. Work on the concrete solution should follow only after this definition of functional values has been determined.

6. The proper mental set may speed the solution of a problem. Maier has demonstrated in a number of experiments (1930, 1931) that, even when subjects have the necessary background knowledge for solving a problem, they may be unable to do so if they lack the proper "direction," or the proper *general* idea of how to solve the problem. His notion here is much the same as one of the key ideas emphasized by Wertheimer (1945), that one of the main processes in thinking is often a *recentering* of the materials, so that something that was formerly a background item becomes an object of central interest. This phenomenon of direction needs further analysis. It seems that Duncker's "definition of functional value" is a form of "direction." But there seem also to be "directions" in other senses as well, and our understanding of inventive thinking would be furthered if the "direction phenomenon" were made more definite.

Most of the factors that *hamper* inventive thinking are simply the lack of the facilitating influences listed above. However, several items deserve specific attention:

1. Birch (1945) demonstrated with chimpanzees a point previously mentioned by Köhler, that a motivation of more than moderate intensity may decrease rather than increase the chances of solution.

2. Duncker (1945) identified an additional specific aspect of the phenomenon of "direction" by his discovery that a subject is less likely to use an object if it is "functionally embedded" in a context other than that of the problem, even though the conditions that create this "functional embeddedness" actually increase the subject's contacts with the object. He gave his subjects the task of making a board stay in position across an open doorway. The materials given provided no means of fixing the board in place except by using a cork as a wedge between one end of the board and the door jamb. The problem was made much more difficult when the cork was present as the stopper in an inkwell than when it was lying, with other materials, out on the table. This was true even when Duncker increased the amount of contact with the cork by requiring the subjects to remove it from the inkwell for the purpose of writing.

3. Some remarkable demonstrations of the hampering effect of *faulty* directions on thinking were given by Luchins (1942), following some exploratory work started by Zener in 1927. His subjects were first given a short series of problems of this type: "If you had three empty jars that hold 21, 127, and 3 quarts, respectively, tell how you might measure accurately 100 quarts of water." These problems established the procedure of getting the required amount by filling the largest vessel and emptying from it with the aid of both the other jars until the required amount was left in the largest jar. Following five or six problems of this sort, other problems were given, such as: "Given three jars that hold, respectively, 23, 49, and 3 quarts, tell how to get 20 quarts." His control subjects showed (if any proof were needed!) that, when no contrary "set" had been established, this type of problem

was always solved by a simple subtraction or addition with two jars, rather than by the use of all three. But the previous experience with the other problems caused 81 per cent of one group of college students to solve these problems by the more involved method. Another group of 86 students had been instructed to write "Don't be blind" on their papers before starting on these further problems. Moreover, Luchins explained to them: "This is to make you aware of the fact that you must be cautious; you must watch out and see that you do not act foolishly while solving the subsequent problems . . ." (1942, p. 5). Yet 55 per cent of the subsequent solutions used the unnecessarily involved procedure. The experiment yielded similar results with large groups of subjects of different ages and educational backgrounds. Furthermore a ninth problem was given (to get 25 quarts, given three jars of 28, 76, and 3 quarts capacity) that could not be solved by the involved method but could be solved by simple subtraction. In half of the 29 groups who were thus tested, 66 to 87 per cent of the subjects were unable to solve this problem within the 2½ minutes allowed for it.

In order to get light on the factors affecting this phenomenon, Luchins explored a large number of conditions, and the part of his monograph (1942, pp. 38-86) that describes these experiments is a model of experimental method. He found that the mechanization or "Einstellung" effect was markedly decreased when, during the original training, he gave alternately tasks that called for the long indirect procedure and tasks that introduced the procedures of adding the contents of two jars in one case and of subtracting them in another (p. 41). He also found the effect lessened when there was an interval of 8 days between the original problems and the test problems. But IQ, age, educational status, and many variations of mode of presentation of the task were unrelated to the appearance of the effect. In

fact, the degree to which the effect occurred was almost incredible in some cases. Thus with five groups of high school and junior college students he followed the original training with this problem: given jars that hold, respectively, 3, 64, and 29 quarts, tell how to measure out 3 quarts. He found that from 52 to 85 per cent of the subjects proposed filling the 64-quart jar, emptying 29 quarts from it twice and 3 quarts once, thus ending with 3 quarts! When he gave this problem in one public school class he told the subjects, "Using one, two, or three of these jars, get the required volume of water." Yet 80 per cent of the 30 subjects went through the long procedure (pp. 72-73). Nor was this because the subjects believed that they were necessarily required to use one procedure rather than another. For, when he showed the subjects how they might have proceeded, ". . . nearly all of these subjects regretted that they had not previously seen it, and many of them bewailed their blindness and stupidity" (p. 73). The effect was increased somewhat when he presented the tasks as speed tests and when he created a competitive atmosphere. From his behavioral observations and from comparisons among different schools he concluded that strong mechanization effects could be attributed partly to mechanical methods of work and unfavorable emotional atmospheres established in the regular school work.

It is certain, therefore, that experience can exert a surprising hampering effect on subsequent problem solving. But it would be a mistake to emphasize too strongly this hampering influence. We may not have as much "experimental" evidence of the contrary effect, but we certainly see, in the whole breadth of educational work by which students learn to use scientific methods, learn to seek comprehensive theories rather than piecemeal formulations, and so on, that past experience can also help to produce exceedingly complex cognitive activities that would otherwise lie far beyond human reach.

SUMMARY

Experimental work indicates that we need to redefine cognitive processes. The older definitions were phrased both in terms of the functional relations of these processes and in terms of their supposed attributes as conscious experiences. However, experiments on successive comparison, complex associations, and concept formation indicate that cognitive processes are often either not conscious or not describable in terms of their conscious attributes, even when these exist. Furthermore research in intelligence testing and animal psychology has shown that fruitful concepts of cognitive processes can be defined solely in terms of functional properties.

Nevertheless in the study of cognitive processes it is still true that introspective reports provide valuable data. Through them we know of the exceedingly active processes by which inductive concept formation generally occurs. The introspective method is not in itself a sufficient means of studying cognitive processes, however, (1) because experiments have demonstrated that processes with the same functional properties continue to exist even when introspectively they are no longer observable, and (2) because some aspects of cognitive activity are from the beginning inaccessible to introspective observation.

Experiments on inductive concept formation have usually been planned as though all inductive concept formation is a matter of forming class concepts. This emphasis on class concepts is consistent with traditional logic, but it is inconsistent with our present knowledge that actual deductive thinking usually starts from a premise that states certain cause-and-effect relations or certain sign-significate relations. Inductive concept formation therefore must be understood in the broader sense of the learning of concepts (the learning of representations that have some generality of application) by means of a process of recognition of some

usually recurrent aspect of perceptual materials as a factor related to some other aspect. Inductive concept formation therefore includes not merely the traditional concept formation experiments with human beings, but also conditioning experiments, discrimination experiments, and many trial-and-error experiments with animals.

Experiments on inductive concept formation have shown that: (1) concepts may be formed, retained, and used unconsciously; (2) concepts frequently result from very active processes in which the subject formulates and tests many hypotheses; (3) difficulties of concept formation are often the result of the meager and selective nature of perceptual processes, even though perceptions usually yield traces of more than just the main attribute emphasized at the moment; (4) concept formation is not determined in simple ways by conditions of reinforcement; (5) two rather different means of concept formation, one a more passive utilization of perceptual experiences, and the other a more active and abstract searching process, occur in different persons or within the same person at different stages, and these two types of process make rather different sorts of contribution to concept formation; (6) concept formation sometimes is helped by an initial use of emphatic examples that "give the subject the idea," as it were; (7) previous learning makes the subject stress and utilize some aspects of the stimulus materials more than others, and this may make later concept formation much easier or much more difficult.

The investigation of deductive thinking has been dominated too much by the principles of formal logic. Deductive thinking is a psychological process, distinct from logic, and it follows rules that can be discovered only empirically. From the point of view of logic, it appears that deductive thinking should not be used except where the major premises are adequately established. Actually it seems that deductive thinking in real life is used most often in cases where the

premises are not well established. Deductive thinking is used because we often have (1) to act on matters that lie beyond the area of adequate inductive study, (2) to get hypotheses in as-yet-unexplored areas, (3) to economize in the utilization of past inductive work, and (4) to mobilize motivational factors previously associated with major propositions. Psychological research on deductive thinking ought to explore the functions subserved by it, and it ought to determine what sorts of errors actually occur, and under what conditions, in the actual use of deductive thinking.

Inventive concept formation is a good deal more narrow than problem solving in general. It has many similarities to inductive concept formation, but it involves more the element of using familiar materials in new ways. Many studies have shown the dependence of inventive thinking on prior mastery of part-solutions and often on fortunate constellations of physical stimulation. There seem to be steps, however, that transcend what is thus given by training and stimulation. Inventive concept formation is favored especially by: (1) certain species characteristics, (2) adequate motivation, (3) long-continued effort, (4) relevant knowledge and skills, (5) definition of the functional value the solution must serve, and (6) favorable "directions." Inventive thinking often is handicapped, on the other hand, by the lack of these. Several studies call attention particularly to the hampering influence of (1) too strong motivation, (2) a "functional embeddedness" of elements needed for the solution, and (3) faulty "directions."

The Psychophysiology of Learning

CLIFFORD T. MORGAN

The Johns Hopkins University

Almost everything we can say about the physiology of learning concerns the nervous system. There are some phenomena allied to learning in unicellular animals, which have no nervous system, but we cannot be sure yet just what these phenomena mean. In general only animals that possess nervous systems are capable of learning, either simple or complex. This chapter, therefore, is about the nervous system and learning.

EXPLORING THE NERVOUS SYSTEM

Most of us, psychologists and laymen alike, are accustomed to thinking that learning goes along with the brain, that learning requires not just a nervous system in general but a particular part of the nervous system, the brain. For a good many years, in fact, we went further than that. We thought learning required the highest center of the nervous system, the cerebral cortex. Pavlov, the famous father of conditioned reflexology, thought the cortex was the site of all conditioning and higher learning processes. And his notions have tended to hang on in behavioristic learning theory and in neurophysiological conceptions of brain functions.

In this chapter it was convenient for the author to use some of the text prepared for the book *Physiological Psychology* (2nd Ed.) by C. T. Morgan and Eliot Stellar (New York: McGraw-Hill, 1950). The quotations are not acknowledged individually but are used with the permission of the publisher.

It is quite true that most of the learning in which we are interested involves the brain, and particularly the cerebral cortex. Since 1935, however, several workers, not contented with the classical dogma, have examined other parts of the nervous system that may be concerned in learning. In the first part of this chapter we shall look at their exploratory experiments and at their attempts to study conditioning in the spinal cord. Later we shall come to the more intensive study of cortical and subcortical functions in learning.

The Neural Locus of Conditioning

The classical phenomena of conditioning, systematically explored by Pavlov and later by many others, may not be so simple as they appear on the surface. The conditioning technique, however, is a handy one for investigating learning phenomena in animals. It consists of (1) an unconditioned stimulus, such as the sight of food or the shocking of a limb, (2) an unconditioned response, such as salivation or the flexing of a paw to shock, and (3) some conditioning stimulus, such as a bell, a light, or some pressure stimulus applied somewhere to the animal's body. This technique has been used almost exclusively to hunt for the parts of the nervous system and its effectors that are fundamental in learning. The purpose has been to determine what routes in the nervous system are set up in the course of learning, what centers are of special importance, and,

in a word, where in the nervous system we can look for the locus of learning. There is a considerable group of studies pointed at this general problem. The problem, like most scientific questions, breaks down into a series of problems.

What route? A first question is whether learning takes place in the route of the unconditioned stimulus or of the conditioning stimulus. Kellogg (1941) has some interesting observations on this point. They do not rest on any surgical disturbance of the nervous system but come from purely behavioral experiments with dogs. The point of them is that conditioned reactions, once formed, may be temporarily lost while the unconditioned response remains intact. In the typical buzz-shock experiments — dogs giving paw-flexure responses to avoid shock when a buzzer is sounded — the dogs appear sometimes to doze off for brief intervals. When they do, their conditioned responses disappear, but their unconditioned responses to shock do not. Similarly, if the dogs are given a light dose of some soporific drug, such as nembutal, they may lose their conditioned responses but not their shock-escape unconditioned responses. Kellogg concludes that there must be different neural centers involved in the conditioned and unconditioned responses.

Is the unconditioned response necessary? Other experiments attack more directly different parts of the unconditioned- and conditioned-response pathways. Several, for example, concern the question whether it is necessary for the unconditioned response to occur in order for learning to take place. In one set of experiments (Kellogg et al., 1940; Light and Gantt, 1936) the muscles involved in the conditioned response were paralyzed during conditioning by crushing the motor nerves leading to them. A complete conditioning procedure was carried out while the dog could not respond. Then time was allowed for the nerves to regenerate, and when it was clear that the muscles could respond again the animals were tested for condition-

ing. They showed by the appropriate flexure of the paw to the conditioning stimulus that learning had taken place while the muscles were paralyzed. These experiments are subject to criticism, because the paralysis did not prevent the animals from giving generalized struggle responses centering about the limb during the original conditioning. These generalized responses were conditioned, and it is possible that it was through them that the correct response was made after nerve regeneration.

Other experiments giving similar results, however, are not open to this objection. In one of them (Crisler, 1930) morphine was employed as the unconditioned stimulus for evoking salivation in the typical Pavlovian type of conditioning. The salivation, however, was blocked by giving the animal atropine during the conditioning trials. Testing later without the atropine produced conditioned responses of salivation to the conditioning stimulus. In a similar study (Finch, 1938) acid was used as the unconditioned stimulus for salivation, but salivation was again prevented with atropine. When conditioning tests were made later without atropine, the animal showed conditioned responses. These experiments, involving the artificial blocking of the motor response, show clearly that response need not occur in order for learning to take place. The parts necessary for learning, therefore, lie upstream from the muscles or glands involved in the execution of the learned response. ✓

Taking a step backward to the motor routes of the spinal cord, we find that these too are not the locus for learning. Loucks and Gantt (1938), instead of evoking paw flexure by the conventional shock to the foot, did it by stimulating directly the motor roots of the spinal cord with an electric current. There was no sign of learning with this technique.

Are motor centers the locus of learning? Pushing even farther back into the nervous system, we come to the motor areas of the cerebral cortex, which are rather essential in

carrying out any voluntary or learned response. In higher mammals, extirpation of the motor cortex causes serious paralysis. But by stimulating the motor cortex electrically, we can evoke the various kinds of movements that occur in conditioned responses. In Loucks' experiment (1936), after an appropriate number of such electrical stimulations, tests were made of whether conditioning had taken place. None had.

Harlow and Bromer (1942), rather than employing stimulation of the motor cortex, used a technique for paralyzing it. During the usual conditioning trials a large area of the cortex of the monkey was 'frozen' by the use of a special drug. This drug prevented responses of the limb to the unconditioned shock stimulus, and there was a complete flaccid paralysis. After the drug used for freezing wore off, however, conditioned responses were observed. These were not movements of the limb, but responses of the eyelids and head and neck, which naturally appear in response to shock. These responses now occurred when the conditioned stimulus, a bell, was sounded. Thus it was clear that learning had occurred, although the complete motor system, from the cerebral cortex on down, had been paralyzed.

From these various experiments on motor systems and pathways we can form the definite conclusion that the locus of conditioning is some place other than the motor pathways of the nervous system. To see what the other places may be, we turn to other studies that attack the role of sensory centers and pathways in learning. These give us some hints, but unfortunately they do not give us the final conclusion. The main idea in all experiments of this type is the use of direct electrical excitation of some part of the nervous system in place of either the unconditioned or the conditioning stimulus. By seeing whether such substitutions could successfully be made at various points, we might hope to get some idea of the centers and routes important for conditioning.

Unconditioned stimulus. Several studies show that stimulation in any part of the sensory system normally activated by the unconditioned stimulus, up to and including the cortex, will suffice for conditioning. When Loucks and Gantt (1938) stimulated the spinal roots, in place of using shock-evoked leg flexion, they noticed that, if the intensity of the stimulation was great enough to spread over into the sensory pathways, conditioning to the buzzer was established. The electrical stimulus, they decided, had served as a substitute for foot shock in activating the pain pathways leading upward to the brain.

In another study, by Brogden and Gantt (1942), there is a very interesting result. Direct electrical stimulation of the *cerebellum* of the dog was substituted for the usual unconditioned shock to the foot pad. As usual, a sound was the conditioning stimulus. The cerebellar stimulation evoked movements of the same sort as those evoked by stimulation of the motor cortex. Strangely enough, after a normal number of conditioning trials pairing buzzer and cerebellar stimulation, a conditioned flexion of the limb to buzzer appeared. That is extremely interesting, but we cannot be sure what it means. The investigators assure us that the cerebellar stimulation was not spreading to the cerebral cortex, and we can rule out that possibility. It has been shown, however (Dow and Anderson, 1942; Snider and Stowell, 1944), that sensory impulses reach the cerebellum, and it is possible that the effect was through sensory pathways. Thus we do not know whether electrical stimulation of the cerebellum serves effectively as an unconditioned stimulus because it activates sensory pathways or because it directly arouses motor responses.

Conditioned stimulus. In all the studies in which an electrical stimulus to the nervous system is substituted for the conditioning stimulus, we find positive results. In Loucks' (1936) study with the dog, a hind-leg movement produced by cortical stimulation could

serve as the conditioned stimulus for a reaction of the forelimb, when shock was the unconditioned stimulus. Anatomists tell us (Bucy, 1944) that there is representation of cutaneous sense in the motor cortex, and we may assume that the result was due to cortical sensory stimulation. Loucks confirmed this assumption when he completely narcotized the hind limb during the conditioning series, so that no movement could occur. Conditioning still took place. This fact, plus the other results with direct motor stimulation, makes it plain that in Loucks' experiment the sensory effects produced by the stimulation were serving as the conditioning stimulus.

In another part of the same study Loucks demonstrated that the forced movement of a limb could serve as the conditioning stimulus. He produced a *hind-limb* movement by electrical stimulation, then followed this with a shock to the *forelimb*. Conditioning occurred. This is quite easy to understand, however, for it simply means that the kinesthetic impulses arising from the forced movement of one limb could serve as a signal for the conditioned response of another limb.

Finally, let us note another fact that is very much to be expected (Loucks, 1938). Direct electrical stimulation of the visual area of the cerebral cortex can serve as the conditioning stimulus. This was tried and proved true in two different conditioning situations, the salivary response to food and the flexor response to shock. It means simply that one can substitute direct excitation of the visual cortex for stimulation by means of a light.

Here is where this part of the story ends, although it is by no means a satisfying closure. All we have learned is that the locus of conditioning is some place in front of the final common motor path from the cortex. We do not know whether the neural changes that occur in learning are in the centers for the unconditioned stimulus, in those for the conditioning stimulus, in some third 'association' center, or in some combination of

all three. Back in 1938, the hope was entertained for a brief moment that learning might be found in special association centers. Culler (1938) reported that a spot on the anterior ectosylvian gyrus, not normally concerned in bell-shock conditioning, would evoke the conditioning response if it were stimulated electrically after conditioning trials. It now appears that this was an artifact of a changing sensitivity of the cortex through repeated stimulation. At any rate there have been no further claims for this association center, either by Culler or by others. So we are still in the dark. Much work and ingenuity are called for if we are to pin down the areas and pathways in which simple learning takes place in the nervous system.

Spinal Conditioning

Although we shall later take up cortical and subcortical functions in learning, let us first consider some exploratory experiments on the possible role of lower centers of the nervous system in learning.

Only a few investigators have looked into the question of spinal conditioning — whether simple learning can take place at the level of the spinal cord. What data we have today we owe chiefly to two investigators, Kellogg and Shurrager. Of these, only Shurrager reported affirmatively. But the two investigators used different techniques, and it is quite likely that the technique has something to do with the results.

Techniques. Shurrager's (1940) method required special surgical procedures to study the conditioning. He stripped out a portion of the semitendinosus muscle from the hind limb of a dog, taking care to keep nerve and blood supply intact. He then looked at this nerve-muscle preparation, either with the naked eye or with the aid of a recording stylus attached to a rotating drum. Whenever the muscle twitched, he could see it. In fact, extremely small reactions, probably involving only one neuromuscular unit, could be observed. As the unconditioned stimulus

for this response he applied an electric shock to the foot pad of the same limb from which the muscle had been dissected. Since the muscle was a flexor muscle, it twitched on application of this noxious stimulus. As a conditioning stimulus he applied either gentle pressure or a weak electric shock to the tail of the dog. Before beginning the experiments, however, he transected the spinal cord at the lumbar level to separate it from nervous influences of higher centers. Such operated animals, as Shurrager used them, do not live very long, and all his work demonstrating spinal conditioning was done with acute preparations.

Kellogg et al. (1947), on the other hand, used only chronic preparations—dogs, with their spinal cords transected, that survived the operation for many days. Instead of watching the twitch of a single muscle, he observed the flexor twitch of the whole leg. His unconditioned stimulus was the same as Shurrager's, an electric shock to the foot pad of the same leg. But his conditioned stimulus was different. It was a shock applied to the opposite hind limb of the animal rather than a stimulus on the tail.

Results. With this technique, Kellogg and his colleagues have failed so far to obtain spinal conditioning. Repeated pairing of the conditioned and unconditioned stimuli for hundreds of trials did not 'stamp in' any learned response to the conditioning shock alone. For such a negative result there are several possible explanations: (1) spinal conditioning does not take place in the dog; (2) spinal conditioning cannot be observed in the gross response of the limb when it might be seen in the twitch of a small muscle; and (3) the conditioned stimulus, a shock to the contralateral limb, brings out an unconditioned crossed extension reflex in the other limb—such responses were actually observed—which interferes with the formation of a conditioned flexion response.

With Shurrager's technique, however, data were obtained that have been called spinal conditioning (Shurrager and Culler, 1940,

1941; Shurrager and Shurrager, 1941, 1946). Paired applications of the stimuli to the foot pad and to the tail gave an increasing percentage of twitches in the semitendinosus muscle to the tail stimulus alone. Initial conditioning occurred in 20 to 120 trials and, on the average, in 51 trials. This 'learning' could be extinguished by presenting the tail stimulus without reinforcement, and it could be reestablished by pairing the tail and foot stimuli. For some reason, however, only 98 of 219 dogs in the experiment could be conditioned.

This report of spinal conditioning is remarkable. Even more interesting, however, are some of the other phenomena of spinal conditioning that Shurrager reports. We must run over them rapidly. (1) Conditioned responses may be extinguished and reconditioned (Shurrager and Culler, 1940). Repeated conditionings and extinctions get faster and faster. The rate of extinction, moreover, is proportional to the rate of conditioning preceding it. (2) Normal reflexes may be permanently extinguished (Shurrager and Culler, 1941). An unconditioned response to tail stimulation of the semitendinosus in one leg gradually extinguishes and stays extinguished when the semitendinosus response of the leg on the other side is conditioned to tail stimulation. (3) A conditioned response can be converted into a permanent 'normal' reflex by cutting the roots on the side of the spinal cord opposite to the conditioned semitendinosus response (Shurrager and Shurrager, 1941). (4) All-or-none twitches of the semitendinosus, presumably representing the response of one neuromuscular unit, can be seen in the early stages of spinal conditioning (Shurrager and Shurrager, 1946). Shurrager believes these responses to represent conditioning taking place at a single synapse. The form of the learning curve for the 'synaptic unit' is rectilinear. From this fact Shurrager suggests that the 'true' learning curve is a straight line and that all other forms of learning curves are due to the compounding of units.

We can accept these facts. We may, however, wonder about their interpretation. The meaning of some of the experiments would have been clearer if appropriate controls had been run. In addition, Kellogg and his colleagues (Kellogg, 1947; Kellogg et al., 1947) suggest that these spinal phenomena are not true conditioning but something that might better be called reflex sensitization. They point to the fact that there is an unconditioned response of the semitendinosus muscle to stimulation of the tail. This, they suggest, may become sensitized by repeated applications of the unconditioned foot stimuli. Only more research will tell us whether this or some other interpretation is the correct one.

Subcortical Learning

Even if we are left puzzled by the data on spinal conditioning, we can be confident that some forms of learning can take place at subcortical levels. Several learning experiments have been conducted with decorticate animals (Culler and Mettler, 1934; Girden et al., 1936; Poltyrev and Zeliony, 1930). Both dogs and cats lacking all significant parts of the cortex have been taught to respond in some manner or other to visual, auditory, or cutaneous stimuli. This learning exhibits certain characteristic deficiencies (Culler and Mettler, 1934). We cannot be sure about monkeys and higher primates, however, because we have no learning experiments conducted on such animals without the cortex. After this drastic operation, primates are very hard to keep alive and healthy.

BASIC LEARNING CAPACITIES

There are many ways of presenting the content of this subject, and one may be as good as another. Before we finish, we shall meet many complex and baffling problems. To understand even the problems, let alone the possible answers to them, we need an

elementary understanding of the organization of the brain in simple learning. It seems best, therefore, first to take up questions of simple sensory-motor capacity, simple motor and discriminative learning, and their relations to centers and pathways of the brain.

Visual Learning

Although the visual system of the brain includes many centers and pathways, all we need to consider here are two centers: the striate area of the cortex, sometimes called Brodmann's area 17 or simply the visual area, and the main subcortical visual center, the superior colliculus of the midbrain. Worth noting in passing is the fact that another area, the peristriate area or Brodmann's 18, also has some visual associative functions.

Pattern discrimination. On the striate area of the cortex depends the capacity to perceive differences in visual detail, patterns of visual stimuli, and, in fact, nearly all aspects of visual stimuli except simple differences in visual intensity. This is true in the rat (Lashley, 1931), the cat (Smith, 1938), the dog (Marquis, 1934), the monkey (Klüver, 1936, 1937), and man (Hines, 1942). Presumably it is also true of all other animals in the mammalian series. The evidence rests on experiments in which the total striate areas were extirpated and the animals were tested for their ability to discriminate differences in visual detail. Experiments have been done to see whether any subcortical centers are also of importance in detail vision, but these do not give clear-cut results (Brown and Ghiselli, 1938).

Relevant to the role of the visual cortex in detail vision are a number of other studies of cortical lesions and detail vision. Lashley (1939) demonstrated nicely that very small remnants of the visual cortex can be used in pattern discrimination. He (1942) made it clear, too, that no other part of the cortex outside the visual area is concerned in pattern vision. An earlier study by Kirk (1936)

purported to show that nonvisual areas are important in complex pattern discriminations, but Lashley, after going over Kirk's results, concluded that these discriminations are probably due to interruptions of the macular projections to the visual cortex.

It seems safe to conclude then that the visual cortex exclusively possesses the capacity to discriminate differences in visual detail. The visual area, and no other, provides animals with their basic capacity to see patterns in their visual environment. If then, the visual cortex provides the capacity for discrimination, what happens, we may ask, when we partially destroy this capacity by taking out part of the visual area, either before or after a habit has been learned?

If very much of the visual cortex is removed, there is usually some disturbance of visual habits. A study by Settlage (1939) with monkeys shows, however, that these disturbances are not due to a disturbance in learning or memory. He took out the occipital cortex on one side in seven animals, thus producing cortical blindness for about half of the visual field. There was a temporary loss, but no final loss, in visual discrimination habits. The trouble seemed to be that the monkeys at first retained their pre-operative habits of visual orientation and of fixation of visual objects. This was incompatible with the existence of a large gap in the operated animals' visual world. As time went on, however, the operated animals improved by stages in their ability to make visual discrimination, presumably because they were learning new habits of visual fixation and 'filling in' their visual world.

To test this hypothesis, Harlow (1939) kept some of these monkeys, with half their striate cortex out, in the dark for a period of 10 days following the operation. He then compared their ability in pattern-discrimination tests with those of animals kept in the light. When brought out of the dark, the monkeys showed no recovery of ability to do pattern-discrimination tests. If left

in a lighted cage for a few days, however, with the opportunity to build up experience with visual fixations, the animals regained their ability to discriminate detail.

These studies with various animals add up to one fairly clear conclusion: any loss by an animal of ability to learn or to remember discriminations of visual detail, when its striate cortex is removed, is a loss in ability to see visual space, not a loss in learning or memory capacity.

Spatial vision. So far we have dealt only with pattern discriminations: the capacity to tell the difference between a triangle and a circle or between an upright triangle and an inverted triangle, and so on. The capacity to see these spatial differences, and as a consequence to learn to discriminate them, is clearly dependent on the striate cortex. But there are aspects of spatial vision other than pattern discrimination, and we may ask to what degree are other kinds of spatial vision dependent on the striate cortex.

One study of the cat (Smith, 1938) shows that there is left a little capacity to discriminate spatial orientation after removal of the striate cortex. Smith was able to demonstrate that the cortically blind cat can learn eventually to tell the difference between an upright bar of light and a horizontal bar, but only if the cat is trained an unusually long time and if the stimuli are presented in total darkness. This, however, is a very primitive capacity and amounts to the ability to tell that there is more light in one sector of the visual field than in another sector. It is only the most primitive type of spatial vision.

Klüver (1942) has done the only really exhaustive studies of the limits of spatial vision in cortically blind animals. He used monkeys. Every aspect of visual space perception, he concluded, is virtually destroyed in monkeys lacking the striate cortex. They have no ability to discriminate differences in visual patterns, they cannot discriminate circles of different size, provided the amount of light coming from the circles is kept con-

stant, nor is there left any depth perception — the ability to tell the relative distance of visual objects. In a word, monkeys without the striate cortex have lost completely their appreciation of visual space.

Intensity discrimination. So much for spatial vision and the striate cortex. Let us turn now to intensity vision and to the sub-cortical visual center, the superior colliculus. It so happens, as a matter of technique, that the superior colliculus is hard to get at without injury to the visual cortex or to other areas of the brain. Consequently most of what we know about the superior colliculus we have learned by removing the visual cortex and seeing what visual learning capacities are left. The remainder, it turns out, is a capacity for learning intensity differences rather than spatial differences.

Two different techniques have been used to study visual intensity learning in animals. One is the usual conditioning technique in which a light is flashed or a change in light intensity is presented as a signal for the animal to make a conditioned reaction. The other technique is a discrimination method in which two lighted panels are placed in front of the animal and he is trained to choose either the lighter or the darker one to obtain the food reward. Unfortunately many experimenters have been inclined to call the animal's performance in this situation a brightness discrimination. Actually, two panels of the same size, lighted with different intensities, differ in two respects: luminous flux (the total intensity of light emitted) and brightness (the amount of light per unit area). It turns out, in the monkey at least, that there is one neural mechanism for discriminating total flux and a separate one for discriminating brightness. It is safer, therefore, to speak here of intensity differences, and to mean differences in either or both brightness and flux.

All conditioning methods using animals in which the superior colliculus is intact but in which the striate cortex has been removed show that the animals can react to differ-

ences in the intensity of light. Marquis (1934) and Marquis and Hilgard (1936) got this result when they used a conditioned eye-wink reaction, in which the closure of the eyelid to a puff of air was the conditioned reaction to a light signal. So did Wing and Smith (1942) when they used retraction of the hind limb to shock, conditioned to the onset of a light. Wing (1946), using this same technique, conditioned dogs to respond to a change in light intensity, as well as to the onset of a light, and found no effect of the removal of the striate cortex upon either the memory or the learning of this differential conditioned response. Finally, Wing (1947), using reward conditioning, in which the animal is taught to lift his leg to a light signal in order to receive food, found dogs to be capable of learning either a simple reaction to onset of light or a differential reaction to change of intensity of light, with the superior colliculus intact and the visual cortex removed.

Discrimination techniques have been used with other animals with similar results: the rat (Lashley, 1929, 1935b), the cat (Smith, 1937), and the monkey (Klüver, 1936, 1942). Cortically blind animals are capable of learning to discriminate the difference when faced with two lighted panels of the same size but differing in intensity. Klüver (1942), however, working with the monkey, has been able to show that the learning capacity is one of reacting to differences in flux, not to differences in brightness. When he varied the size of equally bright panels, the monkeys were no longer able to perform the discrimination. Reaction to brightness, he points out, requires some sort of space perception, in addition to intensity discrimination. This space perception, he has shown in other connections, is dependent on the striate cortex, not on the superior colliculus. There is no reason to believe that the monkey is different from the dog or the cat in this respect, and we can generalize the conclusion to these animals.

We can summarize these results in a single sentence: with the exception of learning based on crude visual orientation, all learning that involves spatial vision—including brightness discrimination per se—depends on the intact striate cortex, and only learning that depends solely on reaction to flux can be handled by the subcortical centers.

This conclusion, it is interesting to note, explains an otherwise puzzling fact reported a few years ago by Smith (1937). He discovered that, although cats deprived of their striate cortex can make intensity discriminations under ordinary conditions of illumination, when he lighted up the room and surrounded the visual panels with a highly illuminated surface, the cats could no longer learn to make the discrimination, even with hundreds of trials of training. This can be explained by the fact that the cortically blind cats can discriminate only gross differences in flux, not brightness. When the general illumination surrounding the panels is raised to a very high level, the value of $\Delta I/I$ in terms of flux falls to the point where it cannot be discriminated.

Auditory Learning

There have been several studies of the ability of animals lacking an auditory cortex to learn simple auditory discriminations based on intensity. After the removal of this cortex, rats learn to localize the position of a buzzer or a tone (Pennington, 1935). They also learn to avoid shock by shuttling from one platform to another when a tone is used as a signal (Pennington, 1937). Cats, too, readily learn a conditioned movement response to avoid shock when a buzzer or a tone is sounded (Raab and Ades, 1946). So we know that simple learning, dependent on changes in the intensity of sounds, does not depend on the auditory cortex, but on subcortical centers, of which the inferior colliculus is most suspect. Unfortunately we have no data to tell us whether the learning or retention of a frequency discrimination depends upon the auditory cortex.

Somesthetic Learning

Coming now to somesthetic learning—learning based on the use of cutaneous or kinesthetic cues—we again find that there are not enough facts for us to come to decisive conclusions.

We meet a somewhat different situation in somatic sensibility. In the rat (Smith, 1939), so far as we know, there is no one well-defined area that is essential for the discrimination of roughness—a measure of cutaneous intensive capacity. In monkeys (Ruch, Fulton, and German, 1938), ablation of the postcentral gyrus does not destroy the capacity; neither does injury to the precentral gyrus. Complete parietal lobectomy on one side causes some deficit in capacity to discriminate roughness. But there are no experiments in which such lobectomy has been made bilateral. And we know that there is some bilateral projection in the cutaneous fields.

It is possible to demonstrate somatic form discrimination in monkeys and chimpanzees by giving them such things as wedges and pyramids or cones and pyramids to feel in the dark (Ruch, Fulton, and German, 1938). That such form or spatial discrimination is dependent in part on the posterior parietal lobe is demonstrated by the fact that the chimpanzee in which this lobe has been removed cannot learn to discriminate between a wedge and a pyramid, which are rather similar in form. They can, however, after prolonged training learn to distinguish such dissimilar forms as pyramids and cones. How completely dependent spatial discrimination is on any part or all of the cortical somatic areas has not been accurately determined.

Motor Learning

Research workers have devised an endless variety of motor problems for animals to learn. The possibilities for the rat are more limited than those for primates because rats are low in manipulative skill, but even here several problems have been devised and used

in studies of motor learning. The problems fall into two main classes.

Locomotor learning. There are locomotor problems that can be solved by the rat's running and climbing movements. The double-latch box, used by Lashley (1935a), is one of these. In order to obtain food the animals simply depress two platforms in the correct order. Lashley has made lesions, large and small, in various parts of the rat's cortex before putting this problem to them. Compared with normal rats, these operated animals with lesions involving up to 58 per cent of the cortex are capable of normal learning. And, no matter where the lesion is, there is still no appreciable impairment of learning ability. Lashley has concluded, therefore, that there are no crucial areas for simple locomotor learning in the rat.

Manipulative learning in rats. A second class of motor problems, those involving more manipulative skill, gives different results (Lashley, 1935a). Four problems of this type have been used: one requires that a lever be depressed, thereby releasing the latch of a door that admits the animal to food; another requires that a paper strip be cut or torn by the animal before he can obtain food; in a third, the door to food can be opened only by pulling a handle; and, in the fourth, a chain must be pulled to secure food. In all problems of this type, sizable injury to the cortex impaired learning ability. In fact, the amount of retardation in learning was roughly proportional to the size of the cortical lesions. Correlations between retardation and extent of lesion ranged between 0.48 and 0.72. The locus of the lesion seemed to be of no special importance. Why there is a correlation with mass, but not with locus of the lesion, is a vexing problem, which we shall take up more seriously later in the chapter.

Manipulative learning in primates. Experiments with monkeys and chimpanzees give a different but clear and understandable result (Jacobsen, 1931, 1932, 1939). Monkeys have been given manipulative

problems calling for the use of sticks, rakes, chains, ropes, etc. Simple learning of this sort has been studied in relation to lesions in different parts of the cortex. Lesions in the posterior cortex and in the precentral cortex do not impair this kind of learning ability. Those in the motor and premotor areas, however, do cause some interference, but, as we shall see in a moment, the interference is with motor skill, not with learning or memory.

The motor area (precentral gyrus) is the area of the cortex through which 'voluntary' movements are initiated. The capacity for skilled movement depends primarily on this area. When it is removed, a monkey shows great difficulty in learning or remembering skilled movements, such as those involved in manipulating sticks and ropes to get food. But it is very clear that the monkey's learning or remembering has not been impaired; only his dexterity has suffered. If the injury has not been too severe, a period of recovery will witness a gradual return of the skill. Then the animal will be able to learn the required patterns or to show that he remembers them if he has learned them previously.

The functions of the premotor area of the extrapyramidal system are difficult to describe briefly. Their removal causes some slight paralysis and interference with ability to make skilled movements, but that is not their primary function. They have something to do with the organization of the components of a skilled movement. For example, when a monkey, deprived of its premotor areas, is faced with a problem of pulling a rope latch, the animal may pick up the rope, but he may not do the next obvious thing, namely, pull the rope. Thus, lack of this part of the motor system interferes to some extent with the skill of an animal, but, after a period of training, he can learn to carry out manipulative skilled movements.

When both the motor and premotor areas are removed simultaneously, there is considerable interference with skilled movements,

but it turns out that this is due to the almost complete paralysis that the removal produces. As far as monkeys are concerned, it is fair to conclude, therefore, that neither the premotor nor the motor area of the cortical motor system is concerned in learning ability for motor problems. They are, however, involved in the capacity of the animal to carry out the required manipulations, if it has succeeded in learning what they are.

NEURAL EQUIVALENCE

What has baffled students of brain function for many years is that they cannot put their finger on the particular areas and pathways responsible for any particular learning performance. For simple learning capacities, as we saw in the last section, the essential cortical and subcortical areas have been identified in most cases. But there is more to the problem than that. What happens over and over again is this: An animal is trained to make some particular discrimination or to solve some problem. A certain area is removed. The animal loses the memory for, or the ability to solve, the problem—but only temporarily. In the course of time or with retraining, the animal regains the habit. In other words, the habit, in the normal animal, appears to depend on one area. It is lost when the area is removed. But, afterwards, some other area or part of the brain apparently steps in to furnish the necessary mechanisms for relearning the habit. This is certainly a very handy mechanism to have—it is a kind of insurance policy against the irrevocable loss of a learning capacity. But it is a little hard to understand.

This substitution of one part for another has been called equivalence, for it is a kind of equivalence of parts of the brain in doing the same job. This is a central problem in our field. So far in this chapter we have avoided it, but it is now time to come to grips with it.

Recovery of Motor Functions

A good example of equivalence in brain functions is seen in motor paralysis due to brain injury. In primate animals, such as the monkey, the chimpanzee, and man, voluntary movement is dependent on the motor cortex (area 4), lying just in front of the central sulcus. Also involved in voluntary movement is the premotor cortex (area 6), lying just in front of the motor area, and a part of the somesthetic cortex, the postcentral gyrus (area 3-1-2). The entire motor areas are topographically organized according to regions of the body, with the leg being represented most dorsally, the arm somewhat to the side of the leg area, and the head and face in the extreme lateral portions of the area. Most of the fibers leaving these areas, leading downward to the spinal motor horn cells, are so crossed that the motor cortex on one side of the brain controls movements of the body on the other side.

Complete bilateral extirpation of all the areas concerned with voluntary movement, including 4, 6, and 3-1-2, results in complete motor paralysis of all voluntary movements in man, chimpanzee, and monkey. From such profound paralysis there is no recovery. If, however, the experimental injuries are made to only a part of the crucial cortical areas, there is some improvement in function and effacing of the paralysis over a period of months following the operation. This recovery of motor functions has been known for a long time, but only recently has research thrown some light on how and why it occurs.

Postcentral gyrus. One study (Ades and Raab, 1946) shows that the postcentral gyrus (3-1-2) may be responsible for some recovery after the removal of the precentral cortices (area 4). Ordinarily, when the motor cortex is removed simultaneously on both sides, a rather profound paralysis results. If, however, a lesion is made on only one side and a period of 3 or 4 months is allowed to elapse before taking out the other side, we do not get the usual paralytic

signs of bilateral injury. Obviously there has been compensation taking place in the interval between the removal of one cortex and the second operation. Moreover this compensation must involve some areas other than those of the motor cortex (area 4). It turns out that the postcentral gyrus (3-1-2) is responsible for this compensation, for, if it also is removed along with the corresponding precentral cortex, paralysis occurs after the second operation just as it would have if both sides had been removed in one simultaneous operation.

Injury in infancy. We see compensation at work when we compare the effects of cortical removal in infant and adult monkeys (Kennard, 1938, 1942). It is interesting that, when cortical areas 4 and 6, the motor and premotor areas, are removed from infant monkeys, there is very little immediate effect on motor performance; there is no paralysis. As time goes on and the monkeys grow older, some signs of paralysis make their appearance, but these are much more moderate than when the injury is made in adult monkeys. From this study it is possible to draw several conclusions: some kind of reorganization of brain functions goes on after the removal of the motor areas; this reorganization is greater in the young monkey than in the mature animal, occurring to the greatest extent in the first 6 months of life. Apparently the parts of the cortical motor system left uninjured are responsible for the reorganization.

To test this hypothesis, Kennard and her colleagues carried out an excellent set of experiments. They made use of three distinctly different methods for determining what reorganization has taken place. One method employed a stimulant during the period of recovery following the operation. A second involved a sedative, and a third used a test of the electrostimulability of the cortical areas before and after the operation.

Stimulants. The stimulant used was strychnine (Ward and Kennard, 1942). This

is a well-known nervous stimulant and probably acts by interfering with cholinesterase activity at the site of transmission of nervous impulses. Ward and Kennard also used two other chemicals that are known to have a stimulating action on the nervous system: thiamin (vitamin B₁) and doryl. By using these drugs postoperatively, singly or in combination, they observed that all animals suffering removal of the cerebral cortex on one side were aided considerably in both the rate and degree of recovery of their motor functions. They concluded that this increased rate of recovery was due to the fact that the stimulus accelerated the rate of functional reorganization in the parts of the motor system remaining after operation.

Sedatives. The opposite result was observed with the use of sedatives (Watson and Kennard, 1945). Several monkeys were deprived of their motor and premotor cortices (areas 4 and 6) on one side and were then treated with sedatives such as phenobarbital and dilantin during the postoperative period. It turned out that phenobarbital, in doses so small that they had no observable effect on the cage behavior of the monkeys, produced a very marked slowing in the rate of recovery of motor functions. In fact, the animals never reached the level of recovery typical of other monkeys subjected to this lesion without the use of sedatives. The investigators concluded, in this case, that the sedatives interfered with the reorganization of remaining tissues of the cortical motor system.

Electrical stimulability. To be noted finally is a study of the electrical stimulability of motor areas before and after operation (Kennard and McCulloch, 1943). Areas 4 and 6 were removed from monkeys in infancy, and the animals were then allowed a long time for recovery. Later, similar operations were performed on older monkeys, and shortly thereafter the two groups were compared with respect to the threshold of electrical stimulus required to produce a movement in various parts of the body.

They found that "the cortex of the animal with motor areas removed in infancy has greater excitability in the region surrounding areas 4 and 6," namely, the posterior lip of the central sulcus (precentral gyrus) and areas 6b and 6a, which lie just in front of area 6, "than has either the normal macaque cortex or that of the animal from which the motor areas have been removed in later age. No regions other than those known to be excitable in the normal animal were found to be excitable in these preparations."

There have been many attempts to explain the phenomena of recovery of motor functions. For a discussion of them the reader should refer to Lashley (1938a). The view taken by Lashley, after a critical review of the data on both animal and man, is that recovery of functions depends upon reorganization of the nervous tissue remaining in the system concerned with the function. Kennard's work on motor functions makes Lashley's view appear correct. In her work it seems clear that the recovery of motor functions depends upon remnants of the motor system remaining intact.

Auditory Equivalence

An interesting demonstration of the equivalence of cortical and subcortical mechanisms in auditory learning comes from experiments using curare and erythroidine. Curare is a poison, used by Indians on arrowheads, that is extracted from various poisonous plants. Actual samples of it vary greatly in strength and purity. The active ingredient, curarine, is an alkaloidal compound with an approximate formula of $C_{19}H_{21}NO_4$. Because the impurity of curare gives varying results in experiments (sometimes underdosing the animal, sometimes killing it), investigators have sought other substitute materials. The drug erythroidine has now been prepared in relatively pure form, and, though it is not chemically identical with curarine, it has similar physiological properties. Thus, experiments in the 1930's used curare, but more recent ones have employed erythroidine.

Conditioning techniques. The outstanding property of these drugs, known for a long time, is that they produce muscular paralysis without affecting appreciably the sensory functions. Physiological experiments have indicated that the site of action is at the neuromuscular juncture. Curare seems to produce its paralytic effects by blocking the transmission of impulses from the motor axon to the muscle fibers. It is this property that first prompted its use by psychologists (Harlow and Stagner, 1933). They wanted to use it as a means of paralyzing an animal during conditioning to see whether it is necessary for responses actually to occur in order for conditioning to take place. In these experiments they gave conditioning training to animals under the influence of curare and tested them for conditioning after the curare had worn off. They found no conditioning, and they concluded that "conditioned reflexes are only possible if a response is made, and do not result merely from stimuli presented simultaneously."

A few years later it was to become clear why this result had been obtained. Girden and Culler (1937) devised a new technique for studying conditioning under curare. They dissected out the semitendinosus muscle of the hind limb, keeping the blood and nerve supply intact. When they applied shock to the hind leg, they could observe muscle contractions in the dissected muscle, even though gross flexor responses of the limb did not occur. By pairing the sound of a bell with the application of a shock they were able to observe conditioning taking place in the semitendinosus muscle under curare. Henceforth, in a series of studies, they used this technique in both normal and curarized animals to observe the course of conditioning and retention in the two states, normal and curarized.

Dissociation. But the most interesting point—the main point of this section—is that the responses conditioned under curare vanished when the animal was returned to the normal state. In the normal state the

animal showed no sign of the retention of the conditioning it had acquired under curare. Conversely, conditioning established in the normal animal disappeared when the animal was put under curare. Thus there was a complete amnesia in one state for conditioning in the other state. This fact has now been verified many times (Culler et al., 1939; Girden, 1940, 1942a, b, c).

Once having established the dissociation of skeletal conditioning in normal and curarized animals, the investigators went on to see whether the same rule also held for autonomic responses. It was easily shown that pupillary conditioned responses to a bell could be established under curare (Harlow, 1940; Harlow and Settlage, 1939). Preliminary experiments indicated too that there was no dissociation of the conditioned reactions established in the normal and curarized state (Harlow and Stagner, 1933). More thorough research later, however, made it seem that the apparent carry-over of conditioning of pupillary reactions from curarized to normal state was an artifact. It now looks as though the pupillary reactions under curare were actually unconditioned reactions to the bell. At any rate, when a light was used for conditioning pupillary dilation, there was a dissociation of conditioning like that seen in skeletal responses. This finding has been established with the use of both curare and erythroidine (Girden, 1942b). Moreover, conditioned reactions of blood pressure to shock, carried out in normal state and under erythroidine, show a clear dissociation (Girden, 1942a). Thus the story is now simple and clear. Conditioning reactions, whether skeletal or autonomic, established under curare or erythroidine, do not carry over to the normal state, and vice versa.

Equivalence. The next question concerns the physiological interpretation of these effects. The explanation comes from a study of the effects of curare upon different parts of the nervous system. Culler et al. (1939), suspecting that the curare was doing more

to the nervous system than simply paralyzing neuromuscular transmission, examined the excitability of the cerebral cortex and the spinal reflex paths in normal and curarized states. They found that the threshold was raised, and the time for excitation was lengthened, for evoking responses in the semitendinosus muscle by cortical stimulation. In a word, the excitability of the motor cortex, and probably that of the cortex as a whole, was considerably depressed. Stimulation of the motor roots leading to the semitendinosus muscle made it clear that curare had not changed the excitability of the neuromuscular response. At first thought this might seem to contradict the idea that curare paralyzes neuromuscular junctures. There is no contradiction, however, because it turns out that curare does paralyze many of these junctions; on the other hand, it seems to sensitize some of the fibers not knocked out. The end result is no net change in excitability.

The conclusion, then, from these electrophysiological studies is that curare considerably depresses cortical excitability but does not affect spinal excitability. This suggests that the dissociation of conditioning seen in curarization is due to a depression of the cortex. Going further, one might conclude that normal conditioning involves the cerebral cortex, whereas conditioning under curare, with accompanying depression of the cortex, is effected through subcortical routes. This subcortical conditioning, then, gets suppressed when the cortex returns to normal.

This hypothesis has been tested and confirmed. Girden (1940), because he was using a bell as the conditioning stimulus, removed the auditory cortex of dogs before conducting the typical experiments with curare. According to the hypothesis above, the auditory cortex, in addition perhaps to other cortical structures, would be involved in the normal state but would be suppressed in curarization. If, however, the auditory cortex were removed, then it could not function in either the normal or the drugged

state. All conditioning whether normal or under drugs would be subcortical, at least in respect of the bell stimulus. One would expect no dissociation under these conditions. This expectation was realized. The conditioned response of the semitendinosus muscle established in either the normal or drugged state carried over to the other state.

The conclusion to this story seems perfectly clear. In the conditioning of skeletal and autonomic responses in normal animals, the cortex is involved, and certain essential parts of the conditioning are not subcortical. Under the drug state, which depresses the cortex and leaves subcortical centers at some level more or less unaffected, conditioning takes place subcortically. There is a dissociation between these two conditionings. The cortex and subcortex are alternates for each other — they are equivalent — but not at the same time. When one is working, the other is not, and vice versa.

Auditory memory. Although that ends the story about curare, there is still a bit more to say about neural equivalence in auditory learning. Unfortunately there is relatively little data on auditory capacities and the memory functions of the auditory cortex, but what there is points to a few conclusions. A series of studies on rats (Pennington, 1935, 1937; Wiley, 1932, 1937) shows that rats without auditory cortex are capable of learning simple auditory habits, like localizing a sound in the correct box, or jumping in response to a tone. Yet animals that learn such responses preoperatively show an amnesia for the habit after removal of the auditory cortex (which is poorly defined in the rat). Another study on cats by Raab and Ades (1946), with conditioned responses to tones, gives a similar conclusion:

Auditory conditioned responses are normally mediated cortically by an all-or-none mechanism of the auditory cortex. In the absence of the projection areas, these habits may be relearned at a midbrain level and are

mediated by the inferior colliculi (discharging through the superior colliculi) with no loss of acuity.

In a word, what all these studies point to is an equivalence of cortical and subcortical centers in auditory learning; when the cortex is intact, it is crucial to the learning; when it is not, subcortical centers mediate the learning.

Visual Learning

In an earlier section we saw that visual space perception, including all capacity to learn or remember spatial cues, is abolished with complete removal of the striate cortex. We saw, too, that all mammalian animals (with the possible exception of man) are capable of learning intensity discriminations in the absence of the striate cortex. The whole story, however, was not told. There are some interesting examples of neural equivalence between cortical and subcortical centers of vision in the learning and retention of visual intensity discriminations. The interesting thing is that we find such equivalence when a discrimination technique is used, but in simple conditioning procedures we do not.

Conditioning. We have already reviewed the studies showing that the conditioning of an intensive discrimination is not impaired by removal of the visual cortex. The main point to add here is that memory, too, for visual conditioned responses is not significantly affected by total extirpation of the visual cortex. This is true both of simple conditioning to onset of light and of conditioned responses to changes in light intensity. It appears, then, that the learning and retention of such visual learning is normally mediated at subcortical levels and does not normally involve the visual areas of the cortex.

Discrimination. It is when we consider studies in which animals are taught to discriminate differences in intensities of lighted panels that we encounter equivalence phenomena. Under this method there have been

many experiments with different animals, including the rat (Ghiselli, 1938; Ghiselli and Brown, 1938; Lashley, 1935*b*), the cat (Smith, 1937), the dog (Marquis, 1934), and the monkey (Klüver, 1942). The central fact in all these experiments is that the destruction of the visual area of the cortex abolishes a discrimination once it has been learned, but it does not interfere with the relearning of this discrimination. Animals that are operated upon after they have learned the discrimination show a complete amnesia for the learning, but they are capable of relearning it. Apparently then, the visual cortex is normally involved in the learning of an intensity discrimination, but in its absence subcortical centers take over this function.

Somesthetic Learning

As we have seen before, the field of somesthetic learning has not yet provided us with very satisfactory data. In the only available study of tactile discrimination in the rat (Smith, 1939), rats were required to discriminate the roughnesses of two sandpaper surfaces. They were subsequently operated upon in such a way that various lesions, taken together, covered the entire cortex. One area, when removed, caused partial loss or complete loss of the discrimination, and this was presumed to be the somesthetic projection area. Animals that lacked it, however, were capable of relearning the discrimination in relatively few trials. Thus it seems that other cortical or subcortical centers could, if necessary, take over the functions normally subserved by this cortical area. Considerably more work on this problem is needed, but the results so far point to a neural equivalence such as we have met in the other sense modalities.

We also find some evidence of neural equivalence in kinesthetic discrimination in monkeys (Ruch, 1935). Monkeys were trained to discriminate difference in weight, and the effect upon retention of the discriminative habit was measured after re-

moval of the precentral, postcentral, and the posterior parietal areas, taken separately and in combination. After the separate removal of any one of these areas, there was some loss of memory for the discrimination, but the discrimination could be remastered after retraining. The memory loss was much less after removal of the precentral and postcentral areas than after destruction of the posterior parietal areas. Combined lesions of the precentral and postcentral areas also resulted in some memory loss, but this could be recouped by training. Thus we meet again the phenomenon of equivalence: areas normally involved in learning are not necessary for learning, for their functions can be 'taken over' by other areas remaining in the somesthetic cortex.

Similar experiments have been done with the tactile discrimination of roughness in the chimpanzee (Ruch, Fulton, and German, 1938). There is no need to go into them in detail, however, for they present the same general results as those for kinesthetic weight discrimination in the monkey. They all point to neural equivalence in somesthetic learning. In many respects, however, both sets of experiments are incomplete. They leave us uncertain of the degree to which different parts of the somesthetic areas are equivalent, and they tell us very little about the role of subcortical centers in somesthetic learning.

The tactile discrimination of form, stereognosis, has been studied in the chimpanzee in combination with lesions to the somesthetic areas of the cortex (Ruch, Fulton, and German, 1938). Abolition of the posterior parietal lobule (areas 5 and 7) can cause complete amnesia for stereognosis. In the case of complex form discrimination, no amount of retraining will get the animal to master the discrimination. Less difficult discriminations may be learned with retraining; for example, the chimpanzee whose posterior parietal lobe has been removed may again learn to distinguish a cone from a pyramid, but the capacity to distinguish be-

tween a pyramid and a wedge, which are more alike than a cone and a pyramid, is apparently never regained, no matter how many trials are given the animal.

This relearning of simple tactual form discriminations after removal of the posterior parietal areas is another case of equivalence. The stereognostic learning ability apparently depends on the posterior area when it takes place in the normal animal, but after removal of the area some other structure takes over part, but not all, of the learning function. Unfortunately the relevant data are not available to tell us whether this other structure is subcortical or cortical.

SELECTION AND VARIABILITY

We have not heard the last of neural equivalence. There will be more of it in this section. Neural equivalence is seen not only within the centers of a particular sensory or motor system but also in the relation of different areas of the cortex to one another. In this section, however, the emphasis will shift from neural equivalence to behavioral equivalence. Equivalence of function is seen in sensory and motor learning behavior, just as it is in nervous function. The two forms of equivalence, neural and behavioral, seem in fact to be different aspects of the same basic organization of brain functions. What is meant by this statement will become clearer as we proceed.

It is a little hard to choose the best terms to describe behavioral equivalence. There are several terms used to denote different aspects of the phenomenon. In some kinds of discriminative learning and in maze learning, an animal has several cues available to him. There may be lights, odors, tactile cues, or spatial cues. He does not need to use all these cues. One or another of them will usually do. Thus these different cues are equivalent. In practice the animal often selects certain cues to use and does not use the others unless it is forced to, and in this case we may speak of *selection* rather than

of equivalence of cues, but we mean essentially the same thing. The concept of *variability* applies to some equivalence phenomena. If the animal does not consistently select a given cue, we can say that it displays variability in behavior. If it sticks to one of two equivalent cues, its behavior is not variable in this respect. To some forms of behavioral equivalence, the term *hypothesis*—a rather anthropomorphic term—has been applied. If from one trial to another the animal varies the cue to which it reacts, one can say that it uses different hypotheses.

There may be objections to some of these terms, but they have been used by one or another of the authors working in the field of neural functions and behavior. The important thing, however, is to recognize the fundamental psychophysiological processes that they denote. In every case they point to organizing or selective processes in the brain in which only certain aspects of a stimulus or stimulus situation are reacted to and only certain responses of many possible responses are given by the subject. These organizing processes can be called selections or hypotheses. In experiments on learning we test our animals in such a way as to find out which of many selections are made.

Spatial versus Visual Hypotheses

A number of experiments have been designed to disclose which of two cues, visual or spatial, the rat had used during learning. Most of these studies were made by Krechevsky, who chose the term 'hypothesis' to describe this selective behavior. His instrument was a maze, made in four units from start to goal box, that could be solved either by entering all lighted alleys or by using a simple directional tendency.

In the first experiment (Krechevsky, 1933) it was demonstrated that rats tend to use different hypotheses in running such a maze. Some react consistently to spatial cues, some to visual cues, and some to both. This could be determined by analyzing the pattern of turns made by the animal on each trial in

the maze. It is interesting to note in passing that, when a bright strain of animals was compared with a dull strain, the dull animals were the ones that used visual cues most extensively.

'S' and 'V' areas. The next interesting question concerns the effect of brain lesions on hypotheses in rats (Krechevsky, 1935). Lesions of various sizes were placed at different locations on the cortex so that the whole cerebral cortex was explored. The conclusion: cortical lesions reduce the number of hypotheses in rats. Whereas normal animals tend to use both visual and spatial hypotheses and to vary from one to another, animals subjected to operation were inclined to take one hypothesis and stick to it. The reason for this became clear when the brains were analyzed. It turned out that a cortical area corresponding fairly exactly with the striate (visual) area of the cortex was responsible for the visual hypothesis; when it was removed, animals shifted to the use of spatial hypotheses. On the other hand, an area a little front of center on the cortex, corresponding to motor and somesthetic areas, was crucial for spatial hypotheses; animals with this area removed preferred to use visual hypotheses. This is a simple, understandable result.

Mass action. The same type of maze can, of course, be used to study intensity discrimination simply by arranging the lights over the correct alleys and eliminating spatial cues. Krechevsky (1936) made relatively small lesions, involving about 10 to 12 per cent of the cortex and overlapping the visual area in most cases. Ghiselli (1938a) made lesions of varying size involving up to 55 per cent of the total surface of the cortex. Both investigators found that such lesions considerably retarded the learning of a brightness discrimination. This is strange because in previous studies (Lashley, 1929, 1935b) based on a simple discriminative technique lesions in the cortex did not impair learning ability, although those in the striate cortex did cause amnesia for the habit. Even

more interesting is Ghiselli's statistical analysis of his cases. There was a correlation of about 0.80 between retardation in learning and the size of the cerebral lesion, whereas the position of the lesion was of no importance.

This correlation between size of lesion and degree of retardation in learning has been called *mass action*. This is the second time we have encountered it in this chapter, but we shall get more of it later. Why the amount of cortex is important in learning the intensity-discrimination maze is rather puzzling, especially since the cortex is of no importance in simple intensity discrimination. Apparently there must be some new factors of significance in learning the maze that do not appear in a simple intensity discrimination.

Spatial Hypotheses

There are some more studies dealing with the brain mechanisms of spatial hypotheses. These do not use the four-unit maze but employ various other techniques. One (Krechevsky, 1937a) was a 'block-maze' in which there were several different routes to the goal, all correct and all of the same length. Errors could be made only by the animal's turning away from the general direction of the goal box or by his entering a blind at the side of the maze. Normal animals were compared with animals suffering lesions of different sizes in various parts of the cortex. The normal animals took many more different paths — nearly twice as many — than did operated animals. Normal animals (run only one trial a day) also shifted from one path to another much more than did the operated animals. Thus the number of hypotheses was cut down by the cortical operations. The decrease correlated rather highly with the size of the cortical lesions ($r = 0.67$ to 0.37). Mass action again!

Quite similar in principle is a study by Morgan and Wood (1943). They ran rats in a simple T-maze with reward on both sides and counted the number of times the

rats alternated right and left choices. Normal animals, as has been demonstrated several times (Dennis, 1939; Heathers, 1940), took alternate paths about 80 per cent of the time. Some operated animals cut down their variability considerably and consistently chose either the left or the right path. Examination of the lesions indicated some localization of function. All animals with lesions in the frontal areas adopted the stereotyped behavior, and some animals with parietal lesions did, too; but animals with occipital lesions in the vicinity of the striate cortex maintained a high degree of alternation.

There are still other experiments by Krechevsky on variability in spatial hypothesis as related to cortical function. In one of them (1937*b*), he ran rats in an apparatus where two paths to food were available. One was a variable path through a block maze similar to the one described above; the other was a standard path involving turns in simple alternation. The animal was permitted to choose on each trial whether to take the standard path or the variable path. Taking the variable path in this case was of no particular advantage or disadvantage in getting the food reward. Normal animals, Krechevsky found, tended to vary their responses more than did operated animals. They chose the variable path about 50 per cent of the time and the standard path about 50 per cent. The operated animals, though they started out in the first few trials at about 50 per cent, gradually reduced their choices of the variable path to about 20 per cent, taking the standard path 80 per cent of the time. Even minor cortical injuries seemed to cause this stereotyping of behavior. No correlation, however, between the size of the lesion or its locus and any of the measures of variability could be found.

Krechevsky was concerned over the fact that the standard path, being about the same length as or perhaps shorter than the variable path, might have something to do with the results. He therefore ran another

experiment (Krechevsky, 1937*c*), identical with the one before, except that the standard path was longer by a ratio of 1.54 than the average variable path. In this test his operated animals did not develop the preference for the standard path. They were, however, less variable in their choices than the normal animals and tended to persevere on one choice longer than the normals. He obtained correlations of -0.36 between the size of the cortical lesions and the number of times the variable path was taken; also he found a correlation of -0.59 between size of lesion and the variability in the choices of the animal.

Somewhat different but still related to spatial hypothesis is a study of *umweg* behavior and brain lesions (Krechevsky, 1938). His apparatus was so constructed that at the first choice-point the rat had to make an intensity discrimination, choosing the path toward a light. It could choose between a long spiral path along which the food and light were visible all the time and a short path through a tunnel directly to the food. This short path, however, was psychologically the *umweg* path because the animal had to leave the field where the light and the food were visible. He found that operated animals made vastly more choices of the spiral longer path (58.9 versus 17.1 per cent of the time). In a control experiment, however, in which the intensity discrimination was eliminated and the animals simply chose the tunnel versus the spiral path, the operated animals chose the spiral path only 12 per cent of the time whereas the normals chose it 18 per cent. This means that the brightness discrimination presented no difficulty to the operated animals. It means also, however, that the operated animals tended to depend on the light cue much more than did the normal.

Variability in Manipulative Behavior

A rough classification, useful for many purposes, divides behavior into locomotor and manipulative behavior. In locomotor

behavior the animal moves his whole body in one direction or another. That is what we have been talking about above in respect of spatial hypotheses. We have really been considering locomotor hypotheses and variability. In contrast to that kind of behavior we can think of patterns in which a more specific movement of the hands or limbs is made in the solution of a problem. There are relatively few data on the neural functions involved in the learning and retention of such problems. Those there are point to the importance of variation and stereotyping of such patterns in learning.

There are two studies, worth mentioning briefly, of changes in handedness in manipulative problems. Lashley (1938a) observed that monkeys readily shifted from one hand to another when neural injury paralyzed one side. Animals were taught a manipulative problem in which they used only one hand. The motor cortex responsible for that limb was then removed, partially paralyzing the monkey. Upon preoperative testing the animal promptly used the other, unparalyzed limb to solve the problem. Lashley cites this as an example of equivalence in motor functions. Peterson (1934) reported a similar phenomenon for rats. He first demonstrated that most rats show some hand preference, either left or right. He then located a point on the cortex, corresponding to the motor cortex in primates, which when injured or removed would shift the preference to the other side. Though the limb originally used was not paralyzed by the operation, it probably was made less usable.

More directly related to the problem of variability in manipulative behavior are Lashley's studies of latch-box behavior in rats (1935a). He prepared a series of different problem boxes on which he trained a group of rats. Four of these problems were distinctly manipulative problems. They required a string to be pulled, a paper strip to be torn in the right way, and so on. One box contained a double platform, and the animal had to step on both platforms in

order to get food. The effects of brain lesions were different for the two types of problems. The ability of animals to learn the double-platform (locomotor) problem was not affected by cortical lesions of considerable magnitude, even up to 58 per cent. Rate of learning was not correlated with the magnitude of any lesions made. However, with other boxes — those requiring manipulative behavior — there was considerable retardation in learning with cerebral lesions. The correlations between the extent of lesion and the amount of damage to the cortex ranged from 0.48 to 0.72.

It is easy to understand why lesions did nothing serious to learning in the double-platform problem. Its solution requires relatively simple locomotor behavior, no complicated hypotheses, and no skilled movements. The other boxes required variable behavior and reasonably good sensory-motor coordination on the part of the animal. It had first to stumble on to the correct solution and later to develop the specific reactions of manipulating latches. It had then to reduce the time spent in exploring particular items in the situation. It is reasonable, therefore, that almost any kind of lesion might affect the behavior and reduce the probability of the rapid solution of the problem. Lashley's observations of his operated animals and his analysis of results convinced him that the difficulty encountered by the operated animals in the manipulative problem boxes was basically a matter of variability in behavior. The number of exploratory acts (motor hypotheses) was cut down.

Mass Action of the Cerebral Cortex

We come now to the concept that has been so widely publicized in recent years — mass action. Almost every student of elementary psychology has at least heard the words. They represent both a concept and a result. The result is what Lashley and others (Lashley, 1929; Lashley and Wiley, 1933) obtained in studying the effects of brain lesions

on maze learning and retention in rats. In brief, they are as follows: The learning ability of rats is retarded in proportion to the size of lesions made in their cerebral cortices. If the lesion is large, the retardation is great; if the lesion is small, little damage to learning ability follows. There is, in general, an exponential relation between size of lesion and degree of retardation, so that the difference between a 50- and a 60-per-cent lesion is much greater in terms of retardation of learning than between lesions of 10 and 20 per cent. It does not matter where the lesion is; the results are the same. It is the mass of the cortex, not its locus, that is important in maze-learning ability. Many people have obtained this result in many different maze situations, and there can be no doubt of it.

The question is, what does it mean? Lashley (1929) interpreted it to mean that cortical tissue, in addition to any specific functions it might have, also possesses general, nondifferentiated functions which it shares with other areas of the cortex. He made mass action into a conceptual property of the cerebral cortex. Hunter and others, however, immediately pointed out another interpretation, that one might expect mass-action results without a concept of mass action. The results might be simply the statistical effect of discrete sensory deprivations.

Supporting this point of view are the studies in which animals have been deprived of various sensory cues. In one (Honzik, 1936), several combinations of sensory deprivation were tried; blindness alone; blindness and deafness; blindness and anosmia; and blindness, deafness, and anosmia. These produce considerable retardation in learning. Blindness alone causes appreciable effect; blindness combined with deafness or anosmia causes even more; and an animal that is deaf, blind, and anosmic shows practically no learning at all, even in a reasonably easy maze. Since peripheral sensory deprivation retards learning, does not cortical injury in

various sensory areas cause a similar effect for the same reason?

There can be no doubt that this interpretation is in part true. Animals use many cues in a maze. If all are available, they pick and choose the ones they will use. If a few are taken away, they can still get along reasonably well; but, when too few cues are available, their ability to learn is injured. And we know that only through the cortex can certain cues be utilized.

But, granting that removal of parts of the cortex is equivalent to taking away cues that are needed in learning, there is still the question whether the facts of mass action are entirely accounted for in terms of sensory deprivation. To test this question, Tsang (1934) devised an experiment in which he compared the effect on learning of removing the visual cortex with the effect produced by blinding the animals. If mass action is a factor operating in addition to sensory deprivation, the animals with cortical lesions should be more affected than those blinded. That was the finding in the experiment. He showed that removal of the visual cortex, in addition to blindness, caused more retardation than did blindness alone.

Tsang's data raise certain questions, however. In his effort to remove completely the visual cortex, he made relatively large lesions which, on the average, invaded other cortical regions in addition to the striate area itself. We do not yet know just what these areas outside the striate area do. Electrophysiological evidence indicates that they are secondary visual areas of some sort (see Woolsey, 1947). Homology with the primate cortex indicates that they correspond to one or both of areas 18 and 19, which are concerned apparently with a system of spatial coordination, tied in with vision but not restricted entirely to vision. So there is the possibility that the greater effect of removal of the visual area is due to involvement of other areas which have their own specific functions in learning.

To control this possibility Finley (1941) carried out another experiment similar to Tsang's but in several respects more thorough. In doing so she made sure not to make lesions outside the striate areas. Since cortical operations in the rat are by no means precise, the result was that most of her lesions did not take out all the visual area. Thus, though the visual cortex includes about 20 per cent of the cortex, her lesions averaged only about 10 per cent. Tsang's lesions had averaged more than 20 per cent. Finley found no mass action. Her rats with cortical lesions got along better in learning than did blinded rats. In experiments in which visual cues were not necessary for maze learning (in the dark), her operated animals were just as good as the normal animals.

This might seem to settle the issue against mass action. Not satisfied with Finley's results, however, Lashley (1943) repeated the experiment, attempting to make his lesions small. He again found evidence of mass action. But again his lesions were too big. Though not so large as Tsang's, they covered slightly more than the area of the visual cortex, and many of them ran well over into adjacent areas.

As matters stand at present, it is not possible to make a final decision about mass action. Further experiments are called for. It would be helpful if we knew about the functions of areas adjacent to the visual cortex. That might resolve the issue as to whether running lesions over into these areas is responsible for the difference in results. Another possibility is a comparison of lesions of approximately the same size made entirely within the visual area with those made adjacent to the visual area to see whether those extending into adjacent areas, though of the same size, are more deleterious to learning than those within the striate area. Specific comparisons of this sort have not yet been made.

Visual Selection

We have previously reviewed the role of the striate cortex in the ability of the rat and higher animals to discriminate patterns. The striate cortex, and that area alone, is essential for such ability. There is another aspect of visual detail discrimination that is of interest. This is visual equivalence.

Lashley (1938*b*) has made a thorough study of the learning of detail discriminations in the normal rat. He used a great variety of visual patterns with all sorts of details in them that could be used by the animals to make the discrimination. After learning, the animals were tested with various patterns that had in them certain elements of the original patterns. By finding out which patterns were discriminated—which ones were equivalent to the ones originally learned—he could determine the parts of the patterns that had been selected as cues in the original learning. Lashley concluded that abstraction of certain details, and the neglect of certain others, is fundamental to the normal learning process. Some animals selected one detail, some others.

To sum up his results and conclusions, it is best to quote directly from Lashley:

Discrimination was found to be based upon the abstraction of certain general properties of the figure which are then recognized in non-identical figures. Ease of discrimination depends upon the presence of certain relational properties, such as predominant direction, in the figures. Differences in the ease of discrimination and recognition of different figures indicate that the rat's visual system functions most efficiently in spatial orientation—the recognition of relative distance and direction—and that the identification of objects or forms, though possible, is secondary to a system of space coordinates. [1938*b*, pp. 187-188.]

Other studies of visual equivalence in complex visual forms were made by Maier

(1939). He found that different rats learned different things when there were several possibilities of reacting to cues in the visual patterns. In general, however, if they could, the rats chose to rely on intensity differences. They could and would sometimes use size differences, independently of intensity differences. And sometimes they chose some absolute property of one of the stimulus cards.

After this initial study of the equivalence reactions of the normal rats, Maier went on to study the effect of cortical injuries (1941). He used a standard pair of cards for original learning, then constructed a series of other cards to use in equivalence tests. From the scores on the equivalence tests he could determine what factors the animals had used in their original learning. Also, the percentage of cards that were equivalent for a rat could be used as the rat's index of visual equivalence. Two results stand out in Maier's study of cortical injury: First, the equivalence scores of animals decreased simply as a function of repeated testing. That is to be expected because equivalence cannot be run without involving some kind of learning or change of response on the part of the animals. Second, however, the effect of cortical injuries was to increase the equivalence reactions of the rats, an effect directly opposite to the effects of repeated testing. This increase in visual equivalence in operated animals occurred for animals whether or not the lesion was in the visual area. Wapner (1944), in a similar but more extensive study, got similar results. Equivalence reactions were increased after brain lesions and decreased with repeated testing. He did not find any correlation between the size of the lesion and the equivalence scores (though Maier did). He was able to show that the equivalence reactions were due to the rat's using some combination of intensity and size. The intensity factor became less important on retesting and more important as a result of operation.

LOCALIZATION OF MEMORY FUNCTIONS IN THE BRAIN

There is a vast literature concerning memory losses in human beings suffering lesions of the brain. As one might expect, most of the studies were conducted under clinical conditions in which it is hard to get either adequate tests of the psychological deficit or precise data on the parts of the brain affected. We shall take a brief look at this material later in this section. Several investigators have realized that it would be valuable to conduct well-controlled studies of the brain localization of memory functions in those primates that resemble man most closely in brain structure and mental capacity. There are now several such studies. The majority of them, it turns out, have to do specifically with functions of frontal lobes, and we shall, therefore, take them up in a special section.

Prefrontal Functions

Clinical observations of the effects of removal of the prefrontal lobes have been on record for many years. In the 1930's, however, a special interest in the prefrontal areas began to grow up. This was sparked by clinical reports that the removal of these areas could be used as therapy in certain kinds of psychotic cases—a practice widely applied in later years. Moreover a series of experimental studies with monkeys was begun that pointed to special functions of the prefrontal areas in memory.

Delayed response. Jacobsen's studies (1935) with monkeys have now become classic. He used the delayed-response test that had been developed earlier by Hunter and others. Monkeys were shown where food was hidden under either the right or the left of two cups, then were forced to wait several seconds before they could reach for the cup, remove it, and get the food. Jacobsen's findings were very simple. Normal monkeys could delay for 30 seconds without much difficulty and still select the correct

cup. Monkeys with bilateral lesions of the prefrontal areas could not solve the delayed response if required to delay more than 1 or 2 seconds.

Jacobsen's study and others showed that this loss was a characteristic function of the prefrontal areas. The removal of these areas did not affect learning or retention for simple visual discrimination habits or for simple problem boxes. But capacity for delayed memory depended on the prefrontal areas. Jacobsen and Elder (1936) demonstrated that this capacity did not depend on temporal lobe lesions, and Jacobsen and Haslerud (1936) also found no effect of motor or pre-motor lesions on the delayed response.

These results made it appear that the prefrontal areas function in immediate memory. Jacobsen and others suggested that other disturbances of more complex memory functions (see below) could be broken down into one simple disturbance — of recent memory. That the matter is not so simple as that, however, has been well demonstrated by a series of recent experiments.

The memory trace. One possible interpretation of the memory deficit in prefrontal lobectomy could be made in terms of a waning of the memory trace. The trace of a memory might fade away more rapidly in the prefrontal animals than in the normal animals. To test this possibility, Finan (1939) ran prefrontal monkeys in several kinds of learning problems in which memory traces had to last some time in order for the animal to make the correct choice. In one problem, monkeys had to shuttle from one grill to another for several seconds after a signal had been presented. In another they learned a temporal maze in which one route took a longer time than the other. Both prefrontal and normal monkeys solved these problems, though they could not solve the delayed response. Finan concluded that the prefrontal monkey had no basic disability in holding memory traces. Whatever was wrong in the delayed reaction must have had some other basis.

Attentive functions. A second possibility is that prefrontal animals have difficulty in establishing the 'correct connection' in the delayed-response situation, that they do not note well where the food is placed to begin with and therefore have nothing to remember during the delay interval. This factor is probably not the whole story, but many experiments indicate that it is of some importance. In another study, for example, Finan (1942) gave the monkeys pre-delay reinforcement. He let them get food in the correct place before the delay as well as after it. With this procedure prefrontal monkeys succeeded in solving the delayed-response problem. In fact, one prefrontal animal could delay for several seconds on the Jacobsen nonreinforced procedure if it had first had training with pre-delay reinforcement. This kind of result points to a difficulty in 'attention' in the prefrontal animal, a difficulty in noting the original relation between the food and the correct cup.

Supporting this interpretation is another study by Wade (1947), who was able to get prefrontal monkeys to solve the delayed reaction without pre-delay reinforcement by keeping them under light sedatives (nembutal or Dial) while working the problem. The sedative apparently slowed the animal down and let him pay more attention to the placing of the food under the correct cup. At any rate, prefrontal animals under sedative could solve the delayed-reaction problem. Again, as in Finan's case, one of the animals was able to continue solving the problem after it was returned to the normal procedure without sedatives.

Another experiment (Spaet and Harlow, 1943) using, in effect, pre-delay reinforcement also showed positive solution of the delayed-reaction problem by monkeys. In this case, a matching-from-sample technique was used. A sample object was presented to the animal and under it was placed food, which the animal was allowed to get by shoving aside the sample object. Then, after a delay, two dissimilar objects were pre-

sented, one exactly like the sample. The prefrontal animal, like the normal one, could pick the correct one. This again points to the ability of the monkey to solve the problem if he is made to pay enough attention to it.

Although Jacobsen's original results have been confirmed many times, it is possible, apparently, for some monkeys to solve the delayed-reaction problem without pre-delay reinforcement and without sedatives. Campbell and Harlow (1945) report that two out of six prefrontal monkeys were eventually able to solve a delayed reaction when they used a method essentially the same as the original Jacobsen technique.

An experiment by Malmo (1942) also points to some disturbance in attention in prefrontal animals. He used the Jacobsen technique (no pre-delay reinforcement) but shut off all lights in the room during the delay interval, then turned them on again at the end of the delay. Under these conditions, prefrontal animals could solve the problem. Attention was apparently a crucial element in the problem.

In fact, all these results seem to show that the prefrontal monkey has difficulty with attention. More specifically, it would look as though there is greater interference from other stimuli and other processes than in the normal animal. Anything that cuts down distractibility or interference, like shutting off the lights or slightly drugging the animal, increases memory ability. And anything that combats interference and forces attention to the task, such as pre-delay reinforcement, assists memory.

That there are disturbances in attention in prefrontal animals is shown in several other types of experiments. In visual discriminations, for example (Harlow and Dagnon, 1943), although the animals can learn and master all ordinary discriminations, there are some signs of deficit. A thorough analysis of their performance on visual discriminations indicates that they make more errors than normal monkeys. Then, when

one attempts to reverse the problem by making the correct stimuli incorrect and vice versa, prefrontal animals make more errors than normal ones in a ratio of about four to one.

To be mentioned finally is a rather simple test that also indicates difficulty in attention (Harlow and Johnson, 1943). It was almost a reaction-time test. A piece of food was exposed to the animal for a given number of seconds; if he did not take it in the time allowed, he lost it. Both normal and prefrontal animals can make the response within all reasonable time intervals, but there is a considerable difference in success when the interval is just 1 second long. Normal monkeys can react within 1 second; prefrontal animals cannot.

Other Memory Functions of the Prefrontal Areas

There are several other kinds of memory functions that have been studied in relation to the prefrontal areas. Both rats and monkeys have been used as subjects. It is hard to interpret the findings because the details of the various problems are different, and we do not know how to break them down into the psychological factors involved in each of them. It is well, therefore, not to attempt an interpretation but simply to review the facts.

Delayed alternation. There are two experiments in which delayed alternation has been studied. In each of them, the correct response for the rat, after a delay of several seconds, was to make a turn opposite to that made before the delay. In an experiment by Loucks (1931), the capacity for delayed alternation survived cortical lesions in the middle and posterior parts of the rat's cortex, but it was abolished by lesions in the frontal third. In another experiment that took advantage of these spontaneous alternations of rats (Morgan and Wood, 1943), a similar result was obtained. Lesions in the prefrontal cortex always reduced considerably the capacity for delayed alternation,

whereas those in the back part of the brain did not.

Anticipatory functions. Another experiment with rats shows the localization of some sort of function in the prefrontal regions of the rat's cortex (Stellar, Morgan, and Yarosh, 1942). In a maze consisting of a long runway from which six alleys led off to the left, the rats were supposed to turn left at the fourth alley to obtain food. The maze was rotated in the room from time to time in order to eliminate the use of exteroceptive cues. Normal animals were compared with operated animals having lesions in various parts of the cortex. Although the results are not entirely clear-cut, the removal of prefrontal areas most severely and most consistently damaged the capacity to solve this problem. In another experiment (Epstein and Morgan, 1943), prefrontal rats lacking control lesions in other parts of the cortex showed a consistent and complete loss of the anticipatory goal gradient (see Hull, 1934) whereas the goal gradient of speed of locomotion was not affected.

Complex problems. In some of the studies on prefrontal functions in primates, learning problems have been used in which the solution calls for more than one act to be performed in a correct order (Jacobsen, 1935). In one problem, for example, the animal is required to pull a rope, push a lever, and undo a latch, in that order. In another he is required to respond to three different platforms in the correct order. In a third the monkey must use a short rake in order to secure a longer rake that will enable him to pull in food that is placed at a distance outside his cage. The problem may be compounded in complexity by increasing the number of rakes that must be obtained successively in order to get food. The results on all these problems can be summarized very simply: the animal with bilateral extirpation of prefrontal areas is unable to solve them. The prefrontal monkey can learn to perform the individual acts necessary for the solution, but it cannot perform them in the

correct order when a series of them is required for solution.

Memory Functions of Other Cortical Areas

For many years there have been wide differences of opinion about the localization of memory functions in man. There have been extreme localizationists, like Henschen (see Teitelbaum, 1943), who argued that each kind of memory can be localized on some rather specific area of the cortex. At the other extreme are writers like Goldstein (1944) who recognize practically no localization of memory functions but hold that any memory is a function of the whole cortex.

The difficulties lie both in the data and in their interpretation. Often the extent of damage to the cortex in human cases is not known, and systematic tests of memory deficit are usually lacking. Even when there is a serious attempt to make careful measures, it is not certain that the classification of memory disorders is a proper one to apply to cases of cerebral damage. In addition to difficulties in obtaining good data, there are often quite different interpretations of the same facts. The data, for example, that Henschen used to support extreme localization were analyzed again by Teitelbaum (1943) with rather different interpretation.

A widely used classification of memory disorders in man is as follows. Memory disorders involving language are called *aphasias*. These, in turn, are divided into two types, receptive aphasias and motor (or expressive) aphasias. Nonlinguistic memory disorders are divided into two categories, the *agnosias*, which are nonlinguistic disorders of perception, and the *apraxias*, which are nonlinguistic disorders of memory for motor acts.

Visual agnosia. There has been relatively little work with complex memory functions in the primates below man. Much can and undoubtedly will be done, but it will require new techniques and extensive training procedures. In addition to the studies of learning and retention of rather specific discrimi-

nations and skills discussed in an earlier section, there is one case of visual agnosia in monkeys that is of interest and importance (Klüver and Bucy, 1939). Lesions in the temporal lobes of monkeys produce a variety of symptoms, some of them not related to memory, but one of them is a 'psychic blindness' or visual agnosia for all sorts of objects. The monkeys do not seem to recognize even food objects by sight but must taste and smell and bite them in order to know whether or not they are edible. Preliminary analysis of the brains indicates that there is no primary visual lesion and that the memory deficit is due to cortical destruction in the temporal lobe.

The rest of the data to be reviewed briefly come from human cases. Though many investigators have believed in rather extreme localization, such views have tended to disappear. Weisenberg and McBride (1935), who made a study of a series of cases, came to the conclusion that receptive disorders were primarily localized in the posterior part of the cortex, and that motor memory disorders were primarily associated with anterior lesions — as one might expect from the general organization of the cortex. But beyond that they do not support a very specific localization of kinds of memory in different areas.

Later attempts to wrestle with the problem have taken a middle course that makes some sense out of the data and promises some possibility of arriving at a systematic notion of how the cortex works in complex memory. Lashley (1937) has proposed that different areas of the cortex have relatively specific functions in memory, but that these functions cut across any particular kind of memory test. He suggests that some areas are concerned in spatial aspects of memory, others in intensive aspects, and so on. Any particular memory test that we ordinarily use, however, is not a pure test — it does not measure the factor, and only the factor, that might be localized in any given area. Lashley proposes that we might find localization

in terms of memory factors (cf. Thurstone) but not in terms of particular memories.

A little different approach, not incompatible with Lashley's, is that of Teitelbaum (1941, 1942, 1943). He has gone over the data of many other workers and in addition has carried out some ingenious experiments comparing psychogenic amnesias (produced by hypnosis) with organic amnesias due to brain lesions. He suggests that there are primary focal areas for different memory functions but that we do not see particular memory losses localized in these areas because there is an interdependence of memory functions. Thus there is a focal area in the temporal lobe, near the acoustic area, in which we tend to get an auditory aphasia. But we find other aphasias and other memory disorders, he suggests, because the ability to understand spoken words is also involved in other aspects of linguistic memory.

This is not the place to go into an extensive review of the vast literature on this subject. The views of Weisenberg and McBride (1935), Lashley (1937), and Teitelbaum (1942) point the direction in which we may finally make some interpretation of localization of functions in the cortex. The interested reader should turn to their discussions and to the bibliographies they cite. Here let us simply note that there is no simple localization of particular memories in different areas of the brain. We may eventually find, however, that *factors* are localized in particular areas but that each factor is involved in several kinds of memory.

Speech and Language

GEORGE A. MILLER

Harvard University

Verbal behavior proceeds word by word. Talking, writing, reading, listening are all embedded in the time continuum. But verbal behavior is not the simple function of time that makes it possible to predict the behavior exactly from one moment to the next. If a man's words could be predicted in advance, he would not need to speak them. On the other hand, verbal behavior is not like the gambler's die, nor like the urn full of marbles that the statistician uses to discuss the probability of equally improbable events. It is a function lying somewhere between the completely determined and the completely random—the connections between successive events limit the range of possibilities, but they do not hold the events strictly to a single path. These connections constitute what we call the verbal context.

In a single chapter it is impossible to treat adequately the entire field of speech and language. In fact, such a treatment hardly seems necessary, for good reviews of many areas are already available.* The following

This chapter was prepared at the Psycho-Acoustic Laboratory, Harvard University, under contract with the U. S. Navy, Office of Naval Research (Contract N5ori-76, Project NR142-201, Report PNR-77).

* The problem of speech development has been discussed thoroughly by McCarthy (1946). Physiological aspects of phonetics are reviewed by Russell (1931), and even Scripture (1902) is not completely out of date. Katzenstein (1930) gives a comprehensive survey of the experimental techniques and procedures, and Negus (1929) discusses the larynx. Acoustic aspects of phonetics

discussion will restrict itself to the subject of verbal context. The relations among successive verbal responses pose problems that range from phonetics through the psychology of thought, and a consideration of contextual dependencies reveals indirectly many of the crucial aspects of verbal behavior.

A DEFINITION OF VERBAL CONTEXT

Context is usually defined by psychologists to include the totality of conditions that affect an individual at a given time. In this sense the word is similar to "frame of reference" or "behavioral environment" or "life space." If material learned in one situation is not recalled until the learner is again in the same situation, we speak of contextual aids to memory. If a gray looks yellow on one ground and blue on another, we refer to

can be found in Fletcher (1929), Paget (1930), Potter, Kopp, and Green (1947), or Joos (1948), and the perception of speech is discussed in Chapter 26 of this volume. Phonetic transcription is treated in Jones (1939), and an Americanized version is given by Kenyon (1932). Philosophical discussions of language are somewhat outside the scope of experimental psychology, but the interested reader will find an excellent bibliography in Morris (1946). Statistical analysis is considered in some detail by Zipf (1935, 1949) and, from a somewhat different point of view, by Gray and Leary (1935). Head (1926) and Weisenberg and McBride (1935) provide detailed treatments of aphasia. Speech pathology is summarized by West, Kennedy, and Carr (1947), and Johnson (1946) discusses the role of language in personal adjustment.

the effects of context on perception. If a situation misleads the subject in the solution of a problem, we often talk of the effects of context upon thinking. This notion of context is so broad as to be almost useless, however, and before we can use the notion, therefore, we must pare it down to fit our particular needs.

Verbal context is less general than context alone. Verbal contexts are the communicative acts that precede and follow the verbal response under consideration, and so the verbal context is limited to the temporal sequence of verbal responses.

What a man says depends upon many factors. Their importance is obvious, and their implications have been discussed in detail by Skinner (1947). In this sense the current state of the man and of his environment forms a large portion of the context of the man's remarks. Viewed in this light, verbal behavior is subject to exactly the same influences as all other behavior, and a discussion of the complete context would be a general psychology that drew upon verbal behavior only for its illustrations. In order to restrict the discussion we shall direct our attention to the influence of linguistic structure upon the form of the verbalization.

The Statistical Approximation to English

In order to illustrate the problem of context we shall borrow a useful device from Shannon (1948).

Suppose that we had no knowledge of English, and that we were presented with a list of all the words in the language and told to compose statements or messages. The best we could do would be to draw words at random from the list. The zero-order approximation to English might run something like this: "nautical pillory alas prolix temporal depraved migrates irritability callous oil cent," etc. Our employer would probably regard this as a poor performance, but in order to improve it we need more facts about the language. Suppose we are provided with a statistical tabulation, like those

of Dewey (1923) or Thorndike and Lorge (1944), that tells how often each word is used in normal discourse. We now select words according to their relative frequency of use, and so produce a first-order approximation that might read, "situation our describe the the of however pattern before test is excess in day if to greater the," etc.

The first-order approximation is nothing to be proud of, so we ask for further data. If we select a certain word, what words might reasonably follow it? We need a tabulation of pairs of words according to their relative frequencies of occurrence. With the half-million words in the *Oxford English Dictionary* we could construct (500,000)² pairs, which makes the job discouraging. But suppose the information is available. We then draw a pair and discover we have the words "they are." Next we take all the pairs beginning with "are" and draw one of them. "Are here" turns up, and our message now reads "they are here." Then we draw from the pairs that have "here" as the first word, and so proceed to construct the message. This second-order approximation might turn out to be, "they are here is not large feet are the happy days and so what is dead weight," etc.

The improvement is enough to encourage us to go on to sequences of 3 or 4 or more words. For a fourth-order approximation we might start with "we are going to," then draw from the set starting with "are going to" and obtain "are going to see," and so proceed to construct "we are going to see him is not correct to chuckle loudly and depart quietly for home," etc. Higher-order approximations to English do not qualify as great literature, but they come close to something somebody might say, given the proper situation. It would be interesting to compare these higher-order approximations with the speech of aphasics or psychotics. A fourth- or fifth-order approximation might be mistaken for automatic writing if it were not for the strong perseverative tendencies in such productions.

Observe what has been done in order to increase the credibility of this imitation English. The necessary information is statistical and consists of the relative frequencies of occurrence of units or sequences of units. The choice of the word as the unit in this process is not crucial, for the same thing can be done with the 26 letters of the alphabet and a space.

We have, therefore, a method for generating statistical approximations to English. The rules of formation require that each unit be selected on the basis of its probability of occurrence after the preceding n units. Viewed from the statistician's side we have a time series with a alternatives at each point but with dependent probabilities of occurrence. The pattern of dependent probabilities — the statistical relations among units — provides a statistical definition for verbal context.

The Amount of Information

Rather than work with a set of 500,000 words, or of 26 letters, consider a very simple example with only two alternatives, A and B . Each alternative might be assigned to one of two possible events. Then it is possible to communicate about the two events by using one of the two symbols, and the person who receives the symbol will be able to make a *decision* between the two alternatives. If four events must be represented, we would have to use combinations, AA , AB , BA , and BB , to represent them. With sequences of three symbols we can represent eight events, and in general a^n events can be represented by sequences of n symbols selected from a alternatives.

If a listener recognizes, as Seashore and Eckerson (1940) say he might, 150,000 words, and if we speak in 10-word sentences, there are $(150,000)^{10}$ or about 10^{52} different events that can be represented, *if we can select each word independently of every other word*. We could, with this language of independent words, convey in 10 words a staggering amount of information, enough

information to enable the receiver to select one from among 10^{52} possibilities. Obviously, English does not work this way. Dependencies among successive words reduce the number of possible sentences and so reduce the number of alternatives that can be represented. In a very real sense, therefore, contextual restrictions reduce the amount of information that can be conveyed by a sequence of n symbols.

We can represent a sequence of dependent probabilities by a discrete Markoff process. Imagine two urns, both filled with black and white marbles, but with different proportions in each. The probability of drawing a white marble from urn I is $p_w(w)$, and the probability of drawing a white marble from urn II is $p_b(w)$. We play the game as follows. Each time we draw a white marble from either urn, we draw next from urn I. Each time we draw a black marble from either urn we draw next from urn II. Thus $p_w(w)$ is the probability that, once we have drawn a white and so must draw next from urn I, we will draw next a white. The probability of drawing a white is therefore different if we have just drawn a white, and so must draw next from urn I, than it is if we have just drawn a black and so must draw from urn II.

The urns represent the different "states" the process can get into; that is to say, they represent the cumulative influence of the preceding events. The model can be generalized by increasing the number of urns and the rules for drawing from them to represent cumulative influences extending over any length sequence with any number of differently marked marbles.

Here we have, then, a statistical model to represent the sequential dependencies observed in human speech. Once we have said certain words, grammar, usage, and sense restrict the range of possible continuations and make some possibilities more probable than others.

By calling the successive items in the sequence "symbols" we imply that they repre-

sent something and carry a certain amount of information. We can quantify the information per symbol in a convenient manner if we assume it is proportional to the logarithm of the number of possible alternatives. If there are a alternatives, each symbol in the sequence carries an amount of information proportional to $\log a$, and a sequence of n such symbols in a row would carry an amount proportional to $n \log a$. The value of $\log a$ — the information per symbol — can be expressed in terms of probabilities. If all alternatives are equally likely, then $p = 1/a$, and $-\log p = \log a$.

As we have seen, however, the alternatives are not always equally likely, and in order to take this situation into account Shannon (1948) writes the equation

$$I = -k \sum_1^a p_i \log p_i$$

where I is the information per symbol, p_i is the probability of occurrence of the i th of a alternatives, and k determines the unit of measurement. This equation represents the "expected value" (mean value) of $\log p_i$.

In a sequence of symbols the distribution of p_i will, if successive symbols are not independent, vary according to which symbols have preceded. This additional complication puts us into the situation described above by the Markoff process. There are a finite number of states that a Markoff process can get into, and the equation tells us how to compute the amount of information per symbol for any particular state. To represent a sequence of changing states, therefore, what we need is the average information per symbol, where the average is taken over all the states and weighted according to their probability of occurrence. This is given by

$$I = \sum_j P_j I_j = -k \sum_{i,j} P_j p_j(i) \log p_j(i)$$

where I is the average information per symbol, I_j is the information of a symbol generated when the process is in state j , P_j is the probability that state j will occur, and

$p_j(i)$ is the transitional probability that when the process is in state j the i th of the a alternative symbols will occur. According to Wiener (1948) this formulation is different from but substitutable for Fisher's (1946) definition of amount of information.

From the equation we see that there is no information in a message if there is only one alternative possible in each of the states, for then $p_j(i)$ is 1, and $\log 1$ is zero. If the message can be predicted exactly in advance, then the message contains no new information. At the other extreme, the information is maximal if successive symbols are independent and all the alternatives are equally likely. In this case there is only one state and P_j is 1, and $p_j(i)$ is equal to $1/a$. If we substitute these values into the equation we get $(-ka/a) \log (1/a)$, or $k \log a$. Thus for this case the complicated formula reduces to the simple one with which we began.

This definition of information can be crudely illustrated by a comparison of normal and Basic English. Basic uses 850 different words to do the job that a non-Basic writer might need 10,000 words to do. To make the very simplest comparison, assume that all words are equally likely and independent. Then the information per word in Basic is proportional to $\log 850$, and in normal English it is proportional to $\log 10,000$. How long would a Basic text have to be in order to represent the same amount of information as a non-Basic text? The answer is given by the ratio of these two logarithms, and we conclude that about 1.36 words drawn from the limited vocabulary of Basic English are needed for every word drawn from the larger vocabulary of ordinary English. In practice Basic can improve this ratio by judicious editing, and since Basic words are short the number of pages required for a novel might be quite comparable for the two languages. Critics of Basic have complained that it seems verbose and roundabout, but an increase by a factor of 1.36 may be a small price to pay for the savings obtained in learning the vocabulary.

The statistical model is a useful one. It enables us to represent the statistical relations among the component symbols of a language and to state in a quantitative way how these relations affect the amount of information—the number of decisions per symbol—the language can convey. The idea that the amount of information in a sequence of symbols is a function of the number of possible alternative sequences of symbols says both a little more and a little less than we ordinarily mean by information. Once the quantitative definition becomes familiar, however, it is very convenient to judge what a man says against the yardstick of all the things he might have said but didn't.

THE EFFICIENCY OF THE SPEECH MECHANISM

A message is a sequence of events (symbols) strung together in time according to a pattern. The most widely used generator of such events is the human larynx, and so we shall examine its capacities and limitations for producing messages. We could perhaps examine the flagman's arms or the typist's fingers with the same idea in mind, but these message generators are of secondary importance.

Rate of Production of Speech Sounds

In order to estimate maximal articulatory rates, Hudgins and Stetson (1937) asked talkers to repeat simple syllables as rapidly as possible in rhythmic groups. "Tat, tat, tat, *tat*," for example, was used to measure the speed of articulatory movements made with the tongue. Their results showed that 8.2 syllables per second could be produced with the tip of the tongue, 7.3 with the jaw, 7.1 with the back of the tongue, and 6.7 with the velum and with the lips. Kaiser (1934) has pointed to the relation between speed and the innervation of the various muscle groups. He found that muscles of the face and lips, innervated by the facial nerve,

could be moved only 2.5 to 3 times each second. To produce a more rapid series of labial sounds the talker relies upon the more rapid movements of the jaw, innervated by the trigeminal nerve, to carry the lips along. The tongue, supplied by the hypoglossal nerve, is clearly the most mobile articulator.

These maximal rates cannot be maintained indefinitely, for speech is an 'overlaid' function of the respiratory system. The talker must stop to breathe. In quiet respiration the *I-fraction*—the duration of inhalation divided by the duration of the entire respiratory cycle—averages, according to Fossler (1930), between 0.40 and 0.45. Thus the top rate would be cut in half were it not for the decrease of the *I-fraction* to 0.16 during speech.

The maximum speed may also be slightly less when articulatory positions are changed for each syllable. If we take 7 syllables per second as the average of Hudgins and Stetson's data, subtract 1 syllable per second to leave time for breathing and 1 to permit changes in articulatory position, we arrive at 5 syllables per second as a reasonable estimate of the speed at which the speech musculature works.

With the aid of the tabulations given by French, Carter, and Koenig (1930) we can estimate the average number of speech sounds contained in 5 syllables. Of all syllables tabulated, consonant-vowel-consonant (CVC) syllables formed 33.5 per cent, CV 21.8, VC 20.3, V 9.7, CVCC 7.8, CCVC and VCC both 2.8, CCV 0.8, and CCVCC 0.5 per cent. These figures indicate that the average syllable must contain approximately 2.5 speech sounds. Thus 5 syllables per second represents 12.5 speech sounds per second. (A similar figure for sounds per syllable is obtained from Dewey's tabulations.)

Number of Different Speech Sounds

If we knew the number of available speech sounds, we could calculate the maximum amount of information carried by 12.5 speech sounds per second. Phonetic transcription

of spoken English can be accomplished with about 40 symbols, 15 for vowels and 25 for consonants. The number varies with the skill and intent of the transcriber, but 40 is a fair average for broad transcription. Table 1 shows the classification of consonant sounds by their place and manner of articu-

whereas p is voiceless. The sounds b and m are formed in the same place and both are voiced sounds, but they differ because b releases the air pressure by a sudden opening of the lips whereas m releases the pressure through the nasal cavity. Other cells of the table can be similarly interpreted.

TABLE 1
ENGLISH CONSONANTS

Manner of Articulation	Place of Articulation							
	Bilabial	Labio-dental	Lingua-dental	Lingua-alveolar	Palatal-alveolar	Palatal	Velar	Glottal
Voiced plosive	b			d			g	ʔ
Unvoiced plosive	p			t			k	
Nasal	m			n			ŋ (sing)	
Lateral				l				
Rolled				r				
Voiced fricative		v	ð (then)	z	ʒ (azure)			
Voiceless fricative	ʍ (whip)	f	θ (thin)	s	ʃ (she)			h
Continuants	w					j (yes)		

lation. The place of articulation is determined by the speech organs principally involved, and the manner of articulation is determined by the movements these organs make. The sounds represented by b, p, m, and w, for example, are called bilabial because they are articulated with the lips. All these consonants are formed in the same articulatory position, but they differ in their manner of production. Thus p and b differ in that b is accompanied by phonation

The classification of English vowel sounds is usually made in terms of the position of the tongue. In this way the back vowels in words like *boot* or *book* are distinguished from the front vowels in *beet* or *bit*. A vowel diagram with key words is given in Fig. 1. Intermediate positions on this diagram are often encountered in other languages and in the imprecise speech of the workaday world.

The classification given includes 23 consonants and 15 vowels. One of these con-

sonants, the glottal stop ʔ, is not used in normal English speech, but we should probably add two more: tʃ in *choke*, and dʒ in *joke*. This gives a total of 39 different speech sounds. If we assume that these 39 sounds are all equally likely and might occur in any order at a rate of 12.5 per second, the amount of information per second is $12.5 k \log 39$.

Shannon suggests that, when $k = 1$ and logarithms are taken to the base 2, the re-

example, are greatly overworked, and Dewey estimates that 9 sounds form over 50 per cent of normal utterance. The histogram in Fig. 2 represents the results of Dewey's count of the relative frequencies of occurrence of 41 speech sounds. Voelker's (1935) data are quite similar.

The reason for the preference shown for some sounds seems to be that they are easier to produce and easier to discriminate. Note that the first 8 consonants listed by Dewey

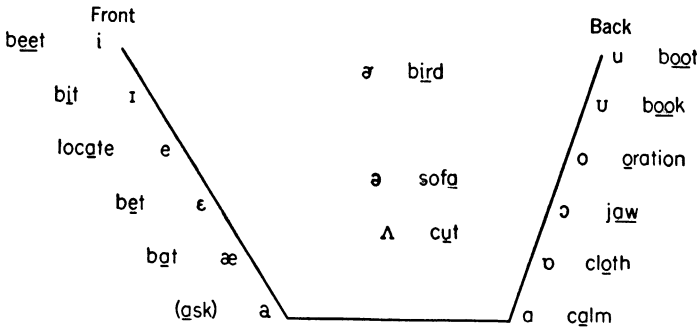

FIG. 1. Schematic representation of the vowel sounds of English according to their place of articulation. Key words indicate the phonetic values of the symbols.

sultant units of information be called *bits*, short for binary digits. A bit is the amount of information necessary for the listener to make a decision between two equally probable alternatives, and 10 bits would be the information required for 10 successive choices between two alternatives. With this unit there are $12.5 \log_2 39 = 67$ bits, or successive decisions, per second. In slightly different words, a talker generating randomly any one of 39 phonemes at a rate of 12.5 phonemes per second might speak any one of 2^{67} (about 100,000,000,000,000,000) different sequences of sounds each second, and the listener who used the information efficiently would be able to select one from among 2^{67} possible referents.

Frequency of Sounds, Syllables, and Words

Obviously the foregoing estimate is astronomically large and completely unrealistic. For one thing, speech sounds do not occur equally often. Some sounds, *i*, *n*, *t*, *r*, for

are lingua-alveolar — produced with the tip of the tongue near the gum ridge. These hard-working sounds are produced with the very agile tip of the tongue while the other articulators remain relatively immobile. The consonants used least are those that require the cooperation of the less agile articulatory muscles. The preference for consonants formed in the same place is convenient for the listener as well as for the talker. Analysis of the confusions made by listeners in articulation tests conducted with nonsense syllables shows that the principal confusions occur among sounds formed in the same manner. Consonants produced in the same place but in a different manner are seldom confused. Thus *p* is often confused with other voiceless plosives, *t* or *k*, but not with the voiced plosive *b*, the nasal *m*, or the continuant *w*, all formed in the same position.

Zipf (1935) has also interpreted phonetic favoritism in terms of articulatory complexity. For example, he argues that a

voiced consonant represents a greater degree of complexity in its production than does a voiceless consonant. (This argument can be disputed. See Lightoller, 1925.) Presum-

based upon the relative number of errors deaf children make in learning the various sounds. Their data for 192 children enable them to rank the sounds in order accord-

FIG. 2. Relative frequencies of occurrence (after Dewey, 1923, p. 125) for the vowels and consonants in English are indicated by the height of the bars. Numbers under the bars indicate the difficulty score developed by Hudgins and Numbers (1942).

ably, voiceless sounds should occur more frequently than voiced sounds. Zipf presents evidence drawn from 12 languages showing that the voiceless plosives, t, p, and k, occur more frequently than their voiced counterparts, d, b, and g.

Hudgins and Numbers (1942) have proposed an independent scale of difficulty

ing to difficulty, and this ranking is indicated by the numbers below the phonetic symbols in Fig. 2. The low numbers indicate the most difficult sounds. A rank-order correlation coefficient of -0.41 was found between the scale of difficulty for consonants and the frequency of use reported by Dewey. The correlation has the expected sign and may

be construed as evidence supporting the notion that our language avoids the difficult phonemes.

It can be shown that the most frequently used sounds are not the ones babies babble earliest or most often. Irwin (1947, 1948) has compiled extensive data on the relative frequencies of the speech sounds as a function of age. In the babbling of 2-month-old babies the glottal plosive ? and the glottal fricative h make up 87 per cent of the consonants, and ε, i, and ʌ comprise 96 per cent of the vowels. As the child matures he employs an increasingly wide range of sounds, and at 2.5 years the distribution is very similar to that for adults. There is no striking correlation between the first appearance of the sound, its eventual frequency of use, and the scale of difficulty.

The effect of phonetic favoritism upon the rate at which the speech mechanism encodes information into speech sounds can be calculated by substituting Dewey's tabulation, Fig. 2, for the assumption of equal probability. The equation, $I = -\sum p_i \log_2 p_i$, along with Dewey's values for p_i (the probability of occurrence of each of the speech sounds), gives approximately 60 bits of information per second. In the sense of the discussion of the preceding section, the values of p_i give us a first-order approximation to the phonetic structure of English. With this closer approximation it appears that the potential amount of information per second is only 60/67, or 91 per cent, of what it might be if English did not favor the easily produced speech sounds. This ratio of actual to maximum information can be conveniently termed the relative information. One minus the relative information is the *redundancy*. For the first approximation, therefore, the redundancy is $1 - 0.91$, or 9 per cent. Our partiality for certain speech sounds requires us on the average to make 9 per cent more sounds in order to represent as many alternatives as could be represented if we used each sound equally often.

The next step in discovering where our potential information capacity is dissipated is to examine the relative frequencies of occurrence of pairs of phonetic symbols. The pairs that occur frequently, like $\delta\alpha$, $\lambda\nu$, m , are those that permit an easy shift in articulatory position. Pairs that are seldom or never used involve difficult articulatory transitions, and preferences for certain sequences are even more striking than preferences for certain phonemes.

French, Carter, and Koenig show that we use a wider variety of consonants at the beginning than at the end of our words, and that there is a tendency for division of labor. Some consonants (w, j, h, b, g, f, p, δ , and θ) are used principally at the beginning, others (η , z, v, r) principally at the end of words. The division is not perfect because some consonants (t, n, l, m, d, k) are handy on either end of a vowel, and others (j, ft, d₃, ζ) are seldom used in any position. The strongest evidence for preferred sequences comes from the casual observation that consonants and vowels tend to alternate in speech. This tendency is so marked that one is tempted to think of the laryngeal and articulatory muscles as antagonistic muscle groups.

Unfortunately, however, all we have are hints, for the actual frequencies of phonetic digrams have not been tabulated. The best we can do is to make some approximations based on Dewey's count for syllables. In a sample of 100,000 words Dewey found 4400 different syllables, and 4500 seems a safe estimate for the number of syllables in English. Next we fit a curve to the distribution obtained ($p_i = 1/8.4r_i$ gives a fair approximation, where r_i is the rank of the i th syllable with respect to frequency of occurrence) and integrate $p_i \log_2 p_i$ between 1 and 4500. The result is 9.2 bits per syllable, and, if we continue to regard 5 syllables per second as the maximum rate, this gives 46 bits per second. Apparently the statistical dependencies among the phonemes used to form syllables restrict us to 46/67,

or about 70 per cent, of the information that could be encoded with the same phonemes in the absence of sequential dependencies.

Longer sequences of phonemes can be studied by considering the statistics of word frequencies. Zipf, following a suggestion made by Condon (1928), uses the equation $p_i = 1/10r$ to represent the relative frequencies of occurrence of English words. Thus Eldridge's (1911) count of 43,989 words from

FIG. 3. Frequency of occurrence is plotted against the rank order with respect to frequency for (I) words in Joyce's *Ulysses*, and (II) words in American newspapers. (From Zipf, 1945.)

American newspapers should give 4399 occurrences of the most frequent word, 2199 occurrences of the second most frequent, 1466 occurrences of the third most frequent, etc. The actual results of the count fit rather well, and with a large sample of words it is probably justifiable to use Zipf's equation. Figure 3 shows rank-frequency distributions for Eldridge's data and for a count of James Joyce's *Ulysses* (Hanley, 1937). Zipf's equation is a rectilinear function on these log-log coordinates.

The real difficulty comes when we try to decide the size of the vocabulary from which the words are drawn. The available estimates range all the way from 2822 (the number of different words used in telephone conversations counted by French, Carter, and Koenig) to 500,000 (the number of

lexical units in the *Oxford English Dictionary*). If we assume that their frequency of occurrence follows Zipf's rule, and that the probabilities sum to 1.0, then we must have 22,000 word types, for the definite integral of $1/10r_i$ is 1.0 between the limits of 1 and 22,000. So we integrate $(\log_2 10r_i)/10r_i$ between 1 and 22,000. The result gives 10.6 bits per word.

Just how many words a talker can say per second is also hard to decide. Many of the words are polysyllabic, but the frequently used words are principally monosyllabic. The inverse relation between frequency of use and length is striking in all languages that have been studied, and because of this inverse relation the efficiency of verbal communication is substantially increased. If the average word length is about 1.7 syllables, the talker can pronounce 3 words, or about 32 bits, per second. The maximum efficiency within the restrictions imposed by the phonetic structure of English words, therefore, is about 50 per cent.

Practical Estimate of Rate of Encoding Information

So much for maxima. If we look at the actual performance of human talkers in a conversational situation we find that their rate of encoding information into speech sounds is far below the maximum. To make some realistic assumptions, take the average rate of talking to be about 1.5 words per second, and the speaking vocabulary to be about 5000 words. Under these assumptions a talker could average about 12 bits per word, or 18 bits per second, if the words could be chosen independently and equally often.

We cannot leave it here, however, for words are not chosen without regard to preceding words. If we consider the structure of the language over sequences of several words, the estimate will probably be reduced to about 5 or 6 bits per word. Said differently, a subject shown a sequence of 100 words from everyday English and told to

add the 101st word that might reasonably follow these 100 will have, on the average, the equivalent of 40 or 50 alternatives from which to choose. (The actual number may be larger, but the various responses will not be equally likely.) He will not be free to combine speech sounds at random, or to draw blindly from the dictionary. The range of possible choices will vary widely for different sequences, and 5 or 6 bits is only an average value. After "the man saw the," many possibilities are available, but, after "should I stand up or sit," anything but "down" would represent an unusual choice of words. An experimental consideration of the range of possibilities might well show that some words are relatively free of the verbal context, and that others are relatively determined. The context-free words would be, presumably, the nouns, verbs, adjectives, and adverbs, and these would carry most of the information. The articles, prepositions, and conjunctions would be determined largely by context and so could carry relatively little information.

To summarize, the average talker generates information very inefficiently in comparison with the "physiological limit" that might be obtained. Ease of articulation restricts his choice of phoneme sequences, but the principal limitation is probably the inability of the central nervous system to collect, collate, and pass on instructions to the speech mechanism at a more rapid rate. Instead of choosing freely among all possible words, the speech-producing system cannot do much better than to select one from about 70 possibilities per second. Within this range of possibilities, motivational and environmental variables have room to operate, and with the additional help of these psychological factors it may eventually be possible to make short-term predictions of verbal behavior with considerable accuracy.

The redundancy of our normal speech is not a complete waste of time. The redundancy involved in the contextual clues means that we repeat everything we say, but repe-

tion is our insurance against errors. By using only a small fraction of the available symbol patterns we make it likely that an error will transform the pattern into some highly improbable pattern and thus enable us to detect the mistake. If all possible sequences were used, an error would transform the message into another meaningful pattern, and the mistake would be hard to discover. (For further discussion of this and related topics, see Chapter 26.)

TALKING AND LEARNING

In order to speak a language, a person must know (1) the semantic rules for a large number of vocal noises, and (2) the syntactic rules for stringing these noises together in patterns. These requirements can be stated in terms of the Markoff process used as the statistical model. The model has urns full of marbles, and rules governing the order in which marbles are drawn from the various urns. Similarly, the talker obeys rules that say "having spoken such-and-such words, the next word must be selected from this limited set." A talker who does not know these rules, or who cannot remember from one instant to the next which verbal marbles he has drawn, cannot know what verbal urn to draw from next. If we do not grant these two abilities to our talker, he will not talk sense.

A device to handle information must deal with (1) a variety of different symbols (2) arranged in a variety of patterns. The 40 speech sounds we use could be reduced to 2 if we were willing to use these 2 as we use the *dit* and *dah* of telegraphic code. By stringing these 2 alternatives together in sequences of 6, we would have more distinctions (64) than we can achieve with one of 40 alternative sounds. Communication would be slower, however, and patterns would have to extend over a longer period of time. It is only when we consider the decoding and storage of information that it becomes clear that some combinations of elements and pat-

terns are more efficient than others, and that pattern and range are substitutable only within rather narrow limits.

Since the span of immediate memory is not infinite, the lengths of the patterns we can use easily in communication are limited. When the length of the pattern is limited, it is necessary to increase the number of different components used in the pattern in order to increase the range of differentiations the language can make. Forty speech sounds combined in patterns extending over approximately 100 successive sounds may be about the most a human being can organize in advance and speak extemporaneously. We can imagine languages with 2 different sounds combined in longer patterns, or with 10,000 sounds in shorter patterns. These imaginary languages could contain as many possible distinctions as does the language we actually use, but they are not designed to hold the information in the form most useful to the human nervous system.

Experimental Studies of Intraverbal Connections

The need for a better understanding of the connections among words has been clearly recognized by the psychologists of language. It is true that some of the early behaviorists — Watson, F. H. Allport, A. P. Weiss, to name a few — had more to say about how our urns get filled with verbal marbles than about the rules for drawing successively from different urns. More recently, however, men like Cofer and Foley (1942), Morris (1946), and Skinner (1947) have carried the analysis further and have outlined a large and important discipline dealing with why words are glued together in some ways and not in others.

It is convenient to refer to the learning underlying the dependencies shown statistically by the name "intraverbal associations," or "intraverbal connections." Such an association or connection means that when one symbol occurs there is a greater than chance likelihood that its associate will

follow shortly. There is more than the word-counters' evidence to make the existence of such connections seem probable. Some of these sources of evidence will be briefly reviewed.

1. *Word-association tests.* One of the oldest and simplest methods of revealing intraverbal connections is the word-association test made famous by Jung (1918). In the usual form of the test the subject hears a stimulus word and is told to respond with the first word that occurs to him. The responses obtained show a large overlap in the associations of different people. For example, Kent and Rosanoff (1910) found that 650 out of their 1000 subjects responded to the word "lamp" with the word "light." Most words show less uniformity, but in every case a limited number of popular responses can be defined. Although the instructions impose no sentence structure on the responses, the distribution of relative frequencies is quite similar to that obtained for words in sentences (Skinner, 1937). There is a limited range of likely responses, and within this set some are used more than others.

Intraverbal connections, as revealed by word-association tests, are well standardized within a given linguistic group. Uniformity is even greater if the responses from members of a single professional group are compared. Foley and Macmillan (1943) found that lawyers respond more like other lawyers than like doctors. Among members of the same family the correspondences are even more striking, especially between parents and their children of the same sex (Jung). The children differ more from their father than from their mother. In short, the more the subjects' past experiences with language overlap, the greater the similarity of their word associations.

There have been many attempts to classify word associations, but the responses are so various that no single classification has gained universal favor. Antonyms (wet-dry), synonyms (pain-hurt), subordinates

(fruit-apple), coordinates (apple-peach), superordinates (apple-fruit), assonants (pack-tack), completions (forward-march), egocentrisms (success-I must), syntactic changes (run-ran), and many other classes have been distinguished. The dimensions along which intraverbal connections get formed are very numerous.

2. *Sentence-completion tests.* A subject asked to complete a sentence has a slightly better defined task, but he may have to contribute a more extensive sample of his verbal behavior. Like word associations, incompleting sentences have proved a useful tool for the clinical psychologist.

In one form of the test a group of sentences that have a certain word in common are selected. This word is deleted, and the subjects are asked to read the sentences one at a time and to guess the missing word. Commonly used words require only one or two sentences before the accumulating context makes the correct intraverbal connections obvious. Infrequently used words are more difficult. Analysis of the responses that precede the final decision reveals words that have intraverbal associations very similar to those of one another and to those of the missing word. For example, in a group of sentences where *sorrow* had been removed, readers substituted *anger, hatred, loneliness, longing, confusion, destruction, horror, fear, grief, pain, anxiety, doom.* When the missing word was *red*, the presolution responses included *pale, bright, hot, large, green, brown, etc.*

3. *Conditioned responses.* Several investigators have reported that a response conditioned to an object generalizes to the name of the object, and that a response conditioned to the name generalizes to the object (Cofer and Foley, 1942). Of more direct concern for us are the studies showing generalization from one word to other words.

Razran (1935) used his salivary reflex to obtain a quantitative estimate of his familiarity with the Russian, English, German, French, Spanish, Polish, and Gaelic

languages. He measured the amount of saliva secreted when the word for saliva was perceived and thought of in each of the various languages. The magnitude of the response varied with his familiarity as measured by reading speed. Encouraged by this result Razran (1939) proceeded to condition human subjects to salivate to the words *style, urn, freeze, and surf.* After conditioning, the subjects were tested with the homophones *stile, earn, frieze, and serf,* and with the synonyms *fashion, vase, chill, and wave.* Their responses showed generalization to the new words, and the generalization was greater for synonyms than for homophones. Essentially the same results were obtained by Riess (1940) with the GSR. Riess' later results (1946) indicate that children tend to generalize more readily to homophones, but this tendency disappears at about 11 years of age.

Diven (1937) asked his subjects to respond as in the word-association test, and to continue free association until told to stop. One of the stimulus words on the list, *barn,* was always followed by shock after the subject had made several responses. The subjects quickly began to show a GSR whenever the word *barn* was presented. This was true for all subjects, although half of them were unable to report at the end of the experiment that *barn* was the critical word. The response to the stimulus word generalized to other rural words on the list, but the generalized responses were smaller in magnitude. Diven's results support the idea that a response conditioned to one stimulus word generalizes to all words intraverbally related.

4. *Transfer effects in memorization.* Quite similar to the conditioning studies are the experiments that explore the effects of one kind of verbal learning on another. Transfer effects for verbal learning have been discussed in Chapter 17, and it is sufficient for our purposes to note that these studies also indicate a highly organized set of intra-

verbal connections. The similarities among the two sets of materials that are learned influence the amount of transfer, and associative spread can be used to gauge the strength and extent of word relations.

5. *Automatic writing.* One of the most dramatic and least explored methods for intraverbal inquiry is usually referred to as automatic writing. In 1896 L. M. Solomons and Gertrude Stein published an account of

6. *Verbal summator.* Skinner (1936) has developed a projective technique for studying the latent verbal responses that would normally be censored and edited before they appear. In a sense the verbal summator is the most free of all free word-association tests, for the stimulus words are not words at all but only faint, mumbled vowels. In his attempt to make sense of these liminal sounds, the subject supplies short statements

FIG. 4. Learning curves for regular and irregular artificial languages. (After Wolffe, 1932.)

their experimental studies of motor automatism. By concentrating on an interesting task while carrying on a dull one, they developed the ability to write sequences of words without having any recall for what was written. Miss Stein often found it sufficient distraction to read what her arm wrote, but following three or four words behind her pencil. These investigators noted a strong perseverative tendency, as if a verbal response had to be 'extinguished' by repetition before another response could displace it.

A sample production: "This long time when he did his best time, and he could thus have been bound, and in this long time, when he could be this to first use of this long time," etc.

Automatic writing may be the result of shortening the range of statistical dependencies and so may give a glimpse of the verbal processes almost completely stripped of their normal contextual determiners.

of his own invention. As in automatic writing, perseverative tendencies are strong.

7. *Artificial languages.* Studies with artificial languages suggest experimental techniques to chart the development of these dependent probabilities. Esper (1925) and Wolffe (1932) taught subjects to identify visual figures by names composed of pairs of nonsense syllables. The figures came in four shapes, and each shape in four colors or sizes. Each shape had its name, each color or size had its name, and the name for the figure was compounded according to the appropriate names for its attributes. To make the situation more closely analogous to language they introduced irregularities—a shape name might be modified slightly when used with one of the color names, but not modified with the other three colors. Figure 4 shows the average learning curves obtained by Wolffe with regular and irregular languages. The more complex dependencies were more difficult to learn.

Learning Meaningful Materials

If subjects come to the verbal learning experiments with an intricate background of response tendencies, their ability to learn new materials must depend in some way upon the degree of correspondence between these tendencies and the statistical structure of the materials to be learned. The materials used to study verbal learning can be considered with respect to the number of different symbols and the lengths of the patterns. We might ask, for example, how to get n bits of information memorized most efficiently. If we used two symbols, 0 and 1, each symbol in the list could carry one bit, but a long sequence of these two symbols would be very difficult to learn. On the other hand, if the n bits are coded into language, the learner's task is to remember which words were chosen. The order of the words requires little additional learning, and the information is mastered much more readily. Learning a new pattern is much harder than learning which items to fit into a familiar pattern.

The meaningfulness of the materials to be learned is one of the most important factors in verbal learning. Whether or not verbal meaning can be identified with verbal context is debatable, but certainly the two have many aspects in common. We might let meaning refer to the totality of conditions affecting the verbal behavior and retain context for the purely verbal environment of the response. Within the narrow frame of verbal learning experiments, therefore, it seems reasonable to speak of nonsense syllables or digits as having little contextual determination and much new information per symbol, and to speak of prose or poetry as having much contextual determination and little new information per symbol. The relative ease of learning prose or poetry reflects a high positive transfer of response patterns, whereas negative transfer is at its worst when the pattern of symbols is arbitrary or unfamiliar.

A notable characteristic of meaningful learning is its selectivity. When we are faced with a problem that demands new information, we do not open an encyclopedia at random and start reading. We seek out the particular passage we need. Similarly, when messages come to us gratuitously, we do not attempt to memorize them all. We learn only those parts that may be of use to us later. Newman (1939) demonstrated experimentally that not all parts of a prose passage are equally important to a learner. His subjects studied stories constructed to include a number of phrases not essential to the plot. The memory was much better for the essential than for the unessential parts. To explain the learning and remembering of meaningful materials Newman concludes that it is necessary to consider the *nature* of the contextual relations. Equivalence, inclusion, superordination, subordination, centeredness, symmetry, etc., can be distinguished. Not all intraverbal connections have the same functional roles, and so long as these qualitative aspects are ignored it is difficult to understand why one part of a meaningful passage is remembered and another forgotten. Postman and Senders (1946) have demonstrated that the subject's set is a powerful determiner of which bits of information are remembered, and that a variety of sets can be used to produce a variety of selections of information.

The selectivity of human learning should not come as a surprise, however. The whole development of our present concept of context and information hinges on this matter of selectivity. A sequence of symbols carries information because it is one selected from a set of possible sequences. In order to represent any particular situation we must figuratively search through this set of possible sequences until we find the particular sequence that does the job. The searching is guided by the motivation, the situation, and the audience. It is natural that this searching and selecting process

should continue to operate during the recall of learned materials.

Readability

How much can a person learn from a paragraph by reading it once? Obviously the answer depends upon what paragraph he reads, for some paragraphs are simple and direct whereas others would tax the wisdom of Solomon. Some symbol patterns present information to the nervous system in a usable form, and others do not.

Difficulty is a dimension of verbal behavior that has received considerable attention. The approach has been to establish relations between the statistical structure of the verbal material and some measure of the reader's success in remembering the contents. The usual procedure is to establish the readability of a passage by the scores on a comprehension test. Various characteristics of the material are then determined, and the results are analyzed in a multiple correlation study.

Gray and Leary (1935) settled on five variables for their predictions: the number of different words, the percentage of uncommon words, the number of personal pronouns, the number of prepositional phrases, and the average sentence length. The multiple correlation of these variables and the criterion was 0.644. Lorge (1944) obtained a multiple correlation coefficient of 0.767 using only three variables: the average sentence length, the number of prepositional phrases, and the number of uncommon words. Flesch (1943, 1946) based his estimate of readability on the average sentence length, the number of affixes (prefixes and suffixes), and the number of personal references. In a later study Flesch (1948) proposed to base "reading ease" on average sentence length and number of syllables per 100 words, and to assess "human interest" separately by an index based on the number of personal words and personal sentences.

These several investigations agree in pointing to two basic variables, and perhaps a third can be added. (1) Long sentences are more difficult than short sentences. (2) Short, familiar words are easier than long, unfamiliar words. (3) Personal references make reading easier because readers are apt to be interested in people. In the first two variables, which all agree are important, we recognize the problems of length of pattern and range of alternatives. Actually the importance of restricting the range of alternatives has been deprecated by Flesch. He feels that the real difficulty with uncommon words is that they are likely to have affixes and so look like one thing while they say something else.

TALKING AND THINKING

The importance of verbalization in thinking is an unsettled issue in psychology. Opinions range from Watson's, who said that thought is implicit movement of the speech musculature, to Wertheimer's, who wrote his penetrating analysis of productive thinking with scarcely a reference to its verbal aspects. Certainly there are individual differences among people in their use of words, images, analogies, etc., for solving problems. The most we can say is that many people converse with themselves, and if they are interrupted they will say they are thinking. These monologues may not constitute all that we want to call thinking, but they are common enough to merit attention.

Determining Tendencies

In the associationistic framework of the early experimental psychology, thought seemed to be the succession of ideas that passed through consciousness. Introspective examination of the process upset this simple view, however, for it became apparent that subjects could arrive at a correct response without any conscious content to report, without any notion of where the response came from. Out of these observations,

which the Würzburg School initiated, grew the long, lively, and fruitless controversy over imageless thought (see Titchener, Woodworth). The positive contribution of the work came via the concept of the set and the determining tendency. According to the Würzburg formulation, the *task* gives the subject a particular *set*, and his set influences his associative sequence by means of unconscious *determining tendencies* that guide the process through to its proper completion.

Watt's (1905) experiments can be used to illustrate the sort of observations that supported the Würzburg formulation. Watt used a variation of the word-association test in which the subjects are told to respond with a word that stands in a certain relation to the stimulus word. If the relation is that of subordination, the stimulus word "animal" might lead to the response "dog." Watt had his subjects pay attention to and report on a small segment of the total process, either the preparatory period, the appearance of the stimulus word, the search for the reaction word, or the occurrence of the reaction word. The surprising result was that little conscious content could be reported during the period of search—the word usually came without hesitation. The experiments were later repeated and amplified by May (1917) with similar results. It was natural to conclude that the preparation during the foreperiod represented the critical part of the thought process. Hence the emphasis on the task and the set.

A process of constrained association, or something very like it, must go on in the extemporaneous patching together of words in ordinary speech. The specific words are seldom chosen before the talker begins, yet they usually occur as they are needed without much conscious searching. The task is to verbalize, the topic provides a set for the talker, and the set determines which response tendencies are weakened and which are strengthened as the verbalization proceeds. In the preceding sections of this

chapter the changing response tendencies were described as an array of probabilities that shifted as a function of the preceding responses. Watt's experiment must reflect a similar array of probabilities—the subject's set is the same as though he had spoken all of a sentence but the last two words. The occurrence of the reaction word should be almost as natural and automatic as the occurrence of a word in a sentence. The determining tendency is made of the same sort of stuff as the transitional probabilities in human speech (cf. Selz).

Syllogistic Reasoning

Since the simple word-association experiment does not produce thoughts for the scientist to study, more complicated tasks are needed. Störing (1908) met the need by introducing the syllogism. He showed his subject the two premises from which a conclusion was to be drawn. The subject read these carefully and gave an introspective account of how he reached the conclusion. For example, the subject would be given

All *i* belong to
the class *o*. All *z*
belong to the class *i*.
Therefore . . .

The subject read the premises, and then introspected, "What are you doing with the second statement? You have to relate it to the first premise. How do you do that? Where was *i* mentioned in the first premise?" He then found the phrase "all *i*," and so went on to see that the *z* belong to the *i*, and therefore *z* is to be put in place of *i*. All this went on without any particular reference to the class *o*.

With syllogistic problems Störing was able to collect extensive protocols. Sometimes the subject visualized the solution; sometimes the conclusion was reached by purely verbal means. The results do not seem to lead to any generalizations about how people think or where successful hypotheses come from, but they show that the laws of

logic are not the laws of thought. The syllogism is a reconstruction of a devious psychological process.

The verbal context has a marked effect upon the syllogizing reasoner, and some conclusions are drawn because the answer 'sounds all right.' For example, one of the premises can be given and the subject asked to continue. What can you say about *B* if you know that all *A* are *B*? Such questions tend to be completed as follows (Wilkins, 1928; Eidens, 1929):

- (a) If all *A* are *B*, then all *B* are *A*.
- (b) If no *A* are *B*, then no *B* are *A*.
- (c) If some *A* are *B*, then some *B* are *A*.
- (d) If some *A* are not *B*, then some *B* are not *A*.

The subjects convert the statements into like statements, and for the letters *A* and *B* the conversions sound plausible. But, if words are properly substituted, the habitual verbal associations make the false conversions sound ludicrous. The person who accepts (a) would never accept "If all dogs are animals, then all animals are dogs." Nor would the person who accepts (d) find it natural to say, "If some dogs are not collies, then some collies are not dogs." The statements rephrased with words are not structurally different — the subject recognizes the conclusion as acceptable or unacceptable, regardless of the logical form. Reverse the substitution, "If some collies are not dogs, then some dogs are not collies," and the conversion is apt to be accepted.

The experiments on syllogistic reasoning are full of demonstrations that the particular choice of words used to frame the question has an important effect upon the verbal reply. Perhaps the best illustration of the way verbal habits lead us astray is to be found in what Woodworth and Sells (1935) have called "the atmosphere effect." To exemplify this notion they point to careless constructions like "The laboratory equipment in these situations were in many instances . . .," where the plural *were* appears

incorrectly because of the atmosphere of plurality created by the two words immediately preceding. Atmosphere effect is another name for intraverbal connections, determining tendencies, or the dependent probabilities of occurrence of verbal units. More specifically, Woodworth and Sells argue that the words "all," "no," and "some" in the premises of a syllogism give a verbal atmosphere that calls for a corresponding conclusion. Sells' (1936) experimental data confirmed this conclusion, and he was able to show that the effect was slightly more pronounced with his bright subjects than with his dull ones. Almost anyone can be trapped into this kind of error. For instance, *POLK* is pronounced *poke*, the *l* is silent, and *FOLK* is pronounced *foke*, also with a silent *l*, and the white of an egg is pronounced . . . ? It is a rare subject that responds "albumen."

In these examples verbal habits operate as a substitute for thought. Habits that function faithfully for the illogical events of daily life are tricked and betrayed by a syllogism. In the realm of logic the most improbable sequences of words are acceptable: "If two is smaller than three, then snow is white." Most nonlogicians regard this sentence as a strange use of "if-then." The fact is that logic is a formal system, just as arithmetic is a formal system, and to expect untrained subjects to think logically is much the same as to expect preschool children to know the multiplication table.

Configurational Theories of Thinking

Modern thought about thinking has developed far beyond the word association and the syllogism. More complex materials have been used, and more complicated interpretations have been proposed. The fullest accounts of thinking seem to be those of Duncker (1935) and of Wertheimer (1945). These men speak of the pattern in which the component parts of the problem are arranged, the reorganizing principles or directions imposed upon the components, and the

eventual restructuring of the components in a form that coincides with the form of the desired solution.

In order to understand the configurational interpretation of thinking we need an example. This we will borrow from Wertheimer who, in the course of determining the area of a parallelogram, manages to introduce most of the puzzles that a theory of thinking must contend with. What, he asks, is the best way to teach school children to determine the area of a parallelogram?

FIG. 5. Wertheimer's parallelogram problem.

One way, an ugly but quite correct way, is to express the area according to the formula $b\sqrt{(a-c)(a+c)}$. The terms a , b , and c are identified as in Fig. 5, and the solution is presented in a series of steps: (1) subtract c from a , (2) add a and c , (3) multiply the sum and difference, (4) take the square root of the product, (5) multiply the root by b . Children can memorize these five steps. They can generalize them to other parallelograms of different dimensions. They get the correct answers. And yet, Wertheimer protests, the method is ugly and the teaching is terrible.

What is wrong with this method of teaching? The principal trouble is that the students are given no opportunity to grasp the inner structure of the situation. They do not understand what they are doing. If you ask them, "Can you show that the answer obtained in this way is really right?" they have no way to answer.

If the area of the parallelogram is given as a problem to children who have just learned to find the area of a rectangle, some do not respond, some try to remember, some start making speeches, some begin to think. For those who think, the trouble with the

parallelogram soon focuses on the two lopsided ends. Resolution comes when they see that one end needs just what is too much at the other end. If one end is cut off and fitted into the other end, the parallelogram becomes a familiar rectangle. The problem is solved.

The example draws a sharp contrast between "blind connections" and a "structural grasp." If thinking were nothing more than behaving in accordance with habits or conditioned responses, there would be little choice between these two methods of teaching. Associative bonds are associative bonds, and one is as good as another. In the simplest form of association theory there is nothing to say that one set of bonds is easier or better to learn than another set of bonds. A configurational view, on the other hand, recognizes trouble regions that must be manipulated and transposed according to the structural requirements of the solution.

We note that the problem is itself a visual problem. Does the visual nature of the task account for such terms as "structure," "form," "see the answer," etc.? For a non-visual example we can use Duncker's problem, "Why are all numbers of the form $abcabc$ divisible by 13?" In this example the subject who cannot get past the visual symmetry of $abcabc$ may waste considerable time before he abandons this fact and searches for a new structural property. This new property emerges when the thinker encounters the number 1001, for then he sees $abcabc$ as abc thousands plus abc units. Duncker tried various aids during the process of solution — these aids, along with the percentages of subjects who solved the problem in each case, are as follows:

1. (59%) The numbers are divisible by 1001.
2. (50%) 1001 is divisible by 13.
3. (15%) If a common divisor of numbers is divisible by 13, then they are all divisible by 13.

4. (14%) If a divisor of a number is divisible by p , then the number is itself divisible by p .
5. (0%) Different numbers can have in common a divisor which is in turn divisible.
6. (15%) Look for a more fundamental common character from which the divisibility by 13 becomes evident.
7. (8%) No aid.

Aids 1 and 2 which involve a specific mention of the number 1001 are the most effective, and the other aids are of no aid at all. Duncker found that it was helpful to give 1001 even in a disguised form, for if the numbers he used to state the problem were 276,276 and 277,277, the solution was easier than if the numbers were 276,276 and 591,591. Duncker's interpretation of this and other examples is that the material given is restructured according to the demands of the situation.

The subjects in these examples have several advantages over thinkers outside the laboratory. They are assured that they have all the relevant information and that there is a configuration of this information that fits the requirements. The practical case is less well defined. We encounter a situation for which we have no appropriate response. We try those habit patterns that are easily available, but if none of them works we begin to realize that we face a problem. The redundancy of our verbal habits constrains us to familiar and perhaps unsuccessful formulations of the problem — our language forces our thought in certain directions. We struggle to reformulate the problem and to obtain the necessary information. But even then we cannot be sure that there is an answer or that the problem will not need to be reformulated. Structural aspects may guide the process, but it is not always so clean and pretty as when the experimenter underwrites the happy ending.

Verbal material has configurational properties of two sorts, and these properties influence the transformations that the thinker will apply. There is, first, the contextual, or syntactic, pattern discussed in this chapter. The answer must come out in a sequence of words that sounds probable against the background of our intraverbal associations. Transformations of the problem materials that lead to improbable sequences of words are distrusted and are often discarded as opposed to common sense. Mathematicians and logicians have found that common sense is a poor guide, for if common sense must verify each step in a solution it is very difficult to arrive at any new conclusion unexpected by common sense. To avoid the traps that implicit linguistic habits can lead us into, scientists make up new languages that have explicitly defined symbols and relations among symbols.

The second configurational property that guides the thinker's transformations depends upon the semantic rules that relate the words or sentences to things or events. The full meaning of the problem extends beyond the contextual pattern of the words that state the problem, and transformations that are not permissible for the referents are usually not permissible for the symbols. Much of our thinking is directed toward this second kind of transformation, which is governed by essentially nonverbal restrictions.

Some of the confusion in the psychology of thinking arises because these two aspects are not distinguished. The experiments of Watt and of Sells reveal intraverbal influences upon the way the thinker restructures verbal material. Duncker and Wertheimer were interested in referential restrictions upon the restructuring transformations.

The difference between these two kinds of restrictions can be illustrated by Huxley's famous group of six monkeys that typed at random for millions and millions of years and eventually produced all the books in the British Museum. If these animals operated according to the transitional probabilities of

normal verbal behavior, they could reduce the time required by several million years. If you could wait, the monkeys would eventually produce the answer to almost any verbal question you could pose. The problem is how the monkeys would know when they had produced an answer. The recognition of a solution depends upon factors other than purely contextual intraverbal habits, and it is the determination of these factors that an adequate theory of thinking must accomplish.

Basic Correlates of the Visual Stimulus

DEANE B. JUDD

National Bureau of Standards

The adequate stimulus to a visual perception is a spatial and temporal pattern of radiant energy impinging on the retina. In order to be effective as a stimulus, an ele-

row bands in the spectrum depends upon wavelength (Wald, 1945). Further work (Griffin, Hubbard, and Wald, 1947) has extended these curves to the vicinity of 1000 millimicrons ($m\mu$), far into the infrared, where the threshold energy is approximately a million times (60 decibels) greater than it is at $750 m\mu$. It is similarly true that the retina responds to energy of wavelength near $320 m\mu$, far into the ultraviolet. This has been shown (Goodeve, 1934) by tests on eyes from which the crystalline lens had been taken out. The visible spectrum thus extends over a range greater than 320 to $1000 m\mu$ and includes much of the ultraviolet and infrared. The extreme limit depends on how much eye injury due to overheating and overexposure to actinic rays the subject is willing to tolerate.

FIG. 1. Reciprocal thresholds in log units (left-hand scale) and thresholds in decibels (right-hand scale) for dark-adapted foveal cones, peripheral rods, and peripheral cones, according to Wald (1945). All thresholds are relative to the minimum for the fovea near wavelength $555 m\mu$. Note that the thresholds for all types of receptors are but little different for wavelengths greater than $650 m\mu$.

ment of this pattern must bring to the receptors (rods and cones) a certain minimal energy. The minimal energy effective in half the presentations is called the absolute threshold. Its value depends upon the spectral composition of the energy. Figure 1 shows how the absolute threshold for nar-

Radiometric Terms

The absolute threshold depends upon the temporal and spatial character of the stimulus. This character of radiant energy requires for its description various radiometric terms.

For extremely brief presentations (less than 0.01 second) and point sources (subtending less than about 10 minutes of arc) the total amount of radiant energy is the important stimulus variable. It does not matter how the energy is distributed in time throughout the 0.01-second interval; it may

TABLE 1

VARIABLES, SYMBOLS, AND UNITS FOR THE VISUAL STIMULUS IN TERMS OF RADIANT ENERGY

Experimental Condition	Stimulus Variable Applying to Retina	Symbol	Unit	
			egs	mks
Point-source flash	Radiant energy	U	erg	joule
Extended-source flash	Areal density of radiant energy	U/A	erg/cm ²	joule/m ²
Steady presentation of point source	Radiant flux	P	erg/sec	watt
Steady presentation of extended source	Irradiance	H	erg/sec × cm ²	watt/m ²
External element	Stimulus variable applying to an external element			
Point source	Radiant intensity	J	erg/sec × ω *	watt/ ω
Extended source	Radiance	N	erg/sec × ω × cm ²	watt/ ω × m ²
Transmitting element	Spectral transmittance	T_λ		
Reflecting element	Spectral reflectance	R_λ		

* The symbol ω refers to solid angle.

all occur in the first 0.001 second, or it may be uniformly distributed over the whole 0.01 second. The same amount of radiant energy is required for a threshold stimulus. The most sensitive part of the retina is not, however, the center (cones only) but rather the zone between 20 and 30 degrees away from the center (rods and cones). Measurements by Hecht, Shlaer, and Pirenne (1942) indicate that the absolute energy threshold is about 3×10^{-10} erg.

If the size of the field is increased up to 1 degree, the absolute threshold is still found not to depend on how the energy is distributed in time, up to 0.01 second (law of Bloch or Bunsen-Roscoe). In this case the important stimulus variable is the areal density of the radiant energy (ergs per square millimeter) incident on the retina (Graham, Brown, and Mote, 1939; Tschermak, 1929).

For steady stimulation of small parts of the retina (less than 10 minutes of arc), the

absolute threshold depends almost wholly (law of Ricco) on the time rate of incidence of radiant energy (ergs per second). It scarcely matters how the areal density of radiant energy varies within the spot subtending 10 minutes of arc (Graham, Brown, and Mote, 1939; Tschermak, 1929).

But for presentations longer than about 1 second, and for fields subtending more than about 1 degree, the absolute threshold depends upon both the time rate of incidence of the radiant energy and its areal density. Ordinarily, therefore, it is appropriate to express a uniform stimulus in terms of areal density of incident radiant flux,* often called irradiance.

Table 1 summarizes the stimulus variables and the units appropriate to various kinds of stimulation by narrow bands of the spec-

* For definitions of terms, see the Glossary at end of chapter.

trum. The terms, symbols, and units are those adopted by the Optical Society of America (OSA, 1944a). The symbols agree with those adopted by the American Standards Association (1943).

It is not possible, of course, to measure these radiant quantities at the retina itself. The approximate retinal pattern has to be computed from the external pattern by taking into account the properties of the lens system of the eye. The exact retinal pattern at any instant is usually unknown because the eye muscles, like other muscles, exert a fluctuating tension. On this account the focus of the lens and the direction of its axis are always changing. It is often, therefore, more useful to correlate visual responses with measurements of the external stimulus.

The stimulating properties of a point source may be expressed in terms of its radiant intensity in the direction of the pupil. Those of an extended source may be expressed in terms of the areal density of point sources of unit radiant intensity to which the extended source is equivalent. This areal density is known as radiance. For either the point source or the extended source the density of the radiant flux incident on the cornea of the observer's eye, known as irradiance, is a useful quantity for correlation with the visual response.

Since the absolute threshold, and indeed all response variables, depend upon the spectral composition of the radiant energy reaching the retina, the foregoing quantities must be given for each wavelength throughout the visible spectrum. When the wavelength has been specified, the quantities are called spectral radiant flux, spectral radiance, spectral irradiance, and so on. The effect of an external transmitting (or reflecting) element may be expressed in terms of its spectral transmittance (or spectral reflectance), that is to say, the ratio of energy transmitted (or reflected) to the energy incident. If the spectral distribution of radiant energy incident on a clear element, such as a goggle lens, is known, we can compute from its

spectral transmittances how the energy leaving the lens will be distributed according to wavelength. Spectral reflectance serves the same purpose for a mirror or a diffuse reflector such as a painted surface. Table 1 summarizes these quantities also.

* Extrapolated.

The effects of the ocular media may be expressed in terms of their spectral transmittance. Table 2 gives the spectral transmittance of these media (Ludvigh and McCarthy, 1938; Wald, 1945).

Photometric Terms

When the stimulus consists of a single part of the spectrum, it may be adequately specified in terms of radiant energy alone. But, if the stimulus consists of two or more parts of the spectrum impinging on the same retinal area, it does no good to add together the radiant energies of the components. It is true that the simple sum gives the radiant energy of the composite stimulus, but the rods and cones respond differently to the different parts of the spectrum, as is indicated by the absolute thresholds. Consequently, in order to obtain a useful measure of a composite visual stimulus, immediate account must be taken of the spectral sensitivity of the receptors. These spectral sensitivities are the reciprocals of the radiant quantities required to produce a threshold response (see Fig. 1). They are also known as luminosity (formerly, visibility) functions. A measure of the effective stimulus is obtained, therefore, by the use of luminous or photometric quantities rather than by the use of the radiant quantities themselves.

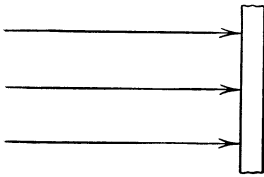

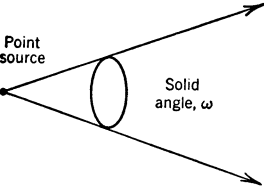

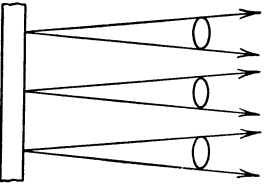

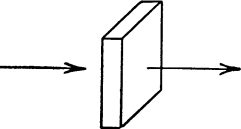

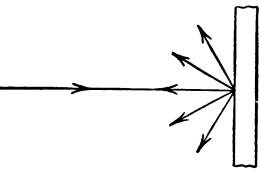

Table 3 lists these quantities together with the symbols and units by which they are expressed. It also shows diagrams of the geometrical ideas involved. Note that irradiance and illuminance both refer to the areal density of flux incident on a surface. No restriction on the direction of this flux is implied except that it must all fall on one side of the object. Intensity (both radiant and luminous) refers only to sources so small, compared to the distance of the receiver, that they can be considered as points. Since intensity is flux per unit solid angle, it may depend on the direction of view. Although we may think of the ideal uniform point source, all actual sources vary importantly in intensity, depending on the direction of

view. Radiance refers to extended sources, as does also, of course, its photometric analogue, luminance. The extended source is specified by the number of point sources of unit intensity required per unit area to give the equivalent irradiance or illuminance, as the case may be. The area taken, however, is not necessarily the actual area of the extended source but is always the projection of that area onto a plane perpendicular to the line of sight. Radiance and luminance vary with the direction of view. Many primary sources (furnaces, incandescent filaments, fluorescent tubes, gaseous discharge tubes) and many secondary sources (blotting paper, magnesium oxide) are almost perfectly diffusing, however. For these sources radiance and luminance vary but little with the angle of view.

From the definitions of these terms it is easy to see how each varies with distance away from the source. The total energy from a point source or an extended source is independent of distance. All that leaves the source eventually gets to the stated distance if the medium is a vacuum or some equivalent. It just takes time, and for ordinary distances not too much time at that, the speed of radiant energy being about 3.0×10^{10} centimeters per second. The areal density of energy, however, varies inversely as the square of the distance of the receiving plane from a point source. But, if the source is uniform and of infinite extent, the areal density of energy, like the energy itself, is independent of distance. The same applies to irradiance and illuminance: for point sources, the inverse-square law; for infinite sources, constant. Total flux, like total energy, is constant regardless of distance from any kind of source. Intensity and radiance (luminance, photometric brightness), being characteristic of sources, do not depend on the distance of the receiver by which they are evaluated. It is easy to see that the intensity of a point source in a given direction does not depend on the distance of the receiving plate. That distance is taken into

TABLE 3

VARIABLES AND UNITS FOR THE VISUAL STIMULUS IN LUMINOUS TERMS

Geometry	Corresponding Radiant Term	Luminous Term	Symbol	Unit, mks
	Radiant energy	Luminous energy	Q	talbot
	Areal density of radiant energy	Areal density of luminous energy	Q/A	talbot/m ²
	Radiant flux	Luminous flux	F	lumen
	Irradiance	Illuminance (illumination)	E	lumen/m ² (lux)
	Radiant intensity	Luminous intensity	I	lumen/ω (candle)
	Radiance	Luminance (photometric brightness)	B	lumen/ω × m ² (candle/m ²)
	Radiant transmittance	Luminous transmittance		
	Radiant reflectance	Luminous reflectance		

account in evaluating intensity. But students often find it hard to understand why the luminance of an extended source should not increase as the observing distance is reduced. As the aperture of a photometer is moved closer to a uniform extended source, it is true that the flux entering the aperture from each element of the source directly in front of the aperture increases according to the inverse square law. But it is also true that elements of the source seen near the edge of the aperture progressively disappear across the edge of the aperture and contribute nothing. For a uniform extended source these two effects exactly cancel.

A common way to evaluate the luminance of an extended source is to measure the illuminance produced by it at a considerable

distance away so that it may be considered as a point source. A distance ten to fifteen times the largest dimension of the source is usually considered adequate. The intensity of the extended source in candles is thus found by the inverse-square law, and the luminance is expressed as the number of candles per unit projected area of the source. This practice has given rise to many different units of luminance and illuminance. Table 4 gives conversion factors by means of which a measurement in terms of one photometric unit may be converted to any of the others. These factors are taken from ASA Z7.1-1942 (American Standards Association, 1942).

A point source of luminous intensity I supplies an illuminance E at a distance D by the inverse-square law:

$$E \text{ (foot-candles)} = \frac{I \text{ (candles)}}{D^2 \text{ (square feet)}} \quad (1)$$

provided the observing conditions are such that they yield cone vision. The luminance B of a perfectly diffusing surface illuminated by E foot-candles is obtained directly in foot-lamberts (equivalent foot-candles) by multiplying by the luminous reflectance R of the surface; thus,

$$B \text{ (foot-lamberts)} = RE \text{ (foot-candles)} \quad (2)$$

As was noted above, this luminance B is independent of the distance from which the observer views the surface, and if it were an ideal perfectly diffusing surface the luminance would also be independent of the direction of view. The luminance of an actual surface in foot-lamberts is numerically equal to the product of its luminous directional reflectance R_θ by its illuminance in foot-candles, thus:

$$B \text{ (foot-lamberts)} = R_\theta E \text{ (foot-candles)} \quad (2a)$$

This luminance, of course, is also independent of the distance between the surface and the observer, but it depends upon the angle, θ , between the perpendicular to the surface and the line of sight. For nearly perfect diffusers, R_θ is nearly constant and less than 1; for any surface that forms mirror images, R_θ rises

TABLE 4

CONVERSION FACTORS FOR PHOTOMETRIC UNITS
(TAKEN CHIEFLY FROM Z7.1-1942, AMERICAN
STANDARDS ASSOCIATION, 1942)

The total flux from a uniform point source of 1 candle is 4π lumens. The illuminance at a distance of 1 foot is 1 foot-candle.

Units of Illuminance (Illumination) in Terms
of Foot-candles

Unit	Number of Foot- Candles	Decibels re 1 Foot- Candle
Lumen/m ² (lux)	0.0929	-10.32
Lumen/cm ² (phot)	929	29.68
Milliphot	0.929	-0.32
Lumen/ft ² (foot-candle)	1	0.00

Units of Luminance (Photometric Brightness) in Terms
of Millilamberts

Unit	Number of Milli- lamberts	Decibels re 1 Milli- lambert
Candle/m ²	0.3142	-5.03
Candle/cm ² (stilb)	3142	34.97
Apostilb		
International units	0.1	-10.00
Hefner units	0.09	-10.46
Candle/ft ²	3.380	5.29
Candle/in ²	487	26.88
Foot-lambert (equivalent foot-candle)	1.076	0.32
Lambert	1000	30.00
Millilambert	1	0.00
Micro-lambert	0.001	-30.00

to indefinitely large values for the direction of mirror reflection as the angular spread of the illuminating beam approaches zero (OSA, 1944a).

When the lens forms a sharp image on the retina, each external element perpendicular to the line of sight is duplicated by a retinal area of the same angular extent. For every surface of luminance B in the visual field of the observer, there corresponds a retinal area illuminated to a retinal illuminance E . This illuminance depends upon the apparent diameter d of the pupil and upon the luminous transmittance T of the ocular media (see Table 3), thus (OSA, 1944a):

$$\begin{aligned} E \text{ (lux)} &= Td^2 \text{ (square centimeters)} \times \\ & B \text{ (millilamberts)} \\ &= 1.076Td^2 \text{ (square centimeters)} \times \\ & B \text{ (foot-lamberts)} \quad (3) \end{aligned}$$

Since luminous transmittance T of the ocular media of any living eye has yet to be determined, considerable use has been made of a unit of retinal illuminance originally called the photon but now called the *troland* after its originator (OSA, 1944a). The retinal illuminance E in trolands is computed from the apparent area A of the pupil in square millimeters and the luminance B of the viewed surface expressed in candles per square meter, thus:

$$\begin{aligned} E \text{ (trolands)} &= A \text{ (square millimeters)} \times \\ & B \text{ (candles per square meter)} \quad (3a) \end{aligned}$$

Retinal illuminance in trolands may be found from retinal illuminance in lux by multiplying by the ratio of A in square millimeters to d^2 in centimeters squared (25π), and by the number of millilamberts in one candle per square centimeter ($10/\pi$, see Table 4), and by dividing by the transmittance of the ocular media, thus:

$$E \text{ (trolands)} = \left(\frac{250}{T} \right) E \text{ (lux)} \quad (3b)$$

It has been known for some years, however, that the direction as well as the flux

density of the light striking the retina influences the brightness perceived (Stiles, 1933). Light striking the retina on the slant from the edge of the pupil may have as little as 20 per cent of the effectiveness of that from the center of the pupil, which strikes the retina perpendicularly. If the natural pupil is used, it may be important to take this property of the eye (known as the Stiles-Crawford effect) into account. If an artificial pupil is used, precautions should be taken to center it with the natural pupil.

Photometric Scales

The conversion of a stimulus specification from radiant to luminous terms is based upon the additivity "law" of luminance: if a stimulus of luminance B_1 (such as is produced by a spot of light on a screen) is added to a second stimulus of luminance B_2 (such as is produced by a second spotlight shining on the same screen), the luminance B of the combination stimulus is defined as the sum of the luminances of the component stimuli; that is, $B = B_1 + B_2$. This law has frequently been studied because it is the basis of photometry (Dresler, 1937; Kohlrausch, 1935; Urbanek and Ferencz, 1942). It has been found to fail unless the eye is kept throughout the series of comparisons essentially in a fixed state of adaptation. That is to say, the law fails unless there is pure cone vision, pure rod vision, or some constant combination of the two. Some reports indicate that it fails anyhow.

If a spot of red light is adjusted to the same brightness as a spot of yellow light, and a spot of green light is similarly adjusted to match the brightness of a second yellow light, the red and green lights added together are often found to be darker than the sum of the two yellow lights (Dresler, 1937). Since it is impossible for an observer to report with high precision and reproducibility which of two spots of light of widely different chromatic character is the brighter, these failures of the law have not been taken very seriously. The usual explanation

is that the observer mistook the high saturation of the red field, relative to that of the yellow, for brightness and so obtained a spuriously high estimate of its luminance in the first place. The next time the observer tests the additivity law his observations are somewhat conditioned by the first experience, and soon he has learned to make photometric settings in accordance with the law. Thus the additivity law provides a basis for a convenient photometric technique that correlates excellently, though not perfectly, with visual experience.

In photometric experiments, cone vision is usually assured by use of a 2-degree field centrally fixated and supplying a retinal illuminance of 100 or more trolands. An additional safeguard is to use a surrounding field nearly as bright as the photometric field. Rod-vision photometry is carried out by photometric fields (Teele, 1945) subtending at least 5 degrees at the observer's eye, because most observers have a central rod-free area of about 2 degrees.

If it is desired to convert the radiant flux (watts) entering the pupil of the eye to luminous flux (lumens), the additivity law is applied. The radiant flux is analyzed spectrally so that for each portion $\Delta\lambda$ of the spectrum the spectral radiant flux P_λ is known. Then, by multiplying the spectral radiant flux by the absolute luminosity K_λ (lumens per watt) for that wavelength region, we find the spectral distribution of luminous flux. But, by the additivity law, the total luminous flux F is equal to the sum of the parts making up this spectral distribution, thus:

$$F = \sum_0^\infty P_\lambda K_\lambda \Delta\lambda \quad (4)$$

where $\Delta\lambda$ is a wavelength interval so small that further reduction fails to alter the sum significantly. Similar formulas serve to convert specifications in other radiant terms (radiant intensity, radiance, etc.) into the corresponding luminous terms (luminous intensity, luminance, etc.). If E_0^λ is the spectral irradiance of an object, $R_{\theta\lambda}$ its spectral

directional reflectance, and $T_{\theta\lambda}$ its spectral directional transmittance, then its luminous directional reflectance and luminous directional transmittance, respectively, may be computed as:

$$R_\theta = \frac{\sum_0^\infty E_{0\lambda} R_{\theta\lambda} K_\lambda \Delta\lambda}{\sum_0^\infty E_{0\lambda} K_\lambda \Delta\lambda} \quad (4a)$$

$$T_\theta = \frac{\sum_0^\infty E_{0\lambda} T_{\theta\lambda} K_\lambda \Delta\lambda}{\sum_0^\infty E_{0\lambda} K_\lambda \Delta\lambda} \quad (4b)$$

Table 5 gives the absolute luminosities characteristic of the average normal eye for adaptation to fields ranging from 10,000 foot-lamberts (snow in sunlight) to 0.00001 foot-lambert (overcast moonless sky) supplied by Jones (1942) for an emergency war standard. The data for intermediate levels were obtained by an arbitrary method of interpolation described by Weaver (1949). Although these intermediate data are subject to revision on the basis of further experimental study, they have served very satisfactorily and may be provisionally recommended. The luminosity function recommended in 1924 by the International Commission on Illumination (ICI) applies well to the luminance range from 1 to 10,000 foot-lamberts. For more dimly illuminated adapting fields the photometric scale is extended to apply to combinations of rod and cone vision by the arbitrary choice of a standard light to which the inverse-square law by definition shall apply (see equation 1). The choice is light of the spectral composition obtained from a small hole in an inclosure uniformly heated to a temperature of 2,360 degrees on the absolute or Kelvin scale. Such a light is said to have a color temperature of 2,360° K. By definition, formulas 1, 2, and 3 apply to such lights regardless of the adaptive state of the observer, but these formulas apply to lights of any other spectral composition only for cone vision (adaptation to 1 foot-lambert or more).

TABLE 5

In the evaluation of a stimulus in luminous terms by application of equation 4, a method of successive approximation may have to be used. If the stimulus to be evaluated has significantly influenced the adaptive state of the observer, an estimate of which luminosity function in Table 5 is applicable must first

FIG. 2. Contours of equal brightness corresponding to constant values of adapting luminance B . These contours show, for 10-decibel intervals in adapting luminance, the relative values of the radiance, in watts, required to produce equal brightness at different wavelengths (Weaver, 1949). The dotted line passing through the minima of these contours shows how the wavelength of maximum luminous efficiency increases with the luminance to which the observer is adapted (Purkinje effect). The top curve represents the reciprocals of the ICI values of Table 5; the other curves have been shifted downward by successive intervals of 10 decibels (1 log unit).

be made. A trial computation may show that the first estimate was wrong, so that a recomputation based on another selection of luminosity function from Table 5 may be needed.

Figure 2 shows equal-brightness contours on a spectral-radiance wavelength plot for values of adapting luminance at 1.0, 0.1, 0.01, 0.001, 0.0001, and 0.00001 foot-lambert. These contours, separated by 10 decibels in luminance, refer to the level of adaptation of the observer to the field itself. For example, the upper contour indicates the spec-

tral radiances required to give a luminance of 1 foot-lambert measured by an observer adapted to a luminance of 1 foot-lambert. The dotted line passes through the minima of the curves and shows how the wavelength of maximum luminous efficiency increases with the luminance to which the observer is adapted. This increase is known as the Purkinje effect and is caused by the transfer from rod to cone vision. The lowest curve specifies spectral stimuli close to the absolute threshold. The other curves correspond to adapting luminances equal to snow illuminated by starlight, quarter moon, full moon, deep twilight, and twilight with the sun a few degrees below the horizon, respectively.

EQUIVALENT COLOR STIMULI

If a normal observer attempts to adjust one controllable element (subtending 1 degree or more) of his central visual field so that it matches the color of a neighboring element, he will discover that three independent adjustments have to be at his disposal. If he is trying to match one spot of light by shining several spotlights of different color onto a neighboring spot of a screen, he finds, in general, that three lights of fixed spectral composition are required. The same rule applies to rotary mixture on a sector disk; four sectors, giving three independent adjustments, are necessary and sufficient. Similarly in pigment combination at least three pigments are necessary. Examples are the red, yellow, and blue paints of the primary grade school, and the magenta, yellow, and cyan colorants used in color photography, lithography, and color printing. Normal color vision is tridimensional.

Since the color vision of a normal observer is tridimensional, it follows that a color specification is expressible by three numbers. For normal observers three numbers are necessary; for partially color-blind observers only two numbers are necessary; and for totally color-blind observers, only one.

Three-Part Classifications

In the examples given (spotlights, sector disks, colorants) the observer, by adjusting three variables, obtains a color match; he sets up a second stimulus equivalent to the first. Except by accident, however, the ternary or binary mixture does not match the first stimulus in spectral composition. The second stimulus appears the same as the first in color, but it is different in spectral composition. The two stimuli form what is known as a metameric pair: they exhibit metamerism. Difference in spectral composition, however, is a matter of degree. When a painted panel is matched by a mixture of red, yellow, and blue paints, the degree of metamerism is likely to be only moderate. But if the paint panel, illuminated by daylight, is matched by shining on a white card three spotlights, each of which contains energy restricted to a narrow wavelength band (such as spectrum red, green, and blue), the degree of metamerism will be extreme. Normal observers may disagree widely on highly metameric matches. Variations in ocular pigmentation (see Table 2) from observer to observer are largely responsible for these disagreements (Sinden, 1923; Wright, 1929). But all observers, normal and color-blind, must, of course, agree on nonmetameric matches.

Normal visual system. To a normal observer the spectrum appears as a series of chromatic colors varying from dim red through orange, yellow, brilliant yellow-green, green, blue, to dim violet. From a study of spectral metamers it has been found possible to summarize concisely the properties of a reasonably average normal eye. This summary utilizes the principles known as Grassman's laws, foreshadowed by Newton's laws of color mixture (Grassman, 1853). If a light composed of known amounts of three components (called primaries) is equivalent in color to another light, the three known amounts may be used

as a color specification for this light. These amounts are called tristimulus values of the color. Grassman's laws state:

1. When equivalent lights are added to equivalent lights, the sums are also equivalent.

2. When equivalent lights are subtracted from equivalent lights, the differences are also equivalent.

3. Lights equivalent to the same light are equivalent to each other.

Thus, when an unknown spot of color is matched by shining on the same spot of a white screen two component spotlights of tristimulus values, X_1, Y_1, Z_1 , and X_2, Y_2, Z_2 , respectively, by Grassman's first law, the tristimulus values, X, Y, Z , of the unknown color spot are simply

$$\begin{aligned} X &= X_1 + X_2 \\ Y &= Y_1 + Y_2 \\ Z &= Z_1 + Z_2 \end{aligned} \quad (5)$$

Any three lights may be used as primaries in a tristimulus system provided only that no one of them is equivalent to a combination of the other two. Tristimulus values, X, Y, Z , of any color expressed in this system of primaries may be transformed into specifications, R, G, B , relative to any other set of primaries. If R_x, G_x, B_x are the tristimulus values of one unit of the X -primary, R_y, G_y, B_y those of one unit of the Y -primary, and R_z, G_z, B_z those of one unit of the Z -primary, then by Grassman's first law a combination of X -units of the X -primary plus Y -units of the Y -primary plus Z -units of the Z -primary will also be equivalent to the additive combination of $R_x X, G_x X, B_x X, R_y Y, G_y Y, B_y Y, R_z Z, G_z Z$, and $B_z Z$. Any stimulus equivalent to the combination of X -units of the X -primary plus Y -units of the Y -primary plus Z -units of the Z -primary will by Grassman's third law also be equivalent to the additive combination of these nine components. By segregating the triads referring to the R -, G -, and B -primaries we find

$$\begin{aligned}
 R &= R_x X + R_y Y + R_z Z \\
 G &= G_x X + G_y Y + G_z Z \\
 B &= B_x X + B_y Y + B_z Z
 \end{aligned} \tag{6}$$

The conditions that no one of the *RGB* set of primaries is equivalent to a combination of the other two may be written

$$D \equiv \begin{vmatrix} R_x & R_y & R_z \\ G_x & G_y & G_z \\ B_x & B_y & B_z \end{vmatrix} \neq 0 \tag{6a}$$

If condition 6a is not met, that is to say, if the determinant of equation 6a is equal to zero, then equation 6 does not, in general, give a specification of the color, *X*, *Y*, *Z*, because the *RGB* system is incapable of expressing a three-dimensional variation. One of *R*, *G*, and *B* is not independent of the other two but is a weighted sum of them.

The reverse transformation equations can be found by solving for *X*, *Y*, and *Z* from equation 6:

$$\begin{aligned}
 DX &= (G_y B_z - G_z B_y)R + (R_z B_y \\
 &\quad - R_y B_z)G + (R_y G_z - R_z G_y)B \\
 DY &= (G_z B_x - G_x B_z)R + (R_x B_z \\
 &\quad - R_z B_x)G + (R_z G_x - R_x G_z)B \\
 DZ &= (G_x B_y - G_y B_x)R + (R_y B_x \\
 &\quad - R_x B_y)G + (R_x G_y - R_y G_x)B
 \end{aligned} \tag{6b}$$

where *D*, as in equation 6a, is the determinant of the system

$$\begin{aligned}
 D &= R_x G_y B_z + R_y G_z B_x + R_z G_x B_y \\
 &\quad - R_z G_y B_x - R_x G_z B_y - R_y G_x B_z
 \end{aligned}$$

Since in the derivation of equation 6 it was assumed that the primaries of the *XYZ* system could be matched by positive amounts of the primaries of the *RGB* system, it follows that the gamut of colors producible by the latter system is larger than that of the former. If we take the specifications, *R*, *G*, *B*, of one of the colors producible by the *RGB* system, but not by the *XYZ* system, and transform them by equation 6b to the

XYZ system, it will be found that one or two of *X*, *Y*, and *Z* is less than zero. Thus equation 6b seems to state that the color *RGB* is also equivalent to some fraction of unit *X* plus some fraction of unit *Y* minus some fraction of unit *Z*. The meaning of the addition of a negative quantity of a primary to one side of the field of a colorimeter is simply that this quantity is added to the other side. Thus, what equation 6b really states, in this case, is that the color *RGB* plus some fraction of unit *Z* is equivalent to a weighted sum of the *X*-primary and the *Y*-primary. The original statement can be restored by application of Grassman's second law.

The principles expressed in Grassman's laws have been established by repeated experiment over a wide middle range of retinal illuminance (Hering, 1885) for all types of vision, normal and abnormal. They break down for very high retinal illuminance approaching that sufficient to produce a permanent change in the eye (Wright, 1936). And they break down if the illuminance of the whole retina continues for 10 minutes or more to be so slight that vision by the retinal rods intrudes significantly (König, 1887; Ladd-Franklin, 1929). Between these two extremes, however, Grassman's laws hold independent of the adaptive state of the eye. Thus, if two stimuli of different energy distributions are once responded to alike by the eye, they will be seen alike even after exposure of the eye to another stimulus sufficient to change considerably the appearance of the two equivalent stimuli.

For example, if a portion of the spectrum near 640 $m\mu$ (red) is superposed on a portion near 550 $m\mu$ (yellowish green), it will be found possible to obtain the color of this combination from an intermediate portion of the spectrum, say 590 $m\mu$ (orange). If the retina is then highly illuminated by light of wavelength near 640 $m\mu$, and if its sensitivity to radiant flux of this wavelength is considerably reduced in this way, it is found that, although neither of the equivalent

stimuli any longer appears orange, they still give identical colors. They may yield identical yellows or identical greenish yellows. The eye thus cannot be trusted to yield the same color perception from a given stimulus; simultaneous and successive induction affect it profoundly. But it is still a satisfactory null instrument, and it obeys Grassman's laws.

Standard observer. Any beam of light, whether it originates from a self-luminous body, or comes by transmission, scattering, or reflection, from a nonself-luminous object, may be considered as made up of a large number of bands of the spectrum. The spectral irradiances of these various bands may be determined by spectrophotometry. The tristimulus specification, \bar{x}_λ , \bar{y}_λ , \bar{z}_λ , of each of these bands of vanishingly small wavelength interval have been determined for a number of normal observers (Guild, 1931; Wright, 1929). Average values are given in Table 6 in arbitrary units for every 5 μ for a spectrum of unit spectral irradiance per unit wavelength (the so-called equal-energy spectrum). The units are chosen so that an equal-energy source will be equivalent to equal amounts of the first primary X , the second primary Y , and the third primary Z ; that is to say, so that $\int_0^\infty \bar{x}_\lambda d\lambda = \int_0^\infty \bar{y}_\lambda d\lambda = \int_0^\infty \bar{z}_\lambda d\lambda$. These specifications for the standard observer are plotted in Fig. 3.

The amounts, X , Y , Z , of the primaries required to produce a stimulus equivalent to any spot of light may be found by Grassman's first law simply by adding together the tristimulus values of the various parts of its spectrum. In this way there is provided a three-part classification of stimuli reasonably valid for all observers with normal vision. All stimuli that are equivalent for the standard observer will be characterized by identical values of X , Y , and Z . In general, for each such color there will be an infinite number of physically different stimuli. The triad of numbers, X , Y , Z , serves as a label for each of this infinity of stimuli and

indicates that they are equivalent to each other.

The tristimulus values, X , Y , Z , of any stimulus producing at the cornea of the ob-

FIG. 3. Tristimulus values of spectrum stimuli of unit irradiance according to the standard observer and coordinate system recommended by the International Commission on Illumination in 1931 (the ICI or CIE system). The \bar{y} -function is the relative luminosity function for daylight vision (see Table 5). At each wavelength the amounts of the three primaries required in an additive combination to color match the spectrum at that wavelength may be found from the curves. For example, equal amounts of the X - and Y -primaries combine to produce for the standard observer a close match for the color of the spectrum at 578 μ .

server's eye the spectral irradiance E_λ may be computed as:

$$\begin{aligned} X &= \sum_{\lambda} E_\lambda \bar{x}_\lambda \Delta\lambda \\ Y &= \sum_{\lambda} E_\lambda \bar{y}_\lambda \Delta\lambda \\ Z &= \sum_{\lambda} E_\lambda \bar{z}_\lambda \Delta\lambda \end{aligned} \quad (7)$$

where \bar{x}_λ , \bar{y}_λ , \bar{z}_λ are the tristimulus values of the spectrum colors (see Table 6) of the standard observer. The \bar{y} -function is the standard luminosity function (see Table 5) expressed relative to its maximum value. The Y -value of a stimulus is therefore its luminous value, in this case the illuminance of the cornea. If radiometric quantities

other than irradiance are used in equation 7, the Y -value will give the corresponding luminous quantity. Thus, if the radiometric quantity is the radiance of a surface in the direction of the observer's eye, Y will evaluate the luminance of the surface. Or, if the radiometric quantity is the radiant intensity of a source, Y will evaluate its luminous intensity in a unit proportional to the candle, and so on. The tristimulus values, X , Y , Z , serve as a three-part classification of visual stimuli for the central 2 degrees of the normal retina. They will continue to serve until data still more representative have been gathered and adopted.

When two stimuli combined additively are equivalent to a stimulus yielding an accromatic or neutral color perception, they are said to be complementary and to correspond to complementary colors. Since it is possible to test by equation 7 whether or not any two stimuli are equivalent for the standard observer, it is possible to derive the spectral complementaries for that observer. That is to say, it is possible to find which pairs of spectrum colors mix to a match for the neutral color ordinarily perceived to correspond to unit amount of the equal-energy stimulus for which $X = Y = Z = 1$. If $\bar{x}_1, \bar{y}_1, \bar{z}_1$, are the tristimulus values of the first spectrum component, it is necessary merely to find a second portion of the spectrum such that the tristimulus values, $\bar{x}_2, \bar{y}_2, \bar{z}_2$ satisfy simultaneously the three conditions:

$$\begin{aligned} a\bar{x}_1 + b\bar{x}_2 &= 1 \\ a\bar{y}_1 + b\bar{y}_2 &= 1 \\ a\bar{z}_1 + b\bar{z}_2 &= 1 \end{aligned} \tag{8}$$

where a and b are the amounts in radiometric terms of the spectrum components, 1 and 2, respectively. Table 7 gives a few of the spectral complementaries, together with the corresponding values of a and b computed by a method worked out by MacAdam (OSA, 1944b).

It will be noted from Table 7 that the components $a\bar{y}_\lambda$ and $b\bar{y}_\lambda$ in photometric

700	493.89	53.9	2.663	0.3438	0.6562

terms sum to unity. This follows from Grassman's law (see equation 5), as well as from the additivity "law" of luminance, since one of the conditions taken was that the equal-energy stimulus is of unit amount ($X = Y = Z = 1$). The components a and b expressed in radiometric terms were found by dividing by the luminosity \bar{y}_λ . They do not, of course, sum to unity; and indeed it may be seen that when one of the spectrum compo-

nents is near either the short-wave or the long-wave extreme of the spectrum the energy input rises high. This rise reflects the insensitivity of the eye. It is worth noting, however, that the smallest energy input required to reduce the complementary to neutral is near 450 $m\mu$ where the luminance is low ($\bar{y}_{450} = 0.038$; see Table 6). And in photometric terms the luminance of component a near the short-wave extreme may drop as low as $\frac{1}{2}I_{70}$ of the luminance of the complementary (greenish yellow). The short-wave extreme of the spectrum is chromatically strong but luminously weak.

Spectrum stimuli in the wavelength range from about 494 to 569 $m\mu$ have no spectrum complementaries. In order to form with these wavelengths an additive combination equivalent to the equal-energy stimulus, we need at least two additional components, one chosen near the short-wave extreme of the spectrum, the other near the long-wave extreme. The amounts required in order for any given choice of such three-part stimuli to be equivalent, for the standard observer, to the equal-energy stimulus may also be computed from Table 6.

As an example of the use of Table 6 a check of one of the pairs of spectral complementaries given in Table 7 is included. Table 7 indicates that a combination of 2.148 radiometric units (irradiance of the cornea, radiance of an extended source, etc.) of wavelength 490 $m\mu$ with 0.877 unit of wavelength 600 $m\mu$ is found by the standard observer to be equivalent to unit amount of an equal-energy stimulus ($X = Y = Z = 1$). From Table 6 the tristimulus values, \bar{x}_λ , \bar{y}_λ , \bar{z}_λ , of the spectrum for unit amount in radiometric terms may be read for 600 and 490 $m\mu$, multiplied by 2.148 and 0.877, respectively, and summed as follows:

Wavelength, $m\mu$	\bar{x}_λ	\bar{y}_λ	\bar{z}_λ
490	0.0320	0.2080	0.4652
600	1.0622	0.6310	0.0008

Amount, N	$N\bar{x}_\lambda$	$N\bar{y}_\lambda$	$N\bar{z}_\lambda$
2.148	0.069	0.447	0.999
0.877	0.931	0.553	0.001
Totals	1.000	1.000	1.000

This computation shows that the components a and b satisfy equation 8 for this pair of complementary wavelengths. A similar check has been applied throughout Table 7.

The acceptance of the ICI standard observer makes it possible to compute the answers to many problems that heretofore have been solved rather unsatisfactorily by direct experiment only. Direct experimental results are unsatisfactory because of doubt regarding the representativeness of the vision of the observer used. To repeat such experiments with a large number of observers is impractical. The computation above is an example of the use of the standard observer and of the three-part classification of stimuli afforded by it. Equally fundamental three-part classifications may be found by use of primaries other than those of the ICI colorimetric coordinate system. That is to say, any numbers, R , G , B , found by any choice of the nine constants in equation 6 satisfying equation 6a can serve in the place of X , Y , Z . The superiority of the ICI colorimetric coordinate system is chiefly that it is widely used, but it is also convenient for the routine reduction of radiometric data to colorimetric terms because (1) there are no negative quantities (see Table 6), and (2) the \bar{y} -function yields an explicit correlate of the luminous aspect of the response separated from the chromatic aspect. The \bar{x} - and the \bar{z} -functions correlate solely with the chromatic aspect of the response; they are unassociated with the luminous aspect (Judd, 1933).

A corollary to the freedom of our choice of R , G , and B to yield a fundamental three-part classification of visual stimuli for the normal observer is that any function not expressible in terms of R , G , and B will fail to yield the same groupings of equivalent stimuli. Such functions therefore will group

together as equivalent some stimuli that the observer of normal vision would find not to be equivalent, and they cannot be used to represent normal vision. Such functions represent anomalous vision.

Anomalous systems. There are three recognized kinds of anomalous vision: protanomalous, deuteranomalous, and tritanomalous (Judd, 1943).

An observer who requires in a red-green mixture more red than normal to match a given yellow is called protanomalous.

An observer who requires in a red-green mixture more green than normal to match a given yellow is called deuteranomalous.

An observer who requires in a blue-green mixture more blue than normal to match a given cyan is called tritanomalous.

These abnormalities of vision cannot be accounted for by abnormal coloration of the eye media. No matter what spectrally selective filter is looked through by an observer of these types, his vision cannot be made normal (Sinden, 1923). If he is only mildly anomalous, his description of the spectrum will agree rather well with that of the normal. But, if he is extremely anomalous, it will scarcely differ from that of a color-blind observer. The distinctions made by such an observer are light-dark, yellow-blue, and red-green. But his ability to make one of the chromatic distinctions (red-green for protan and deuter-, blue-yellow for tritanomalous) is relatively weak.

Anomalous trichromats are intermediate in their ability to make chromatic distinctions between normal and dichromatic observers of the protanopic, deuteranopic, and tritanopic types, respectively. Thus, an anomalous trichromat can make with difficulty the distinctions that the corresponding dichromat cannot make at all. However, in other respects anomalous trichromatism is not intermediate between normal trichromatism and dichromatism. For example, the luminosity function of protanomalous observers (McKeon and Wright, 1940) of all degrees is

depressed at the long-wave end like that of the protanope (see Fig. 4).

There is no way of setting up a single three-part classification of visual stimuli that will be valid for each of the three types of anomalous trichromatism in the same way that the standard observer serves for normal trichromatism. Anomalous trichromats differ from one another much more than do normal trichromats. The most that can be said about anomalous trichromats is that visual stimuli can be given a three-part classification, valid for each observer separately, by means of functions significantly different from any of the triple infinity of sets (see equation 6) suited for normal trichromatism.

Two-Part Classifications

An observer requiring a mixture of but two lights to produce all the colors that he is capable of experiencing is said to possess a dichromatic visual system. He can make two kinds of visual discrimination, one achromatic (light-dark) and one chromatic (either yellow-blue or red-green). Dichromatic observers are therefore said to be partially color-blind.

Partial color blindness. The spectrum to an observer having red-green blindness appears in two hues only: the short-wave end of the spectrum appears blue; the long-wave end, yellow. These two bands are separated by a region near $495 \text{ m}\mu$ that, like average daylight, has no hue at all. This region is called the neutral point. From zero at the neutral point the saturations of the spectrum colors increase toward both the long-wave and the short-wave ends. There are two subtypes of red-green blindness: one characterized by abnormally low luminosity of the long-wave portion of the spectrum and by inability to distinguish what to the normal is red and blue-green from gray (protanopia); the other characterized by a substantially normal luminosity function and by inability to distinguish what to the normal is purplish red and green from gray (deuteranopia).

The spectrum to an observer having yellow-blue blindness appears in but two hues, red and green. There are two subtypes of yellow-blue blindness: one characterized by inability to distinguish what to the normal is purplish blue and greenish yellow from

gion at or just beyond the short-wave extreme of the spectrum. To a tetrantanope, the long-wave portion of the spectrum appears red at the long-wave end, green in the middle, and red again at the short-wave end, with neutral regions near 580 and 470

FIG. 4. Relative luminosity functions of anomalous trichromats (6 deuteranomalous, 12 protanomalous) compared to averages for dichromats and to limits for normal trichromats.

gray (tritanopia); the other by inability to distinguish what to the normal is blue and yellow from gray (tetartanopia). Both types have a normal or nearly normal luminosity function. A possible slight defect on the short-wave end is hard to separate from the effect of abnormally heavy ocular pigmentation (see Table 2). To a tritanope the short-wave half of the spectrum appears green; the long-wave, red, with a neutral region near 570 $m\mu$. But the saturation of the short-wave green diminishes with wavelength as if there were a second neutral re-

$m\mu$. This type is rare and is associated with impaired inability to distinguish red from green so that many students of vision treat it in connection with total color blindness (Sloan and Newhall, 1942).

An important characteristic of dichromatic vision is that metameric pairs set up for normal vision are also equivalent stimuli for the dichromat. Dichromatic systems on this account are called reduction systems of normal vision. It is therefore possible to set up two-part classifications for dichromatic vision by means of the same functions used to set

up three-part classifications for normal vision. For example, the \bar{y} -function and the \bar{z} -function taken together isolate all the visual stimuli that are equivalent for deuteranopic vision, except for variations ascribable to abnormally heavy or abnormally light ocular pigmentation. The \bar{y} -function alone evaluates the luminous aspect of the stimulus, and the

Figure 5 shows the wavelength distribution of these functions (Judd, 1945).

Stimuli of small angular extent. The normal retina yields trichromatic vision only for large centrally fixated fields. For stimuli subtending less than 10 minutes of arc the normal retina responds with tritanopic vision (Hartridge, 1947). A two-part classification

FIG. 5. Tristimulus values of spectrum stimuli of unit irradiance according to a dominator-modulator form of the three-components theory. The primaries, K , W_p , and W_d , are close to the color process whose absence corresponds, respectively, to tritanopia, deuteranopia, and protanopia. These primaries are also close to those of the Helmholtz and the later König theories.

ratio of \bar{y} to \bar{z} evaluates the yellow-blue aspect of the stimulus. Two stimuli having identical values of Y and Z are equivalent stimuli for an average deuteranope.

A two-part classification of visual stimuli for protanopic vision may be formed by combining the \bar{z} -function with $-0.460\bar{x} + 1.359\bar{y} + 0.101\bar{z}$. Tritanopia may be represented by a combination of this same function with the \bar{y} -function. Since these three functions, taken together, can also yield (by equation 6) the three-part classification suited for normal vision, they form the basis of an explanation of the relation between normal and dichromatic vision similar to that proposed by Young and elaborated by Helmholtz and König.

of stimuli suited to tritanopia thus serves fairly well for the normal receptors stimulated one small group at a time. If the stimulus falls outside the macular pigment, however, account must be taken of the resulting higher transmittance of the ocular media (see Table 2).

Peripheral stimuli. For a given size of stimulus, say 2 degrees, and a given luminance, say 1 foot-lambert, there is a distance from the center of the fovea beyond which red-green distinctions can no longer be made, but light-dark and yellow-blue distinctions can be (Tschermak, 1929). For stimulation of this portion of the periphery the normal retina responds with deuteranopic vision.

Since no one can make precise distinctions of any sort between stimuli applied as eccentrically as these, it is not known whether the same functions that serve to yield a two-part classification of stimuli for deuteranopic vision also serve precisely for eccentric stimulation of the normal retinas. But if account is taken of the effect of macular pigmentation the same functions may be used without introducing notable contradictions.

One-Part Classifications

An observer requiring but a single light to produce all the colors that he is capable of experiencing is said to possess a monochromatic visual system. Since he can match any two stimuli merely by adjusting them to equal brightness, the luminosity function applying to his visual system is a sufficient basis for one-part classification of his visual stimuli. He is capable of light-dark discrimination but of no chromatic discrimination whatsoever. His spectrum does not have merely one or two neutral points; if any point is neutral, all are neutral. On this account the visual system of most monochromats can be called achromatopsia or achromatopia (Sloan and Newhall, 1942).

Total color blindness. The most common form of monochromatism is often called cone blindness since it is universally ascribed to nonfunctioning of the retinal cones (Müller, 1922-23, 1924, and Tschermak, 1929). The most common designation is congenital total color blindness. The luminosity function is the same as that of the dark-adapted normal observer (see Table 5, last column, and Fig. 1).

There are two less-common forms of monochromatism, both of which are thought to arise solely from disease of the eye and the optic nerve. Unlike cone blindness, these forms are characterized by normal visual acuity as well as by good foveal vision. The first type is characterized by a normal or deuteranopic luminosity function (see Table 5, first column, or \bar{y}_λ of Table 6); the second, by

a protanopic luminosity function whose maximum is at about 540 m μ (see curve of $W_p = -0.460\bar{z}_\lambda + 1.359\bar{y}_\lambda + 0.101\bar{x}_\lambda$ in Fig. 5). The second form is regarded as the result of a person's being born with protanopic vision and then acquiring tritanopia as a result of disease (Müller, 1924).

Twilight vision. The normal retina adapted to fields of luminance in the neighborhood of 0.0001 foot-lambert responds with monochromatic vision. Since this luminance is below the threshold of the retinal cones, this monochromatic vision is ascribable to the retinal rods. The visual stimuli for this condition can be evaluated by means of the rod luminosity function alone (see last column, Table 5; Müller, 1930; Tschermak, 1929).

Theoretical Implications

The one-, two-, and three-part classifications of visual stimuli appropriate to various types of observers and observing conditions that may be derived from the standard observer, combined with the luminosity function for rod vision, are basic to theories of color vision. These classifications are the best established of all visual functions, and the first criterion of any attempt to explain visual phenomena is whether it yields them correctly.

It is fairly well accepted that the rods and cones of the retina are the immediate organs of vision and that they contain substances or mixtures of substances that absorb radiant energy incident on these receptors. The receptors respond by initiating nerve impulses that find their way to the fibers of the optic nerve. It is well established that the response of the rods is due to the photochemical substance known as rhodopsin (Hecht and Williams, 1922), but the substances giving the cones their spectral sensitivities are still matters of conjecture, as are the combinations of cone responses effective in producing impulses in the optic nerve.

TABLE 8

SUMMARY OF A FEW OF THE BETTER-KNOWN VISUAL THEORIES

Name	Anatomical Location	Fundamental Colors	Relation to Standard Observer	Chief Limitation
Young, three components	Cone pigments	Red Green Violet	$+3.1956X + 2.4478Y - 0.6434Z$ $-2.5455X + 7.0492Y + 0.4963Z$ $+ 5.0000Z$	Fails to explain dichromatic vision as intended.
Helmholtz, three components	Cone response	Red Green Violet	$+0.070X + 0.945Y - 0.015Z$ $-0.460X + 1.359Y + 0.101Z$ $+ 1.000Z$	Fails to explain color perceptions of protanopes and deutanopes.
Dominator-modulator, late König	Cone response	Red Green Violet	$+ 1.000Y$ $-0.460X + 1.359Y + 0.101Z$ $+ 1.000Z$	Fails to explain color perceptions of protanopes and deutanopes.
Ladd-Franklin, three components, early König	Cone response	Red Green Blue	$+3.7656X + 1.4635Y - 0.2291Z$ $-1.3973X + 6.1289Y + 0.2683Z$ $+ 5.0000Z$	Implies that the blue function has a negative luminosity for normals and deutanopes, positive for protanopes.
Hering, opponent colors	Optic nerve	Red-green Yellow-blue White-black	$+1.000X - 1.000Y$ $+ 0.400Y - 0.400Z$ $+ 1.000Y$	Fails to give an account of protanopia and tritanopia.
Von Kries-Schrödinger, zone or stage	Cone response	Red Green Blue	$+3.7656X + 1.4635Y - 0.2291Z$ $-1.3973X + 6.1289Y + 0.2683Z$ $+ 5.0000Z$	Implies that the blue function has a negative luminosity for normals and deutanopes, positive for protanopes; fails to give an account of tritanopia.
	Optic nerve	Green-red Blue-yellow White-black	$-3.537X + 3.196Y + 0.341Z$ $+1.341X - 5.884Y + 4.542Z$ $+ 1.000Y$	
Adams, zone or stage	Cone pigments	Red Green Violet	$+3.1956X + 2.4478Y - 0.6434Z$ $-2.5455X + 7.0492Y + 0.4963Z$ $+ 5.0000Z$	Explanations of protanopia and tritanopia based on subsidiary assumptions.
	Cone response *	Red Green Blue	$+1.000X$ $+ 1.000Y$ $+ 1.000Z$	
	Optic nerve *	Red-green Blue-yellow White-black	$+1.000X - 1.000Y$ $- 0.400Y + 0.400Z$ $+ 1.000Y$	
Müller, zone or stage	Cone pigments	Red Green Violet	$+3.1956X + 2.4478Y - 0.6434Z$ $-2.5455X + 7.0492Y + 0.4963Z$ $+ 5.0000Z$	Implausible explanation of protanopic luminosity by resort to luminosity of the <i>yR</i> cone response and luminosity-inhibiting action of the <i>bG</i> cone response, both of which disappear with the <i>yR-bG</i> cone response to produce protanopia.
	Cone response *	<i>yR-bG</i> <i>gY-rB</i> Luminosity	$+5.741X - 4.601Y - 1.140Z$ $-0.932X + 2.750Y - 1.819Z$ $+ 1.000Y$	
	Optic nerve *	Red-green Yellow-blue White-black	$+6.325X - 6.325Y$ $+ 2.004Y - 2.004Z$ $+ 1.000Y$	

* The theory allows for a nonlinear dependence of the responses upon the stimulus in addition to the linear dependence indicated here.

Equation 6, when combined with the properties of the standard observer, is the key to all such conjectures. It serves not only for normal vision but also for all reduction forms (dichromatism, acquired total color blindness). It also has a powerful negative implication for anomalous vision (protanomaly, deuteranomaly, tritanomaly) in the sense that no explanation in terms of functions

(1905), and Müller (1930) theories, respectively. These functions show how the various assumed processes depend on the spectral distribution of energy incident on the cornea of the observer. The corresponding dependence on the energy incident on the retina may be found by dividing by the spectral transmittance of the ocular media (see Table 3, last column).

FIG. 6. Tristimulus values of spectrum stimuli of unit irradiance according to the primaries of the Young theory.

defined by equation 6 is admissible for these types of vision. Combinations of these functions yield exactly the same implications as the functions for the standard observer. They yield the same spectral complementaries, etc. (see Table 7).

Table 8 indicates the particular coefficients of equation 6 used for the theories that have attracted most attention so far. It also gives the name by which the theory is known, the particular structure whose activity the functions are now considered to describe, an indication of the color associated with the function, and an indication of the chief limitations of the theory. Figures 6, 7, 8, and 9 show the spectral distributions of the functions listed in Table 8 for the Young (Helmholtz, 1911), Ladd-Franklin (1929), Hering

Figure 5 corresponds to König's later views (1897) and also serves to illustrate the Helmholtz theory. By the Helmholtz theory the deuteranopic luminosity function is located slightly to the long-wave end of the spectrum compared to normal, but the amount, too small to be statistically significant from the number of deuteranopes so far studied, is likewise too small to be seen at all easily on Fig. 5. König was the first to point out that the deuteranopic luminosity function, being almost normal, requires that the red function for the normal be likewise almost identical with the luminosity function. The idea that there is a separate receptor or dominator for the luminous aspect of the visual response has recently been proposed by Granit (1943) under the name of domi-

FIG. 7. Tristimulus values of spectrum stimuli of unit irradiance, according to the primaries of the early König theory and the Ladd-Franklin theory.

FIG. 8. Tristimulus values of spectrum stimuli of unit irradiance, according to the primaries of the Hering theory.

nator-modulator theory. This proposal is based on evidence obtained through measurements of the nerve activity of single fibers isolated by a microelectrode.

secondary assumptions (not published in detail) elaborate the theory to meet these requirements without sacrificing any of the structure. Figure 10 is a diagram of the retinal

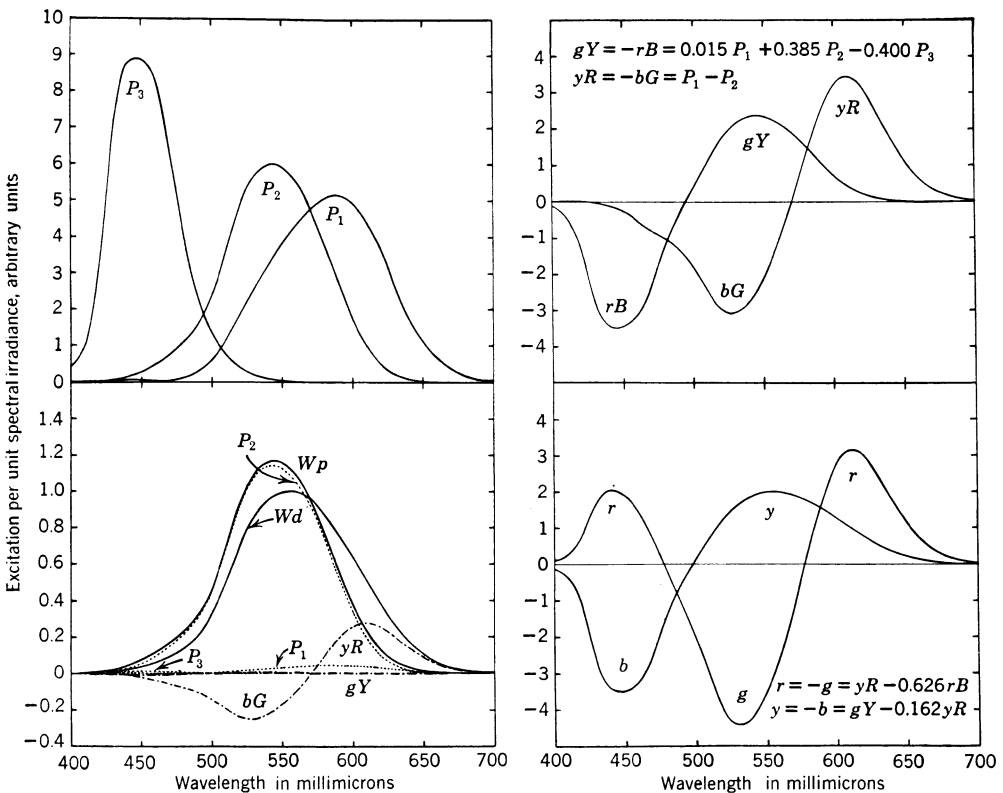

FIG. 9. Tristimulus values of spectrum stimuli of unit irradiance, according to the three stages of the Müller theory (Judd, 1949). Upper left: initial photosensitive-substance stage (same as the Young theory). Upper right: stage of the chromatic retinal sensory processes. Lower right: chromatic processes in the optic-nerve fiber stage (same as the Hering theory). Lower left: components in the luminosity functions (solid lines) for normal and deuteranopic vision (W_d) and for protanopic vision (W_p). The direct contributions to luminosity from the initial photosensitive-substance stage are shown in dotted lines; the indirect contributions from the retinal sensory process stage in dot-dash lines. Protanopic luminosity (W_p) differs from normal luminosity through absence of the indirect contribution from the yR - bG retinal sensory process. The tristimulus values of the spectrum for the first stage are given directly by the excitations, P_1 , P_2 , P_3 (upper left); those for the last two stages are made up of the luminosity function combined with the chromatic functions shown on the right.

The E. Q. Adams (1923, 1942) stage theory is probably the first dominator-modulator theory. It antedates the coining of the phrase by twenty years. The coordinate systems listed in Table 8 for this theory do not themselves give a simple account of protanopia and tritanopia, but plausible sub-

nerve connections on which the Adams theory is based. It is assumed that there are rods (S) and three kinds of cones (R , W , and B) in the retina. The rods and the W -cones have a direct connection to the W -fibers of the optic nerve and produce a white sensation. The R - and B -cones modu-

late the response of the *W*-cones by means of assumed lateral connections. Only an excess of *R*-response over *W*-response can reach the *R*-fiber of the optic nerve and so produce a red sensation. If the *W*-response is in excess, the *R*-fiber responds with the negative of red, which is green. Similarly the blue fiber may respond either yellow or

FIG. 10. Diagram of the retinal nerve connections on which the Adams theory is based. It is assumed that in the retina there are rods *S* and three kinds of cones, *R*, *W*, *B*. The photosensitive pigments contained in these receptors are the first stage of the theory. The receptors themselves are the second stage, represented by the tristimulus values, *X*, *Y*, *Z*, of the standard observer. The final stage is produced by lateral nerve connections in the retina whereby the responses of the *R* and *B* cones are opposed by the *W* responses, giving the net responses $a_x(V_x - V_y)$ and $a_z(V_z - V_y)$, which correspond exactly with the Hering theory.

blue. This is the same as the Hering formulation. Although it is assumed that the photochemical decomposition of the pigments in the *R*-cone is measured by the *X* tristimulus value, the response of the *R*-cone V_x is assumed to be nonlinearly related to *X*. The Adams theory is a very promising suggestion and is the only stage theory so far that yields fruitful results from the assumption of a nonlinear connection between stages.

The Helmholtz theory is the simplest and most widely followed of visual theories. It states that whenever all three receptors are equally excited a neutral or achromatic color is perceived. Also, if the receptors yielding violet are unstimulated or only weakly stimulated, and those yielding red and green are

about equally excited, a color perception of yellow hue will result. Protanopia is explained by failure of the red receptors to function; deuteranopia, by failure of the green; and tritanopia, by failure of the violet. This leads to the prediction that protanopes should experience simply blends of green and violet, and that deuteranopes should experience simply blends of red and violet. But evidence from observers color-blind in only one eye indicates that both protanopes and deuteranopes experience blends of blue and yellow (Müller, 1924).

Adherents of the Helmholtz theory regard the prediction of the wrong color perceptions for protanopes and deuteranopes as a very minor drawback. Some take the position that the names by which an observer describes his color experiences are subject to change by education, and that such data have therefore relatively little interest compared to the data on equivalent color stimuli and should not be allowed to complicate the representation of those facts. Such adherents ignore the evidence based on a stimulus found to produce the same color perception for the normal and for the dichromatic eye of a unilaterally color-blind observer.

Other adherents of the Helmholtz theory resort to an ingenious suggestion by Fick (1879) modifying the Helmholtz explanation of dichromatic vision. According to Fick we should consider the possibility that dichromatic vision is due to failure to segregate properly the photosensitive substances in the two types of receptors. If both red and green cones are supplied with the substance or mixture of substances proper to the red cones, the observer will have a luminosity function nearly or quite equal to the normal luminosity function. But since both red and green cones have identical spectral sensitivities they must always be equally stimulated, and this is the condition for the perception of colors of yellow hue. This type of vision is deuteranopic and an analogous explanation yields protanopic vision. This suggestion by Fick resembles a stage theory of vision be-

cause it deals separately with the cone substances and the cone responses.

The Hering (1905) theory of opponent colors has come to be fairly well accepted as the most likely description of color processes in the optic nerve and cortex. Thus this theory reappears as the final stage in the stage theories of von Kries-Schrödinger (von Kries, 1905; Schrödinger, 1925), Adams (1923, 1942), and Müller (1924, 1930). By far the most completely worked out of these stage theories is that of Müller. It takes at least qualitative account of nearly every known visual phenomenon and is noteworthy on that account alone. Its structure, based partly on conjecture, is formidable, and many aspects of it are implausible. There is slight chance that all of the conjectures are correct, but, even if some of the solutions proposed by Müller prove to be unacceptable, he has nevertheless made a start toward the solution of important problems that will eventually have to be faced by other theorists.

PERCEPTIONS ARISING FROM A KNOWN VISUAL FIELD

By means of his visual sense a human observer is able to perceive positions, sizes, shapes, motions, textures, and colors of objects in his environment. He also perceives the difference between opaque, translucent, and transparent objects. He can tell whether a surface is glossy or matte. And he can even make some estimate of the amount and color of illumination pervading space. This information comes from the relation between the colors of the elements that make up the visual field and the momentary changes that they undergo as a result of object movements and movements of the observer.

Many aspects of these perceptions can be predicted from the characteristics of the environment. Before presenting the basic correlates of the visual stimulus, let us consider the attributes of visual perceptions. Colors

may be perceived in various modes; they may belong to objects, or to lights; they may be perceived as filling a hole in a screen, or as belonging to the illumination filling an illuminated space (Katz, 1930; Martin, 1922). The color of an opaque object is perceived as belonging to its surface; the color of a translucent or transparent object belongs partly to its interior and therefore consists partly of surface color and partly of volume color.

There are normally three attributes to the perception of the color of an aperture. These attributes are hue, saturation, and brightness, although, alternatively, an aperture-color perception may be described in terms of redness (whose opposite is greenness), yellowness (whose opposite is blueness), and brightness (whose opposite is dimness). The color perception of an object, however, is closely linked with other aspects of the perception. It is convenient to start the presentation of basic correlates with a classification of the nonshape, nontemporal attributes of visual perception for the more important modes of appearance (OSA, 1943). (See Table 9.)

The chromatic attributes of an object-color perception are the same as those of aperture-color perception. The achromatic attributes of an object-color perception may be lightness (whose opposite is darkness) varying from black to white, or they may be directly stated in terms of whiteness and blackness, or they may be further analyzed in terms of whiteness, grayness and blackness. By this latter method, proposed by Dimmick and Holt (1929), an achromatic object-color perception is expressed in terms of two neighbors in the achromatic series (either white and gray, or gray and black). And a chromatic object-color perception is expressed in terms of these two neighbors in the achromatic series combined with two neighbors in the closed series of chromatic colors, red, yellow, green, blue (red). Thus, a light tan might be expressed as 25 per cent each of white, gray, red, and yellow.

TABLE 9

NONSHAPE, NONTEMPORAL ATTRIBUTES OF VISUAL PERCEPTION

Classification of Visual Perception	Mode of Appearance	Nonshape, Nontemporal Attribute
Nonlocated in depth	Aperture	Hue, saturation, brightness (alternatively: red-green, yellow-blue, bright-dim).
Located in depth	Illuminant	Hue, saturation, brightness, transparency (alternatively: red-green, yellow-blue, bright-dim, transparent-opaque).
	Object	
	1. Volume	Hue, saturation, lightness, transparency (alternatively: red-green, yellow-blue, black-white, transparent-opaque).
	2. Surface	Hue, saturation, lightness, transparency, glossiness (alternatively: red-green, yellow-blue, black-white, transparent-opaque, glossy-matte).

Some of the attributes listed in Table 9 have stimulus correlates that have already been mentioned. The correlate for the brightness perceived to belong to an aperture or self-luminous area is luminance. The perceived brightness varies from very dim to very bright as the luminance varies from the absolute threshold to a value beyond which the observer can detect no further increments in brightness. Fechner pointed out that the function relating brightness to luminance is approximately logarithmic, but the precise nature of this relation has not been determined. The logarithmic relation is closely approximated for limited middle ranges of luminance when the observer is adapted to the average luminance of the two fields being compared (E. Q. Adams, 1922). In other words, under these conditions the decibel scale of luminance relative to the threshold corresponds to the psychological scale of brightness more closely than does a linear scale of luminance.

The lightness of the color perceived to belong to a surface approaching the ideally diffusing surface may be predicted with good reliability from the luminous reflectance of the surface. Under ordinary viewing conditions the perceived lightness varies from black to white as the luminous reflectance varies from zero to one. For actual surfaces (glossy and semiglossy) luminous reflectance must be

replaced by luminous directional reflectance in this correlation. Again, too, a better perceptual scale is yielded by functions of luminous directional reflectance similar to the logarithmic, such as $(R_\theta)^{1/2}$ or $R_\theta/(R_\theta + R_f)$, where R_f is the average for the visual field (E. Q. Adams, 1922).

The glossiness perceived to belong to a surface (Bixby, 1926) is correlated with the degree to which the surface reflects light regularly, so that it forms mirror images. There are several kinds of glossiness, all of which may be correlated with various functions of luminous directional reflectance. Table 10 lists five of these kinds of glossiness (Hunter, 1937) together with the functions of luminous directional reflectance with which they correlate. Note that the correlates for the last three kinds of glossiness explicitly indicate that the observer views the specimen from two different directions. This double direction of view is implied in the first two cases also. Vitreous glossiness (luster) corresponds to a moderately bright highlight of the same chromaticity as that of the illuminant. Metallic glossiness (luster) corresponds to a bright highlight not necessarily of the same chromaticity as that of the illuminant.

The transparency perceived to belong to a volume is correlated with the degree to

TABLE 10
 VARIOUS KINDS OF GLOSSINESS AND THEIR CORRELATES

Kind of Glossiness	Correlate in Terms of Luminous Directional Reflectance	Diagram of the Angular Conditions
Specular	Ratio of $R_{60,-60}$ for the specimen to that of a perfect mirror.	
Sheen	Ratio of $R_{85,-85}$ for the specimen to that of a perfect mirror.	
Contrast	Ratio of $R_{60,-60}$ (specular) to $R_{60,0}$ (diffuse).	
Distinctness of image	Rate of change of $R_{i,-\theta}$ with angle of incidence, i , where the angle of view $-\theta$ differs by a few minutes of arc from that of mirror reflection, $-i$.	
Absence of bloom	Ratio of $R_{i,-i}$ to $R_{i,-\theta}$, where the angle of view $-\theta$ differs from the angle of mirror reflection $-i$ by a few degrees.	

which the elements of the volume transmit light regularly, so that it forms images. Transparency is correlated with luminous directional transmittance in the direction of regularly transmitted light. The ratio of this luminous directional transmittance to the average of the directional transmittances in all other directions (diffuse transmittance) is also a useful measure. The attribute of transparency is closely related to the question whether a volumic appearance is produced at all. Transparency of volumic perceptions approach but do not reach zero. Continuous gradients of luminance (as opposed to discontinuous breaks) often are a sufficient stimulus to a volumic appearance of nearly zero transparency (Fry, 1931). For nearly perfect transparencies the correlate most often used is the ratio of the average directional transmittance for all directions different from that of the regularly transmitted beam to the average for all di-

rections. This ratio, diffuse transmittance to transmittance, is sometimes called haze (American Society for Testing Materials, 1945), and is said to correlate with the haziness of the perceived volume. Haziness is related inversely to transparency and is often applied to nearly clear air or nearly clear plastics. The more transparent a volume is perceived to be, the less hazy.

The transparency perceived to belong to a surface is correlated with the degree to which the surface transmits light regularly. All the stimulus variables applying to the transparency of volumes are also applicable to surfaces. In addition, for transparencies approaching zero, the ratio of luminous reflectance of the surface with a black backing to the luminous reflectance of the surface with a standard white backing is widely used (paint-films, paper) under the name, contrast ratio (Judd, 1938). Contrast ratio may also be of some use as a stimulus corre-

late for the transparency of volumes having a front surface parallel to the back surface, but account must be taken of the light lost through the sides of the volume (edge effect).

The transparency perceived to belong to a light source is probably correlated with the fraction of the total number of elements in unit projected area of the illuminant that are luminous. A light source is probably never perceived as perfectly opaque (Kreezer, 1930). Even an incandescent filament is transparent in the sense that no front surface is perceived for it: it can be looked into but not through. Nor is a light source ordinarily perceived as perfectly transparent. Between these limits the transparency of a light source correlates with a contrast ratio of the luminance of the light source backed by a white backing to its luminance when backed by black. This is a relatively unexplored field.

Color perception for all modes of appearance has the attributes hue and saturation (see Table 9). There is one additional attribute for each mode. For the aperture and illuminant mode this additional attribute is brightness, varying from dim to very bright. For the (nonself-luminous) object modes this additional attribute is lightness, varying from black to white. A plot of hue, lightness, and saturation in cylindrical coordinates yields the psychological surface-color solid. Lightness is plotted as distance above the base plane; hue by angle about the central black-white axis, and saturation as distance from the axis. An alternative way to plot this solid is by use of rectangular coordinates, red-green being one horizontal coordinate, yellow-blue the other. The boundaries of this solid, often called the color pyramid, are determined by the properties of the visual mechanism. These boundaries are roughly those of a rounded rhomboid with saturated yellow being high in lightness, and saturated blue, low.

Other attributes of object-color perception are insistence and pronouncedness (Katz,

1935; MacLeod, 1932). Pronouncedness does not belong exclusively to the perceived object, however, but relates to the combination of object-color perception and illumination-color perception. It correlates with the illuminance of the scene. Insistence correlates with the luminance of the object and would seem to be nearly the same as the brightness of the aperture-color perception that could be derived from the object by interposition of a screen with a hole in it (reduction screen).

Analysis of the chromatic aspect of color perception in terms of blue, yellow, red, and green, alternative to the use of the terms, hue and saturation, is preferred by many. Anyone who practices this kind of analysis soon learns to think of colors as combinations of various amounts of these primaries and even to experience color directly in these terms. With sufficient practice fairly reproducible estimates may be made. These estimates indicate that blue and yellow cancel, so that a bluish yellow is usually not reported. Nor is a reddish green usually reported. One may, for example, have a yellowish red or a bluish red, but it is considered illogical to experience a red that is at once bluish and yellowish, though such reports are not unknown. This basis for the analysis of chromatic experiences is so universal that blue, yellow, red, and green have become known as the psychological color primaries. These are the fundamental colors taken to describe color processes in the optic nerve by all four of the theories listed in Table 8.

Other bases for the analysis of color experience may, however, be learned with greater or less difficulty. That which accords with the primaries of the Ladd-Franklin theory (see Table 8) is easy to learn, since it differs only in the one respect that red and green are yellow-forming instead of canceling. It is difficult, however, to learn to analyze color in terms of the Young-Helmholtz-König primaries, red, green, and violet.

Color Perception for Adaptation to Daylight

There have been many attempts to determine stimuli corresponding to color perceptions of the unitary hues, red, yellow, green, and blue. Spectrum stimuli and binary mixtures of such stimuli are used because of the comparative ease of specifying them. The appearance of the spectrum, however, depends upon the type of vision possessed by the observer, the size and location of the retinal region stimulated, the retinal illuminance, and the pre-exposure stimulus. Table 11 summarizes the chief results of these attempts to find stimuli for the unitary hues

TABLE 11

STIMULI FOR COLOR PERCEPTIONS OF UNITARY HUE (CF. DIMMICK AND HUBBARD, 1939a)

Experimenter	Date	Wavelength in Millimicrons			
		Red	Yellow	Green	Blue

Ladd-Franklin		495.7c	574.3	510.6	468.9
von Kries, Schrödinger		495.7c	574.3	495.7	468.9
Müller		498.2c	578.1	498.2	477.0

(Dimmick and Hubbard, 1939a, b). In these studies the observers were either presumed to be normal or found by test not to be seriously anomalous. They looked

directly at the spectrum stimuli so that a region near the center of the retina was used. The spectrum was neither too bright nor too dim to prohibit the characteristic appearance, and the pre-exposure stimulus was darkness, sunlight, overcast-sky light, or some other stimulus chosen with intent to avoid chromatic adaptation.

Analysis in terms of primary color perceptions. For adaptation to stimuli of nearly equal energy distribution (such as daylight, or noon sunlight) various of the functions given in Table 8 correlate well with measurements of the primary colors, red, yellow, green, and blue. Table 11 shows the spectrum stimuli corresponding to color perceptions of the unitary hues according to four of the theories listed in Table 8. The stimuli for unitary red (combinations of the short-wave and long-wave extremes of the spectrum) are identified by the wavelength of the complementary (relative to the equal-energy stimulus, see Table 7). The experimental result by Dimmick (495c in Table 11) is given on this basis also, so that it will be comparable. It will be noted that these theoretical stimuli agree quite well with the experimental results both for yellow and for blue, but they tend to indicate stimuli for red and green that experiment has shown would be called slightly bluish red and slightly bluish green, respectively.

The functions taken to represent the Ladd-Franklin theory correlate with experiment better than the other three because this theory conforms to the principle that red and green are yellow-forming rather than canceling. As may be seen from Table 11, this principle seems to accord with experiment; that is to say, the wavelength for unitary green is higher (more toward yellow) than the complement of unitary red, but it has never been fitted into an acceptable theory. Work by Tschermak and his associates (1929) indicates that failure of observers to be adapted to an achromatic color accounts for the failure of red and green to cancel exactly. But careful work by Dimmick and

TABLE 12
 CHROMATICITY COORDINATES (x, y, z) OF THE SPECTRUM COLORS

Hubbard (1939*a, b*) still shows unitary red and green to be yellow-forming instead of canceling.

Chromaticity diagram (Maxwell triangle). For adaptation to daylight or other nearly neutral light a convenient and widely used correlate of the chromatic aspects of the perception is the chromaticity diagram or Maxwell triangle (Hardy, 1936; Judd, 1933). The tristimulus values, X, Y, Z , in the standard coordinate system (or any transformation by equation 6, such as those given in Table 8) are expressed as ratios of their total: $X/(X + Y + Z)$, $Y/(X + Y + Z)$, $Z/(X + Y + Z)$. These ratios are called chromaticity coordinates, x, y, z , because they correlate well with the chromatic aspect, or chromaticness, of the color perception. (Note that $x + y + z = 1$.) Table 12 gives the chromaticity coordinates (x, y, z) of the spectrum colors at intervals of 5 $m\mu$. Figure 11 shows the chromaticity diagram formed by plotting the second of these ratios, y , against the first, x . This is probably the most widely used chromaticity diagram. Chromaticity diagrams have also been aptly called mixture diagrams because they indicate in a very simple way the chromaticity of the color resulting from the additive combination of any two lights. The point representing this chromaticity is found on the straight line connecting the points representing the two lights.

The primaries of the system are represented by points at the corners of a triangle. (Maxwell used an equilateral triangle, whereas Fig. 11 shows a right triangle, obtained by extending the line $x + y = 1$ from $x = 1$ to $y = 1$.) Every point within the triangle represents the chromaticity of a mixture of primary lights whose proportions are indicated by the chromaticity coordinates. [It is not necessary to plot z , because $z = 1 - (x + y)$.] In Fig. 11 the spectrum colors are shown by a curve known as the spectrum locus. They are identified by wavelength in millimicrons. It will be noted that

the spectrum locus is substantially straight from 540 $m\mu$ to the long-wave extreme. This means that the standard observer would find binary mixtures of, say, 550 $m\mu$ with 700 $m\mu$, closely equivalent to some intermediate portion of the spectrum. But the spectrum locus from 540 $m\mu$ to the short-wave extreme is convex. This means that for the standard observer a binary mixture of 540 $m\mu$ with, say, 400 $m\mu$ would differ importantly in chromaticity from the intermediate parts of the spectrum.

By drawing straight lines through any central point (such as $x = y = \frac{1}{3}$, representing the stimulus whose spectrum has constant irradiance per unit wavelength, the so-called equal-energy stimulus) and extending them until they cut the spectrum locus, we find the spectral complementaries relative to a stimulus represented by that point. That is to say, we may find the two parts of the spectrum that, when combined in proper proportions, will for the standard observer be equivalent to the central stimulus (see Table 7).

The straight line in Fig. 11 joining the extremes of the spectrum locus represents the chromaticities of the mixtures of the two extremes of the visible spectrum. The area bounded by the closed curve made up of the spectrum locus and this straight line is the locus of all physically realizable chromaticities. Note that the points representing the primaries of the standard coordinate system, the apices of the triangle ($x = 1, y = z = 0$; $x = 0, y = 1, z = 0$; $x = y = 0, z = 1$) all fall outside this area; that is to say, the primaries have chromaticities that are imaginary and not physically realizable.

Most of the primaries defined in Table 8 share this property. They are intended to indicate independent processes in the visual mechanism that are usually such that no part of the spectrum or combination of parts can succeed in stimulating them to the exclusion of the other processes. The three exceptions are the red processes in the Young

theory and in the initial stages of the Adams and Müller theories. The long-wave extreme of the spectrum is assumed to release these

spectrum locus comes close to this line. This means that although a short-wave spectrum stimulus has the power to elicit in the stand-

FIG. 11. The (x, y) -chromaticity diagram of the ICI system. The abscissa is the ratio of the tristimulus value X to the sum of all three $(X + Y + Z)$. The ordinate is the ratio of Y to this sum. The parts of the spectrum locus are identified by wavelength in millimicrons. The region bounded by this locus and the straight line (purple border) joining its extremes represents all chromaticities producible by actual stimuli. The central curved line represents the chromaticities of the complete radiator and is called the Planckian locus. Points on this locus are identified by the temperature of the radiator expressed on the Kelvin scale.

processes but to leave unstimulated the other processes of the systems.

The line, $y = 0$, is unassociated with luminosity and is known as the Alychne or lightless line. The short-wave extreme of the

ard observer considerable X and Z response, resulting under ordinary observing conditions in a vivid bluish purple color, radiant flux of wavelength 380 to 420 $m\mu$ is only slightly luminous. Note in Table 7 how very small

the complementary proportions are for this spectral region expressed in photometric terms. Since both the X and Z primaries fall on the Aychne, they are quite unassociated with the luminous aspect of the response, and refer only to the chromatic aspect.

maticity coordinates x, y, z are important correlates of the visual stimulus.

On the (x, y) -chromaticity diagram (Fig. 11) colors perceived under conditions of near daylight adaptation as grayish are represented near the center ($x = y = z = \frac{1}{3}$). Vivid colors are represented far from the

FIG. 12. Chromaticity confusions of the protanope and deuteranope (after Pitt, 1935) shown on the (x, y) -chromaticity diagram. The dotted lines connect points representing chromaticities found experimentally to be indistinguishable by the partially color-blind. The solid lines correspond to the latter König theory and to the Müller theory. Either set of lines indicates, for example, that the typical protanope will not be able to distinguish daylight (C) from a part of the spectrum near $493 \text{ m}\mu$ (normally perceived as bluish green).

The chromaticity diagram is the most convenient way to show the chromaticity confusions of dichromatic observers. It was pointed out by Maxwell in 1855 that all chromaticities confused by a dichromat with some given chromaticity are represented by points falling on a straight line on the chromaticity diagram. Figure 12 shows the families of straight lines on the (x, y) -chromaticity diagram that represent the chromaticity confusions of protanopic and deuteranopic observers according to Pitt (1935). The chromaticity diagram thus shows very completely the relation between the chromatic aspects of normal and dichromatic vision, and on this account alone the chro-

center. Thus this diagram forms a map on which the relations of the various chromaticities can be seen at a glance. The diagram, however, is considerably expanded in the green portion relative to the other portions, much as the Mercator projection of the earth's surface is expanded near the poles. Thus the saturation of the color perception correlates rather poorly with distance between the center of the (x, y) -diagram and the point representing the chromaticity.

Figure 13 shows the so-called uniform-chromaticity-scale diagram formed by plotting in triangular coordinates the ratio, $R/(R + G + B)$ called r , against the ratio, $G/(R + G + B)$ called g , where

$$\begin{aligned}
 R &= 3.1956X + 2.4478Y - 0.1434Z \\
 G &= -2.5455X + 7.0492Y + 0.9963Z \quad (9) \\
 B &= 0.0000X + 0.0000Y + 1.0000Z
 \end{aligned}$$

For colors having luminance equal to about 10 millilamberts and a gray surrounding field

The uniform-chromaticity-scale diagram has sometimes been used to derive hue and saturation scales and combination scales that are approximately uniform (OSA, 1944*b*). It indicates that the most saturated spectrum-color perception for a luminance of about

FIG. 13. Uniform-chromaticity-scale (UCS) triangle, according to Judd (1935). The primaries, *R*, *G*, *B*, are represented at the apices of the triangle: for example, the *R*-primary corresponds to $r = 1$, $g = b = 0$; and the line *BG* corresponds to $r = 0$. On this triangle the distance between two points is approximately proportional to the number of just perceptible chromaticity steps between the two chromaticities represented by the points. For example, it may be seen that Abbot-Priest sunlight is more confusable with the wavelength band near 570 $m\mu$ than it is with any other part of the spectrum.

of about the same luminance, the distance between a point representing the illuminant (such as Abbot-Priest sunlight, $r = 0.461$, $g = 0.466$, $b = 0.073$) on this diagram and the point representing the chromaticity of the color correlates somewhat better with the saturation of the color perception. If there is a considerable difference between the luminance of the color and of its surroundings the correlation again becomes poor.

10 millilamberts is that belonging to the long-wave extreme; the least saturated, that belonging to some point in the spectrum near 570 $m\mu$. For colors of considerably lower luminance (say 0.1 millilambert), the most saturated color perception would probably belong to the short-wave extreme (Haupt, 1922; Martin, Warburton, and Morgan, 1933; Purdy, 1931*a*). Work in this field is fragmentary.

Dominant wavelength and purity. A stimulus yielding an achromatic color perception for daylight adaptation will be found to be represented on the standard chromaticity diagram (Fig. 11) somewhere near to $x = 0.310$, $y = 0.316$ (ICI standard illuminant C, representative of average daylight). If straight lines are drawn from this point to the extremes of the spectrum locus, the area of the diagram representing physically realizable chromaticities will be divided into two parts. That part touching the spectrum locus is said to contain all the spectral colors because these chromaticities can be produced by mixing the achromatic light with light from some part of the spectrum. That part touching the purple boundary is said to contain all the nonspectral (or purple) colors because these chromaticities cannot be so produced. The hue perceived for a spectral color correlates fairly well with the wavelength of the part of the spectrum required to match it by mixture with the achromatic light. This wavelength is called the dominant wavelength of the spectral color. It can be found graphically from the chromaticity diagram (Fig. 11) by drawing a straight line from the point representing the achromatic light through the point representing the color and extending it until it cuts the spectrum locus. The wavelength of this intersection is the dominant wavelength.

The hue perceived for a nonspectral or purple color similarly correlates with the wavelength of that part of the spectrum required to be mixed with the color in order to match the achromatic light. This wavelength is called the complementary wavelength. It is likewise found graphically from the chromaticity diagram by drawing a straight line from the point representing the color through the point representing the achromatic light and extending it until it cuts the spectrum locus.

Both dominant wavelength and complementary wavelength can be found with reference to any fixed light, regardless of whether the observer is so adapted as to make the

fixed light appear neutral. But if the observer, who judges the hue belonging to the color, is so adapted that he perceives the fixed light importantly different from neutral or achromatic, it is obvious that the correlation between hue and dominant (or complementary) wavelength must break down. For a dark surrounding field the usual choice of fixed light is that having an equal-energy spectrum. This light has a chromaticity close to that judged to be neutral with a dark surrounding field. But, if the color refers to a surface perceived as a part of a surface-color environment, the illuminant of this environment is chosen as the fixed light.

In the color systems patterned after the opponent-colors theories (Table 8) constant dominant wavelength corresponds to a constant ratio of neighboring chromatic primaries (constant ratio of red to yellow, constant ratio of yellow to green, and so on) provided the sensitivities of the processes remain constant. Similarly, in the color systems (Table 8) patterned after the three-components theories, constant dominant wavelength may correspond to constant ratio of the amounts of the two highest primary processes. With isolated exceptions colors of equal dominant wavelength and unequal purities are perceived as having somewhat different hues, even by an observer adapted approximately to daylight. The correlation is therefore only approximate. It has been pointed out by Adams (1942) that in his stage theory of vision this correlation can be improved by assuming a nonlinear dependence on the stimulus of the processes in the cone response stage; for higher stimulations it is assumed that the sensitivities of the processes diminish.

The degree of approach of an unknown color to the spectrum color of the same dominant wavelength is commonly indicated by the ratio of the amount of the spectrum color to the total amount of the two-part combination. This ratio is called purity, and if the amounts are specified in luminance units the ratio is called colorimetric purity.

Colorimetric purity for nonspectral colors has been defined in two ways, both awkward, and little used in actual practice. By far the most common convention is to express the amounts in units of the excitation sum, $X + Y + Z$, the resulting ratio being called excitation purity (Hardy, 1936; OSA, 1944b).

Excitation purity corresponds simply to distance ratios on the chromaticity diagram of the standard coordinate system. But, in general, excitation purity has more complicated correspondences in transformations of the standard system. This distinguishes it from colorimetric purity which has a meaning apart from the coordinate system and is therefore invariant in transformations.

It is also conventional to define excitation purity for nonspectral colors by assigning to colors that fall on the line connecting the extremes of the spectrum locus a value of excitation purity equal to unity. Excitation purity p_e is thus defined simply in terms of the chromaticity coordinates, x_b, y_b , of the border (be it spectrum locus or purple boundary) at the intersection of the straight line connecting the point, x, y , representing the unknown color with the point, x_w, y_w , representing the fixed light, thus:

$$p_e = \frac{x - x_w}{x_b - x_w}$$

or

$$p_e = \frac{y - y_w}{y_b - y_w} \quad (10)$$

Ordinarily both these expressions yield the same result. But if, as may easily be, both y and y_b are nearly the same as y_w , the y -expression reduces to the ratio of two very small numbers, each of which is uncertain because of rejection errors in the computation. Excitation purity should be computed from the expression having the larger denominator because this one will be less affected by rejection error.

Colorimetric purity p_c can be computed from the same chromaticity coordinates, thus

$$p_c = \frac{(y_b/y)(x - x_w)}{x_b - x_w}$$

or

$$p_c = \frac{(y_b/y)(y - y_w)}{y_b - y_w} \quad (10a)$$

whichever is determinable with the least rejection error. Formulas converting excitation purity to colorimetric purity, and the reverse, have been worked out (OSA, 1944b).

Both forms of purity arbitrarily assign all colors on the border of the chromaticity diagram the same maximum value (100 per cent). Since the spectrum colors are perceived as having different saturations, good correlation between the purity of the color and the saturation of the color perception can exist only within a group of colors of constant dominant wavelength. It is also true, as for the chromaticity diagram just discussed, that the approximate correlation holds only for colors of nearly identical luminance. The two forms of purity are alike in these respects, but colorimetric purity for dominant wavelengths less than $460 \text{ m}\mu$ yields saturation scales that are perceptually less uniform than those yielded by excitation purity. In the former scales large purity differences near the spectrum are almost imperceptible whereas small differences near zero purity are easily perceptible. Dominant wavelength and purity have been used rather widely in spite of their limited correlation with the hue and saturation of the perceived color (Hardy, 1936).

Munsell hue, value, and chroma. The most generally applicable correlates of hue, lightness, and saturation of object colors in daylight are the recently developed definitions of Munsell hue, value, and chroma (Newhall, Nickerson, and Judd, 1943). They apply to an observer adapted approximately to daylight and viewing objects in an object-color environment such that the average luminous directional reflectance of the surroundings is not less than 10 per cent. They do not apply well to object colors viewed with dark surroundings, nor to self-luminous

areas in fields whose elements differ in luminance by factors much above 100.

Table 13 gives the definition of Munsell value in terms of luminous directional re-

decibel scale of luminance when the observer is approximately adapted to the luminance of the field. Actually the Munsell value scale differs from the scale of log reflectance by

fectance relative to magnesium oxide. If the object is transparent, Y_V should be taken as its luminous transmittance. Munsell value correlates better with the lightness of the color perception than does luminous directional reflectance (or luminous transmittance in the case of a transparent object) in the sense that it gives a scale perceptually more uniform. Equal value intervals are about equally easy to distinguish, whereas a given difference in luminous directional reflectance near 100 per cent is much harder to distinguish than the same difference near 1 per cent. Munsell value thus plays for objects in an object-color environment a role similar to that played for aperture colors by the

giving larger reflectance intervals near zero (black). This may be seen by plotting the values in Table 13. It reflects the higher threshold of an observer adapted to a daylight illuminated gray of 10 per cent directional reflectance compared to a nearly dark-adapted observer.

In Figs. 14, 15, and 16 the definitions of Munsell hue and chroma are given in terms of the standard (x, y) -chromaticity diagram for dark (Munsell value = 1/), middle (Munsell value = 5/), and light (Munsell value = 9/) colors. Similar definitions for other Munsell values are given by Newhall, Nickerson, and Judd (1943). Note that the loci of constant Munsell hue are curved and

Fig. 14. Definition of Munsell hue and chroma for dark colors (Munsell value = 1/) in terms of the (x, y) -chromaticity diagram. The slightly curved lines intersecting at the point representing standard source *C* ($x = 0.310$, $y = 0.316$; representative of average daylight) correspond to constant Munsell hue. The approximately elliptical closed curve corresponds to Munsell chroma /2. The elliptical curve surrounding this curve and intersecting the spectrum locus near Munsell hue 7.5YR corresponds to Munsell chroma /4. Parts of the loci for Munsell chromas /6, /8, /10, and /12 are also shown. For colors darker than Munsell value 1/ (daylight reflectance equal to 0.0121), these loci become progressively farther from the source-*C* point. And as Munsell value (and daylight reflectance) approaches zero, the distance between the source-*C* point and all points on these loci becomes indefinitely great. (From Newhall, Nickerson, and Judd, 1943.)

FIG. 15. Definition of Munsell hue and chroma for middle colors (Munsell value = 5/, or daylight reflectance equal to 0.1977) in terms of the (x, y) -chromaticity diagram. Note that the part of the spectrum having the lowest Munsell chroma corresponds to Munsell hue of about 9Y (573 $m\mu$, upper right-hand corner). (From Newhall, Nickerson, and Judd, 1943.)

Fig. 16. Definition of Munsell hue and chroma for light colors (Munsell value = 9/) in terms of the (x, y) -chromaticity diagram. It will be noted that the hue loci drift somewhat from one Munsell value to another, and that the chroma loci become progressively smaller with increase in Munsell value. Furthermore the chromaticity range for which definitions of Munsell hue and chroma are given is much smaller at value 9/ than it is at lower values (see Figs. 14 and 15). This is because it is not possible to produce chromaticities outside this range by means of diffusely reflecting specimens and still have the Munsell value come up to 9/ (daylight reflectance equal to 0.787); that is to say, chromaticities outside this range correspond to Munsell value 9/ only if the spectral reflectance is greater than 1.000 for some parts of the spectrum. These boundaries between real and imaginary colors are called the MacAdam limits (OSA Committee on Colorimetry, 1944b). (From Newhall, Nickerson, and Judd, 1943.)

deviate from lines of constant dominant wavelength, which are straight on the chromaticity diagram. To a first approximation, Munsell hue compensates for the failure of dominant wavelength to correlate with the hue of the color perception.

Note that the chroma loci on Figs. 14, 15, and 16 do not parallel the course of the spectrum locus, as would lines of constant purity. On the contrary, Fig. 15 indicates that the colors of the spectrum in the neighborhood of hue 9Y (about 573 $m\mu$) yield color perceptions of considerably lower saturation than those of other portions of the spectrum. To a first approximation, Munsell chroma corrects the failure of purity to correlate with saturation by its arbitrary assignment of the same designation (100 per cent) to all spectrum colors.

Note also that the locus defining chroma /2 for dark colors (Munsell value of 1/; Fig. 14) embraces a much larger fraction of the chromaticity diagram than that defining chroma /2 for light colors (Munsell value 9/; Fig. 16). This disparity between the two loci reflects the experimental fact that, of two chromatic colors of identical chromaticity, the light color yields a color perception of considerably higher saturation than the dark. On this account the Munsell chroma of an object color represents, to a first approximation, the saturation of the perception of object colors of all hues and lightnesses.

To summarize, Munsell hue, value, and chroma may be taken as the correlates of the hue, lightness, and saturation, respectively, of object colors when the observer is adapted to daylight. These correlates have the further advantage of being related approximately linearly to the magnitudes of the corresponding subjective attributes. Thus Munsell hue, value, and chroma reflect the psychological facts of object color to a good approximation, whereas dominant wavelength, luminous directional reflectance, and excitation purity reflect them only to a poor approximation. The Munsell notation

for an object color may be obtained by calculation from its reflectance (or transmittance) and its chromaticity coordinates (x , y) as in Table 13 and Figs. 14, 15, and 16, or it may be estimated by direct visual comparison with the color scales of the *Munsell Book of Color*.

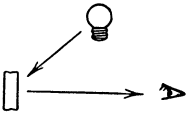

Table 14 summarizes the stimulus correlates for the perception of color for (1) self-luminous areas, (2) transparent objects, and (3) matte, opaque objects. The fact that it is possible to list photometric and colorimetric variables that are in close correspondence with the attributes of color perception emphasizes the great strides made in visual psychophysics since 1900. Expressed in terms of radiometric quantities, the attributes of color perception are complicated interdependent functions of wavelength. In the standard luminosity function we have a simpler correlate for lightness and brightness, for all modes of appearance. But the precise functional relation between perceived brightness and luminance has not yet been determined as explicitly as has the relation between loudness and sound intensity, for example. Hue and saturation of object colors correlate closely with Munsell hue and Munsell chroma, respectively, which depend upon the firm establishment of colorimetry on the basis of X- and Z-chromatic functions of the standard observer. Further work remains to develop correlates yielding better agreement than dominant wavelength and purity with the hue and saturation perceived to belong to colors of self-luminous areas against a dark surrounding field.

Color Perception for Any Adaptation

The discovery of photometric and colorimetric functions by means of which we might predict the color perception belonging to any element or aspect of any visual field is the goal of theories of color perception. This goal is far from reached. But some of the relations already developed have considerable generality.

TABLE 14

SUMMARY OF STIMULUS CORRELATES FOR THE PERCEPTION OF COLOR BY A DAYLIGHT-ADAPTED OBSERVER

Radiometric	Photometric and Colorimetric	Perceptual
Spectral radiance 	Luminance Dominant wavelength and purity, or chromaticity coordinates	Brightness (dim to bright) Hue and saturation, or red-green, blue-yellow
Spectral transmittance 	Luminous transmittance Dominant wavelength and purity, or chromaticity coordinates	Lightness (dark to clear) Hue and saturation, or red-green, blue-yellow
Spectral directional reflectance 	Luminous directional reflectance Dominant wavelength and purity, or chromaticity coordinates, or Munsell value Munsell hue Munsell chroma	Lightness (black to white) Hue and saturation, or red-green, blue-yellow Lightness (black to white) Hue } { red-green Saturation } { blue-yellow

Retinal adaptation (negative after-image, Bezold-Brücke phenomenon). When a light gray spot on a uniform field of darker gray is fixated steadily for more than a few seconds, it is perceived to grow darker and thus approaches more closely the appearance of the background. In the same way the difference perceived between a dark gray spot on a lighter gray field decreases with steady fixation and finally reaches a state of equilibrium in which the difference in lightness is far below what it was at the start. Sometimes the difference falls below threshold, and the spot disappears momentarily. Any slight movement of the eyes restores the originally perceived difference. A few involuntary random eye movements may cause the spot to be perceived as a ring differing much from the background, and surrounding a center differing little. These temporal changes are usually attributed to depletion of photosensitive substance in the retina and are said to be the result of retinal adaptation.

Similarly, if the spot is chromatic, say saturated yellowish red, it is seen to lose its

chromatic character with continued steady fixation, becoming less and less saturated until it approaches gray. This transition from a saturated yellowish red to a nearly gray color does not, however, yield a series of colors of constant hue. There is a hue change toward yellow as well as a loss of saturation. The hues that are invariant during adaptation are close to the unitary red, green, yellow, and blue (see Table 11), and according to Tschermak (1929) they correspond to them exactly if precautions are taken to have the observer adapted initially to a background truly gray.

When a spot on a background is fixated for a time and then removed, a negative after-image is perceived, a dark image for a light spot, a greenish image for a red spot, and a bluish image for a yellow spot. Since the hue of the negative after-image is approximately the psychological opposite of that of the original spot, it is said to be complementary. But the hue deviates both from the opposite hue and from the complementary shown in Table 7 by being more reddish blue.

The chief aspects of the negative after-image resulting from local chromatic adaptation may be accounted for qualitatively according to the three-components theory of vision, and moderate degrees of general adaptation can be accounted for quantitatively in much the same terms. This explanation is expressed by the so-called coefficient law enunciated by von Kries (1905).

It is a corollary of Grassman's laws that the components of a metameric pair will remain a match over a wide range of luminances and states of retinal adaptation. The appearance of each component may change from light to dark or even from red to green, depending on the adaptive state of the retina and on the background against which both members of the metameric pair are viewed. But, for a wide middle range of luminance they change appearance together. This behavior would be expected in a visual mechanism that starts with three independent photochemical processes, each having a sensitivity dependent on the concentration of a photosensitive substance.

The particular concentration present in a given retinal area at a given moment would be the result of a balance between the decomposing action of radiant energy previously incident on that area and the nutritive action of the retina. If a given stimulus produces in a rested portion of the retina the activities R , G , and B (see Fig. 7), and if S_r , S_g , and S_b are coefficients (less than 1) expressing diminished sensitivity of a pre-adapted retina or portion of the retina, then the coefficient law states that the appearance of the stimulus for the nonrested retina will be indicated by the products, $S_r R$, $S_g G$, and $S_b B$, just as the appearance for the rested retina is indicated by R , G , and B . Thus, if a color match is set up for a pair of stimuli between a rested and a nonrested retinal area, a comparison of the respective values of R , G , and B for the two stimuli will serve to evaluate the sensitivity coefficients, S_r , S_g , and S_b , and so to define the state of chromatic adaptation. Once these

sensitivity coefficients are known they may be used to determine by computation whether any other pair of stimuli, one for the rested, the other for the nonrested retinal area, will be equivalent.

Wright (1934) has verified this coefficient law in the course of an attempt to determine the primaries referred to by R , G , and B . He was able, by application of the law, to deduce primaries that would be perceived to change in brightness alone, without any chromatic change during adaptation. The R - and G -primaries are not far different from those of the Ladd-Franklin theory (see Fig. 7), and the B -primary, less well determined, may not depart much either. The functions given in Table 8 for the Ladd-Franklin theory would therefore be the correlates for retinal adaptation in so far as it is described by the von Kries coefficient law.

There are reasons to believe, however, that the adjustment of the sensitivities of the initial receptor processes is only a part of the explanation of local and general color adaptation. Studies by Schouten and Ornstein (1939) on the change in retinal sensitivity resulting from stimulation of neighboring areas indicate that sensitivity changes may spread over the retina too rapidly to be explained by photochemical processes. Electrical action or nerve action influencing retinal sensitivity and taking place laterally in the retina is suggested. A momentary flash of strong light yields a complicated series of after-images (Judd, 1927) that also requires an explanation involving more than photochemical changes.

The coefficient law does not account for the failure of the color of the negative after-image to be an exact complementary to the color of the primary image. It does not account for the hue change with duration of stimulus, nor for an aspect of the negative after-image known as the Bezold-Brücke phenomenon.

The Bezold-Brücke phenomenon refers to the fact that the hues of most stimuli change with luminance. Spots of red, yellow, green,

or blue often exhibit a decreased saturation but little or no hue change when luminance is increased. But yellowish red and yellowish green spots are yellower at high luminance, and bluish red and bluish green are bluer. It should be noted that in order to obtain this hue change the observer may fixate one spot of light while it is changed from a high luminance to a low. Or he may fixate the brighter spot, then the darker. By either procedure he projects the after-image of the first spot onto the second. The Bezold-Brücke phenomenon is thus usually obtained as an aspect of the negative after-image produced by retinal adaptation. Only if the time interval between presentation of the bright and dark spots is too prolonged would there be no after-image involvement.

The best attempt to explain the Bezold-Brücke phenomenon by the three-components theory of vision rests on a simple and likely assumption (Purdy, 1931*b*). The perception of a yellowish red light, produced, say, by 610 $m\mu$, results from a major activity in the red-generating process and a minor activity in the green-generating process (see Figs. 5, 6, and 7). It is therefore assumed that the retina will become desensitized chiefly by loss of red-generating substance and only slightly by loss of green. For a portion of the retina partially adapted to light of 610 $m\mu$, the appearance of this light should therefore incline toward that of shorter-wave light (toward yellow). For spectral regions near the crossing points of the curves of spectral sensitivity (Figs. 5, 6, and 7) the corresponding two photosensitive substances are assumed to be depleted equally, and no hue change is to be expected. By this argument, the original forms of the Young-Helmholtz theory (Figs. 5 and 6) do not work, because the crossing points fall at the wrong places in the spectrum. In order to account for the invariant hue found experimentally near 470 $m\mu$ we have to use the primaries of the Ladd-Franklin, or early König, theory (Fig. 7). But we find by this theory that a red-

dish-blue spot should change toward red (Purdy, 1931*b*) with increase in luminance, the reverse of the experimental result. The simple account of the Bezold-Brücke phenomenon in terms of the three-components formulation has, therefore, to be given up.

Since the invariant hues correspond well with the psychologically unitary hues (red, yellow, green, and blue), the Hering theory is often used as a basis not only for stating the facts of retinal adaptation but also for explaining them. Figure 17 shows Purdy's results (1931*b*) on the Bezold-Brücke phenomenon compared with the wavelength change corresponding in the Hering theory (see Table 8) to a hue change equivalent to a reduction of 20 per cent in the red-green response relative to the yellow-blue response. The ratio of the amounts of the two neighboring primary processes (red to yellow, yellow to green, green to blue, blue to red) is the correlate of hue. It will be seen that Purdy's results on the hue change due to an increase in retinal illuminance from 100 to 1,000 trolands may be described as closely equivalent to a 20-per-cent reduction in the red-green response relative to the yellow-blue. The basic determiners of this phenomenon are therefore the red-green and yellow-blue responses whose expressions are given in Table 8. This explanation does not prove that an adjustment of retinal sensitivities in the sense of the von Kries coefficient law is nonexistent; it simply indicates that the essential mechanism of the Bezold-Brücke phenomenon is to be found later in the chain of events.

The lower sensitivity of the red-green response compared to the yellow-blue response is ascribable to a nutritive preponderance of the yellow-blue process (Müller, 1930). This nutritive preponderance of the yellow-blue process leads to a prediction that the hue of a color should vary with duration in a manner analogous to the change with luminance. This prediction is borne out fairly well by experiment.

As already mentioned, there is a similar, but not exactly analogous, change in hue when a chromatic color is mixed with an achromatic color. The chromaticities produced by this mixture are shown by straight lines on the chromaticity diagram (Fig. 11). These lines

Y/Y_0 , and Z/Z_0 , called chromatic reflectances, in which X_0, Y_0, Z_0 , are the tristimulus values of a standard white surface. The third stage is evaluated by the numbers, V_x, V_y , and V_z , found from Table 13 by substituting in succession the chromatic reflectances, in per

FIG. 17. Bezold-Brücke phenomenon in terms of the Hering theory. The circles are Purdy's experimental determination of the wavelength difference corresponding to the hue change caused by increasing retinal illuminance from 100 to 1000 trolands. The dots are derived from the Hering theory. The index of hue is the ratio of chromatic excitation for neighboring chromatic primaries (red to blue, blue to green, green to yellow, yellow to red). The dots show the hue change corresponding to a reduction of the red-green excitation by 20 per cent relative to the yellow-blue.

correspond to constant dominant wavelength. The experimental facts are shown fairly well on Figs. 14, 15, and 16 on which the lines of constant Munsell hue are seen in general to be curved instead of straight. The two exceptions are found near Munsell hue 10Y (about 572 $m\mu$) and 5P (complementary to about 560 $m\mu$). Adams has applied his theory to this problem and has shown that it can be closely solved by the assumption of a non-linear dependence of the third stage on the second. The second stage of the Adams theory (Table 8) is given directly by X/X_0 ,

cent, for Y_V . By plotting amount of blue-yellow process, $0.4(V_z - V_y)$, against amount of red-green process, $V_x - V_y$, we obtain a chromatic-value diagram on which the loci of constant hue should appear as straight lines passing through the origin, and those of constant saturation as circles. Figure 18 shows the hue and chroma contours for the ideal Munsell colors plotted on this diagram. The chroma contours do indeed approximate circles. The contours of constant Munsell hue show significant deviations from straight lines, but there is some basis for believing that

straight lines on the chromatic-value plot correlate better with color perceptions of constant hue than does Munsell hue, itself.

Postretinal adaptation (simultaneous color contrast, color constancy, color transformation). Color contrast is the name given to

by projection of a negative after-image of the red background onto the gray. Simultaneous color contrast thus seems superficially to correspond to a weak exertion of processes that yield retinal adaptation and, indeed, is sometimes called simultaneous in-

FIG. 18. Munsell renotations on the Adams (1942) chromatic-value diagram (after Nickerson, 1947). The abscissa ($V_x - V_y$) refers to the optic-nerve-fiber stage of the Adams theory (see Fig. 10) and evaluates the red-green response. The ordinate ($V_z - V_y$) similarly evaluates the blue-yellow response. Lines of constant hue on this diagram are straight lines passing through the origin which represents an achromatic color. Lines of constant saturation correspond to circles centered on the origin. Note that the experimental data expressed by the Munsell renotations, and intended to be in accord with the ideal Munsell system, support the Adams theory remarkably well, though not perfectly.

the effect exerted on the appearance of a portion of the visual field by the stimulation of the retinal regions corresponding to the neighboring portions of the field. If a small piece of medium gray paper is placed on the background of a large sheet of red paper and its center fixated, the gray paper takes on a greenish-gray appearance. Similarly a green background induces purple, and a yellow background induces blue.

If the fixation point is shifted from time to time, the appearance of the gray paper changes to a rather saturated bluish green

duction to emphasize its similarity to successive induction often ascribed to retinal adaptation. The explanation that accords with this view is that the red-generating substance is used up in the surrounding retinal areas, the deficiency being supplied from the central area by a process of diffusion, leaving the central region relatively blue-green sensitive. This, in turn, makes the gray take on a greenish appearance.

The evidence is against this view, however. Color contrast is too nearly instantaneous to arise from a process of diffusion of

retinal fluids or substances. It is enhanced rather than diminished by elimination of clearly defined contours. Binocular simultaneous color contrast can occur (Tschermak, 1929). Likewise there can be obtained under some conditions the contrast color for the area corresponding to the blind spot, the exit point of the optic nerve. Further evidence is available from pathological cases (Müller, 1930). Simultaneous color contrast is accordingly considered to have its chief seat in the nerve processes outside the retina, and to be of the same nature as other contrast phenomena involving not only the eye but also other sense organs. Electroadaptation of the retina (Schouten, 1939) probably also contributes to it, but diasceral light and light diffracted, scattered, and reflected within the eyeball opposes it.

When the illumination of a room is changed from daylight to candlelight, the observer perceives readily that there is a reddish-yellow character in the illumination not present before. After about 5 minutes, presumably because of retinal adaptation, this reddish-yellow character is perceived much less definitely. Even at the instant of change, however, objects perceived to be white in daylight are usually perceived to be white, or nearly white, in candlelight, despite the fact that the spectral composition of the radiant energy reaching the eye of the observer has changed markedly. The transformation of an object color perceived under chromatic illumination from the appearance proper to the spectral composition of the radiant energy leaving it back nearly to its daylight appearance is called color transformation (Jaensch, 1921).

Color transformation depends on the grasp of the situation by the observer. If he perceives that the illumination is reddish yellow, he also automatically adjusts his perception of object color accordingly. Color transformation has therefore been described as an automatic discounting of the illumination color. The perception of illumination color is drawn from the organization of the

visual field itself. If the observer fails to make an organization that includes objects illuminated by reddish-yellow light, he will perceive the object colors to be quite different (more reddish yellow) than in daylight, or he may even fail to organize the visual field into objects in an illuminated space at all. Such failure may come from destruction of cortical tissue as by a gunshot head wound (Gelb, 1920) or from an insufficiently structured visual field. Changes from one organization to another take place rapidly, much as the reversible-staircase picture changes from a bottom view to a top view. Color transformation is therefore ascribed to cortical processes, but these processes are rapid and largely automatic rather than deliberate like those of intellectual judgment.

In studies of color transformation, and also in studies of the effects of local changes in the amount and spectral composition of the illumination (as when an object in shadow is compared with another outside the shadow), the most striking result is the tendency of object colors to be perceived as of the same hue, lightness, and saturation, regardless of the illuminant. Often the object-color constancy (Gelb, 1929; MacLeod, 1932, 1940) is virtually perfect, but it is possible for the same observer to respond to the stimulus in very different ways. If he regards an element of the object merely as a patch of color, his responses may exhibit only a slight tendency toward constancy with change in the illuminance of the working plane. His estimates of lightness may correlate better with luminance (see Table 14) than with luminous directional reflectance, or his estimates may correlate with some intermediate factor. But if he judges the object color relative to others in the field of view, his estimates of lightness will correlate well with luminous directional reflectance.

The observer will, of course, perceive a difference between a highly illuminated object and a poorly illuminated one. The former is sometimes reported as having a more

pronounced color (Katz, 1930). Pronouncedness is an attribute of the colors perceived to belong to all objects in a uniformly illuminated space. It correlates with the average luminance of the visual field corresponding to the illuminated space, or with the illuminance of the observer's eye by light from the illuminated space, or with some other equivalent photometric quantity (Bocksch, 1927; Bühler, 1922; Gelb, 1929; Katz, 1930; Koffka, 1935; Pikler, 1931, 1932).

By color transformation an observer is able to make object-color perceptions immediately that accord well with what he obtains a few minutes later after he has become completely adapted to the new illuminant. Also by color transformation an observer is able to perceive an object in shadow or colored light as having a color resembling that perceived to belong to it when it is taken out of the local deviating illumination and viewed by the general illumination (MacLeod, 1932, 1940). Simultaneous color contrast also tends in the direction of preserving object-color constancy, though to a much smaller degree, according to Jaensch (1921).

Another factor tending to preserve the color constancy of visual objects is memory color (G. K. Adams, 1923). If the room is full of familiar objects, recognition of the object in an unfamiliar illumination will often cause its color to be perceived as it would be in the usual kind of illuminant, say daylight. Substitution of an object of the same size and shape but of considerably different color may often go unrecognized. Memory color leads to perfect color constancy of visual objects and is ascribed to cortical processes. Sometimes the phenomenon of color transformation has been falsely ascribed to memory color. But color transformation occurs in a regular way, including regular deviations from color constancy. Furthermore the phenomenon can be obtained characteristically with quite unfamiliar test objects. It is probably true, however, that in daily life color transformation and memory color work together to promote recognition

of objects in unfamiliar illuminations and to prevent disorientation. In producing this effect they are aided greatly by retinal adaptation, and somewhat by simultaneous color contrast.

Indices of the attributes of color perception. Perfect correlates of the attributes of color perception have yet to be worked out. There are two methods of approach to this problem. One is the analytical approach; another is the configurational approach.

In the analytical approach an attempt is made first to evaluate the direct contribution from the element of the visual field under consideration, then to evaluate the indirect contribution to the color of this element induced by other elements neighboring in space and immediately preceding in time. The sum of these contributions gives the perceived color. By this view the basic correlates are the expressions for white-black, yellow-blue, and red-green given in Table 8. White, black, yellow, blue, red, and green take on the nature of elementary sensations and apply not only to matte opaque objects but also to elements of the visual field perceived to belong to self-luminous objects and to elements perceived as film or aperture color. According to this view both the lightness of a nonself-luminous object and the brightness of an aperture or self-luminous object are to be correlated with the white-black response. Hue is to be correlated with the ratio of responses of neighboring chromatic primaries (red to yellow, yellow to green, green to blue, and blue to red). Saturation is to be correlated with the fraction of the total chromatic response relative to the total achromatic plus chromatic.

The advantage of this view is that it sanctions experimentation, with simple, controlled conditions of observation, for the purpose of building up a store of information regarding the color inductions produced by various pre-exposure and surrounding fields (Müller, 1930; Tschermak, 1929). It gives an insight into the working of the visual mechanism by ascribing various portions of

the induced contribution to such elements as changes in sensitivity of the initial photochemical processes, to contrast, and to nutritive differences among the assumed neural processes. The chief disadvantage of using the analytical method exclusively is that it has so far proved to be impossible to put the pieces together so as to predict successfully the color perceptions belonging to elements of a complicated field. It is not clear whether the present limitations of the analytical method are ascribable to errors in evaluating the relative importance of the various components, or whether the analysis has itself caused an essential aspect of color perception to be ignored.

In the configurational approach an effort is made to take direct account of the total stimulating situation, simple or complex. The basic idea is that color perception correlates with gradients in the visual field relative to some frame of reference rather than with an absolute response to each element separately (Koffka, 1935). Explicit account is taken of the mode of appearance of the color. For the aperture and illuminant modes of appearance, brightness is correlated with the luminance of the spot relative to a function of the average luminance of the whole visual field (Kardos, 1935). Hue and saturation are similarly correlated with the chromaticity of the spot considered in relation to a function of an average chromaticity of the whole visual field (Judd, 1940).

For colors perceived to belong to nonself-luminous objects it has been found possible to deal successfully with complicated experimental situations in which the various matte objects are in a visual space that is perceived to be uniformly and diffusely illuminated (Helson, 1938, 1940). The color change perceived when the illuminant, or the background, or the state of adaptation is changed has been termed *color conversion* by Helson (1938). The principle of color conversion for object colors is that objects whose luminous directional reflectance is above a certain critical value, called the

adaptation reflectance, tend toward the hue of the illuminant color, and those whose reflectance is below this value tend toward the after-image complementary of the illuminant hue. In this configurational approach the reference point is the adaptation reflectance. It is found to be about half the average luminous directional reflectance of all objects in the visual field (Judd, 1940).

The lightness of the object-color perception was found to correlate well with $R_{\theta}/(R_{\theta} + R_f)$, where R_{θ} is the luminous directional reflectance of the object, and R_f is the average luminous directional reflectance of all objects in the visual field. R_{θ} is computed from equation 4f by using the actual spectral irradiance of the (usually non daylight) illuminant.

The fundamental reference point on the chromaticity diagram for estimates of hue and saturation is the point corresponding to an achromatic color. As a first approximation this point corresponds to that representing the chromaticity of the illuminant. That is to say, a series of spectrally nonselective (gray) papers appears nearly gray under any kind of illumination. However, for strongly chromatic illuminants a nonselective surface whose reflectance is close to adaptation reflectance appears slightly off-gray in the direction of reddish blue. The point corresponding to an achromatic color is therefore slightly on the green side of the illuminant point for surfaces whose reflectance is close to adaptation reflectance. For lighter and darker objects the achromatic point deviates in a regular way from this region slightly on the green side of the illuminant point.

Work by Judd (1940) shows that hue is indicated approximately by the direction on the UCS triangle (see Fig. 13) of the line connecting the achromatic point with the point representing the object color, and that saturation is indicated approximately by the length of this line. More careful work by Bouma and Kruithof (1947) indicates, however, that hue does not correlate perfectly

with the direction of this line on the UCS triangle, or with any transformation of it.

Unpublished work by Helson and his associates has also led to a principle of color conversion for aperture or illuminant color. The reference point on which this principle is based is the adaptation luminance, which is found to be about half the average luminance of the visual field. This principle states that parts of the field above adaptation luminance tend toward the color of that part viewed under daylight adaptation, and parts below the adaptation luminance tend toward the after-image complementary. The Bezold-Brücke phenomenon is a special case of this principle of color conversion for aperture and illuminant color.

For visual space perceived to be directionally illuminated, the color perceptions of opaque objects depend upon how the observer perceives their surfaces to be oriented with respect to the chief direction of the illumination. Luminous directional reflectance fails under these circumstances to be a reliable correlate of the lightness of the perceived color, and no substitute for it has yet been worked out. If there are glossy surfaces in the field of view, some of them may have luminous directional reflectances greatly exceeding unity. In a rough way any excess of luminous directional reflectance above unity correlates with the glossiness of the perception. But other aspects of the situation, such as the shape and character of the mirror images seen by light reflected from the surfaces relative to other shapes in the field, have a bearing on the glossiness of the object perception. These same aspects also influence the lightness of the color perception of glossy objects. Similarly it is known qualitatively that the shape and character of the transmitted images determine the transparency perceived to belong to volumes and surfaces. Color perception of objects is interrelated with the perception of their transparency and glossiness in ways that have not yet been evaluated quantitatively.

GLOSSARY

- ABSOLUTE LUMINOSITY.** Luminosity (which see) expressed in absolute terms, such as lumens per watt (see Table 5); distinguished from relative luminosity (see \bar{Y} of Table 6).
- ACHROMATIC COLOR.** Color perceived to have no hue, same as neutral color.
- ACHROMATOPIA.** Type of vision by which all colors are perceived as achromatic.
- ACHROMATOPSIA.** Same as achromatopia.
- ADAPTATION REFLECTANCE.** Reflectance above which spectrally nonselective surfaces tend toward the hue of the illuminant, and below which the hue tends toward the after-image complementary; equal to about half of average of the luminous directional reflectances of the surfaces filling the visual field.
- ALYCHNE.** Line on the chromaticity diagram (outside the area representing physically realizable colors) corresponding to zero luminosity; lightless line.
- ANOMALOUS TRICHROMATISM.** Trichromatic type of vision possessed by an observer whose metamers depart from normal in a way not to be explained by abnormal ocular pigmentation.
- APERTURE COLOR.** Color perceived as filling a hole in a screen; same as film color (see Table 9).
- APOSTILB.** Unit of luminance equivalent to $\frac{1}{10}$ millilambert (see Table 4).
- BEZOLD-BRÜCKE PHENOMENON.** Change of hue with luminance.
- BLIND SPOT.** Exit point of the optic nerve; also the part of the visual field corresponding to this point.
- BLOOM.** Appearance of haze near the highlight of a glossy specimen.
- BRIGHTNESS.** Psychological attribute of aperture and illuminant-color perceptions in terms of which they may be ordered on a scale from dim to bright.
- CANDLE.** Unit of luminous intensity; a source of 1 candle in all directions emits 4π lumens (see Table 4).
- CANDLE PER SQUARE CENTIMETER.** Unit of luminance equivalent to 1000π millilamberts; same as stilb (see Table 4).
- CANDLE PER SQUARE FOOT.** Unit of luminance equivalent to 3.380 millilamberts (see Table 4).
- CHROMATIC ADAPTATION.** Process by which the visual mechanism comes to equilibrium under the influence of a stimulus of nondaylight chromaticity.
- CHROMATIC COLOR.** Color perceived to have a hue.
- CHROMATICITY-CONFUSION LINES.** Lines on the chromaticity diagram indicating the normal chromaticities confused by a partially color-blind observer (see Fig. 12).
- CHROMATICITY COORDINATES.** Ratio of one of the tristimulus values of a color to the sum of all three (see Table 12, Figs. 11 and 13, and equation 8).

CHROMATICITY DIAGRAM. Plane diagram obtained by plotting one of any set of chromaticity coordinates against one of the other two coordinates of the same set (see Figs. 11 to 16).

CHROMATICNESS. Aspect of a color perception determined by its hue and saturation taken together; psychological correlate of chromaticity.

CHROMATIC REFLECTANCE. Name given by Adams (1942) to the ratios X/X_0 , Y/Y_0 , and Z/Z_0 , where X , Y , Z are the tristimulus values of the light reflected from a surface, and X_0 , Y_0 , Z_0 are the tristimulus values of the light reflected from a standard white surface such as magnesium oxide, similarly illuminated and viewed.

CHROMATIC VALUES. Name given by Adams (1942) to the differences, $0.4(V_x - V_y)$ and $V_x - V_y$, where V_x , V_y , V_z are the Munsell values found by substituting chromatic reflectance in percentage ($100X/X_0$, $100Y/Y_0$, $100Z/Z_0$) for Y_v in percentage in Table 13.

COLOR. Characteristics of light other than spatial and temporal inhomogeneities.

COLORIMETRIC PURITY. Ratio of the luminance of the spectral component of a mixture to luminance of the mixture, itself.

COMPLEMENTARY COLORS. Colors whose additive combination in some proportion is equivalent to some arbitrary choice of achromatic color.

COMPLEMENTARY WAVELENGTH. Wavelength of the spectral band that when mixed with the color produces a match for some arbitrary choice of achromatic color.

CONTRAST RATIO. Ratio of the luminance of an object backed by black to that backed by white; a correlate of transparency.

DECIBEL. A logarithmic measure of the ratio between two quantities. The number of decibels denoting the ratio is 10 times the logarithm to the base 10 of the ratio. (The decibel is widely used as a measure of ratios between electric powers and between acoustic powers, less widely used for photometric quantities such as luminance.)

DEUTERANOMALY. Type of anomalous trichromatism.

DEUTERANOPIA. Type of partial color blindness.

DIASCLERAL LIGHT. Light entering the eyeball through the sclerotic coat.

DICHROMATISM. Type of vision requiring two primaries to duplicate by addition the colors seen; partial color blindness.

DIRECTIONAL REFLECTANCE. The reflectance that a perfectly diffusing surface would have to possess in order to yield the same luminance as the object in question under the same illuminating and viewing conditions (see equation 2a).

DIRECTIONAL TRANSMITTANCE. Ratio of the luminance (candle per unit area) of the second surface of a light-transmitting specimen to the illuminance (lumens per unit area) of the first surface.

DOMINANT WAVELENGTH. Wavelength of the spectral band that when mixed with some arbitrary

choice of achromatic color produces a match for the chromatic color.

DOMINATOR-MODULATOR THEORY. Visual theory based on the assumption that a separate dominating receptor exists for the brightness aspect of vision with chromatic distinctions introduced by receptors modulating the dominant response (see Table 8).

EQUAL-ENERGY STIMULUS. Stimulus whose irradiance per unit wavelength is constant throughout the spectrum.

EQUIVALENT COLOR STIMULI. Stimuli producing identical colors.

EXCITATION PURITY. Ratio of two distances on the standard chromaticity diagram (see Fig. 11), the first distance being that between the point representing some arbitrary choice of achromatic color and the point representing the chromatic color to be specified, and the second being that between the achromatic point and the point on the border of physically realizable colors (spectrum locus, line connecting its extremes) of the same dominant or complementary wavelength as the chromatic color to be specified.

FOOT-CANDLE. Unit of illuminance; the illuminance produced by a uniform point source of 1 candle on a surface every point of which is 1 foot away from the source (see Table 4).

FOOT-LAMBERT. Unit of luminance equivalent to 1.076 millilamberts; a perfectly reflecting, perfectly diffusing surface illuminated with an illuminance of 1 foot-candle has a luminance of 1 foot-lambert, regardless of the direction of view (see equations 2 and 2a, and Table 4).

FREQUENCY. Rate of vibration of electromagnetic radiation; frequency in cycles per second is found by dividing the velocity of electromagnetic radiation (3.0×10^{17} millimicrons per second) by its wavelength. Under ordinary conditions the highest frequency to which the eye responds is that corresponding to $380 \text{ m}\mu$ or about 790×10^{12} cycles per second; the lowest frequency corresponds to $780 \text{ m}\mu$ and is about 385×10^{12} cycles per second.

GLOSSINESS. Attribute of surface perception ranging from matte to glossy. There are various kinds of glossiness; absence-of-bloom glossiness characterized by absence of haze near the highlight; contrast glossiness characterized by brightness of a highlight judged relative to that of the surrounding area; distinctness-of-image glossiness; specular gloss characterized by brightness of the highlight; sheen characterized by brightness of the highlight seen at grazing incidence; metallic glossiness or luster characterized by an intense highlight not necessarily achromatic; and vitreous glossiness or luster characterized by a moderately intense achromatic highlight.

HAZE. Characteristic of light-transmitting specimens, specifically the difference between its transmittance and its regular transmittance divided by its transmittance, thus: $(T - T_r)/T$; correlate for transparency.

- HUE.** The attribute of a color perception that determines whether it is red, yellow, green, blue, purple, or the like (see Tables 9 and 14).
- ILLUMINANCE.** Areal density of incident luminous flux; formerly called illumination; the most common unit of illuminance is the foot-candle (see Tables 3 and 4).
- ILLUMINANT COLOR.** Color perceived as belonging to a self-luminous object (see Table 9).
- ILLUMINATION.** Process of supplying an area with luminous flux.
- ILLUMINATION COLOR.** Color perceived as belonging to the illumination pervading a space.
- IMAGINARY CHROMATICITY.** Chromaticity not producible by any part of the spectrum or any combination thereof; chromaticities conceived as corresponding to some one process in the visual mechanism in the absence of activity of other processes are usually imaginary.
- INSISTENCE.** Attribute of object-color perception correlated with its luminance; closely allied to and perhaps identical with the brightness of the aperture-color perception derivable from the object by interposition of a screen with a hole in it (reduction screen).
- INTERNAL TRANSMITTANCE.** Ratio of the flux reaching the second surface of a specimen to that penetrating the first (see Table 2).
- IRRADIANCE.** Areal density of incident radiant flux; radiometric analogue of illuminance (see Table 1).
- LAMBERT.** Unit of luminance equal to that of a perfectly diffusing surface emitting or reflecting light at the rate of 1 lumen per square centimeter (see Table 4).
- LIGHT.** That aspect of radiant energy of which a human observer is aware through the visual sensations that arise from the stimulation of the retina of the eye.
- LIGHTNESS.** Attribute of an object-color perception ranging either from black to white (surface) or from black to perfectly clear (non-light-diffusing volume). See Table 9.
- LUMEN.** Unit of luminous flux equal to that through a unit solid angle (steradian) from a uniform point source of 1 candle; the total flux emitted by such a source is 4π lumens (see Table 4).
- LUMINANCE.** Luminous flux emitted per unit solid angle (steradian) and unit projected area of source; formerly called photometric brightness; the most common unit of luminance is the millilambert (see Tables 3 and 4).
- LUMINOSITY.** Ratio of any photometric quantity to the corresponding radiometric quantity in standard units (such as the ratio of luminous flux to radiant flux in lumens per watt; see Table 3); formerly called visibility or radiant luminous efficiency.
- LUMINOUS DIRECTIONAL REFLECTANCE.** See Directional reflectance; also equation 2a and 4a.
- LUMINOUS DIRECTIONAL TRANSMITTANCE.** See Directional transmittance; also equation 4b.
- LUMINOUS FLUX.** Rate of transfer of luminous energy (see Table 3).
- LUMINOUS INTENSITY.** Flux luminated per unit solid angle in a given direction from a point source (see Table 3).
- LUX.** Unit of illuminance equal to that produced at a surface, all points of which are at a distance of 1 meter from a uniform point source of 1 candle; same as meter-candle or lumen per square meter; equivalent to 0.0929 foot-candle (see Table 4).
- MAXWELL TRIANGLE.** Chromaticity diagram.
- MEMORY COLOR.** Color perception based on recognition of the object.
- METAMERIC PAIR.** Pair of stimuli having the same color but different spectral composition.
- METAMERISM.** The property exhibited by a metameric pair; if the members of the pair are of greatly different spectral compositions, they are said to exhibit a high degree of metamerism.
- MILLILAMBERT.** The most commonly used unit of luminance; one-thousandth of a lambert (see Table 4).
- MILLIMICRON ($m\mu$).** Unit of length equal to one-thousandth of a micron, or one-millionth of a millimeter, or one billionth of a meter, or 10 Angstroms; unit of length most frequently used to specify wavelength of visible radiant energy.
- MILLIPHOT.** Unit of illuminance equal to one-thousandth of a lumen per square centimeter, or one-thousandth of a centimeter-candle, or one-thousandth of a phot (see Table 4).
- MODE OF APPEARANCE.** Characterization of a color according to whether it is perceived to belong to an aperture, a surface, a volume, an illuminant, or the like (see Table 9).
- MONOCHROMATISM.** Type of vision requiring only one primary to duplicate the colors seen.
- MUNSELL BOOK NOTATION.** Munsell hue, value, and chroma of a color estimated by interpolation and extrapolation from the color scales of the *Munsell Book of Color*.
- MUNSELL CHROMA.** Expression of the degree of departure of an object color from the nearest gray color on arbitrary scales defined in terms of its Y-value (luminous reflectance, or luminous transmittance) and its chromaticity coordinates (see Table 13, and Figs. 14, 15, and 16).
- MUNSELL HUE.** Correlate of hue on arbitrary scales defined in terms of Y-value (luminous reflectance, or luminous transmittance) and chromaticity coordinates (see Table 13, and Figs. 14, 15, and 16).
- MUNSELL RENOTATION.** Munsell hue, value, and chroma of an object color obtained by reference to the definition of the ideal Munsell system (see Table 13, and Figs. 14, 15, and 16).
- MUNSELL VALUE.** Expression of the luminous reflectance, or transmittance, of an object on an arbitrary scale giving approximately uniform perceptual steps under usual conditions of observation; correlate of lightness (see Table 13).
- NEUTRAL COLOR.** See Achromatic color.
- PHOT.** Unit of illuminance equal to that produced at a surface, all points of which are at a distance of 1 centimeter from a uniform point

- source of 1 candle; same as centimeter-candle; same as lumen per square centimeter (see Table 4).
- PHOTOMETRIC BRIGHTNESS. See Luminance.
- PHOTON. See Troland.
- PROTANOMALY. Type of anomalous trichromatism.
- PRIMARY COLOR PERCEPTIONS. Color perceptions in terms of which all color perceptions are analyzed; usually black, white, blue, yellow, green, and red, but sometimes middle gray is added (see Tables 9 and 14).
- PRONOUNCEDNESS. Attribute of nonself-luminous object-color perceptions correlated with illuminance of the objects in the field of view.
- PROTANOPIA. Type of dichromatism.
- PURITY. Degree to which a color approaches that of the spectrum at the same dominant wavelength; approximate correlate to saturation. Two scales of purity have been widely used: colorimetric purity, and excitation purity (which see).
- RADIANCE. Radiant flux radiated per unit solid angle (steradian) and unit projected area of source; radiometric analogue of luminance (photometric brightness). See Tables 1 and 3.
- RADIANT ENERGY. Energy traveling through space in the form of electromagnetic waves of various lengths (see Table 1).
- RADIANT FLUX. Time rate of transfer of radiant energy; the most common unit is the watt (see Table 1).
- RADIANT INTENSITY. Radiant flux radiated per unit solid angle (steradian) about a source (see Table 1).
- REDUCTION SYSTEM. Visual system differing from the normal trichromatic system simply by non-function of one or two of the three processes.
- REFLECTANCE. Ratio of reflected to incident flux; see equation 2.
- RELATIVE LUMINOSITY. Luminosity expressed relative to maximum (near 555 $m\mu$ for daylight vision); see \bar{y} -function of Table 6.
- REVERSE TRANSFORMATION COEFFICIENTS. Coefficients of transformation required to return tristimulus values from a transformed color system back to expression in terms of the original system (see equation 6b).
- SATURATION. The attribute of any color perception, possessing a hue, that determines the degree of its difference from the achromatic color perception most resembling it (see Table 9).
- SPECTRAL COMPOSITION. Distribution of any radiant quantity as a function of wavelength (see Table 1).
- SPECTRAL REFLECTANCE. Ratio of reflected to incident radiant flux of narrow wavelength range.
- SPECTRAL TRANSMITTANCE. Ratio of transmitted to incident radiant flux of narrow wavelength range.
- SPECTRUM LOCUS. Locus of points on a chromaticity diagram representing the chromaticities of the spectrum colors (see Figs. 11, 12, and 13).
- STAGE THEORY. Theory of vision in which separate account is taken of processes at various stages or zones of the visual mechanism (photosensitive substances, receptors, retinal nerve fibers, optic-nerve fibers, etc.); same as zone theory.
- STILB. Unit of luminance equal to 1 candle per square centimeter; equivalent to 1000π millilamberts (see Table 4).
- TETARTANOPIA. Controversial form of partial color blindness.
- TRANSFORMATION EQUATIONS. Equations whereby tristimulus values expressed in terms of one set of primaries may be transformed into those expressing the same color relative to another set of primaries (see equations 6 and 6b).
- TRANSFORMATION COEFFICIENTS. The coefficients of a set of transformation equations (see equations 6 and 6b, and Table 8).
- TRANSMITTANCE. Ratio of transmitted to incident flux.
- TRANSPARENCY. Perceptual quality of a volume correlated with the degree to which the elements of the volume transmit light in an image-forming state.
- TRICHROMATISM. Type of vision requiring three primary lights to duplicate the colors seen; normal vision is trichromatic.
- TRISTIMULUS VALUES. Amounts of the primaries required to produce a match with the sample, either by addition of all three, or addition of one primary to the sample to match any pair of primaries, or the addition of any pair to the sample to match the remaining primary; amounts of a primary added to the sample are indicated by a negative algebraic sign.
- TRITANOMALY. Form of anomalous trichromatism.
- TRITANOPIA. Form of partial color blindness.
- TROLAND. Unit of retinal illuminance equal to that produced by viewing a surface whose luminance is 1 candle per square meter through an artificial pupil whose area is 1 square millimeter centered on the natural pupil (see equation 3).
- UNIFORM-CHROMATICITY-SCALE DIAGRAM. Maxwell triangle within which the separation of two points is an approximate measure of the perceptibility of the difference between the chromaticities represented by them (see equation 8 and Fig. 13).
- UNITARY HUE. Hue perceived as having no admixture of neighboring hues; the unitary hues are red, yellow, green, and blue (see Table 11).
- WAVELENGTH. Distance traversed by spectrally homogeneous radiant energy during a single period of vibration.
- ZONE THEORY. Same as stage theory.

Visual Perception

C. H. GRAHAM
Columbia University

Historically considered, the problems of visual perception have centered about such topics as span of perception, size constancy, fluctuations of perception, illusions, grouping of stimuli, precision of perception, and influence of context. These topics entail such questions as the following: (1) Within what limits do stimuli, arranged according to a given numerical classification and exposed for a short duration, elicit "number" responses that meet certain criteria of classification? (2) What is the relation between response and retinal image size? (3) What are the stimulus variables that underlie response alternation? (4) In what manner are certain changes in stimulus configuration associated with a change in response? (5) How does the spatial and temporal ordering of stimuli affect response? (6) What change on a stimulus dimension is required to produce a change in response? (7) How does previous stimulation influence the response to a present stimulus?

The questions as formulated call for an experimental program, one that seeks to determine specific, explicitly stated relations between stimulus, response, and whatever hypothesized variables become logically necessary.

The stimulus-response relations of the perception experiment derive from the experimental methods involved. Consider first the

This account was prepared under Project NR142-404, Contract N6onr-271, Task Order IX, between Columbia University and the Office of Naval Research, U. S. Navy.

matter of response specification; in particular, let the discussion center about a specific case: the determination of a visual threshold. When a visual threshold is determined by the method of constant stimuli, the subject's responses may be restricted by the "instruction stimulus" to two categories: * "Yes (I see it)" and "No (I don't see it)." We accept these responses as different, if for no other reason than that one is an affirmation and the other a negation, although it is true, but probably not crucial, that their physical sound-wave properties are also different.

* In using the psychophysical methods, we restrict the subject's responses by means of the "instruction stimulus." When specific instructions to restrict response categories are not given, the subject's responses are relatively uncontrolled and are in the nature of introspective verbal reports. Such responses usually demonstrate so many degrees of freedom that their classification is difficult or impossible.

In general it seems desirable to concentrate our unknown variables in the instruction stimulus and to restrict responses. When such a procedure is followed, it may, with some reason, be assumed that the conditions of the organism are constant for a given instruction stimulus; and for the constant condition we may quantify restricted responses in a way that is not possible with unclassifiable responses. Perhaps it may turn out that unknown conditions of the organism, due to instruction, may be specifiable as parameters of observable stimulus-response relations. Such an outcome would present a great advance over our present knowledge, for it is certain that instruction stimuli are now specifiable only at the level of social conversation; i.e. no instruction stimulus may be related to another within a framework of quantitative relations.

It turns out in an experiment of this sort that, as we vary the energy of the physical stimulus, the frequency of occurrence of each response follows a different function. Because of this fact we no longer have to specify response differences on the basis of conversational "significances," but may explicate such differences more reliably and more specifically by the operation of plotting response frequencies. Similarly, in using the psychophysical methods of single stimuli, limits, and sense distances, we are provided with various types of frequency distributions of contrasting responses plotted as functions of stimulus variables. The method of adjustment which strictly speaking involves only one class of response — adjustment — may be made to provide an *arbitrary* specification of response classes on the basis of the distribution of stimulus settings (e.g. on the basis of the standard deviation.*

Now consider the classification of stimuli. Various classifications exist at the present time; but all are subject to the condition that the specified variables must be unequivocally related to response.

In certain areas of sensory psychology it can be shown that stimulus energies are important correlates of response, and one measures stimulus strength in the proper units. For example, a description of visual stimuli may involve classifications with respect to wavelength, distance from fovea, and amount of energy. In this type of classification,

* It might be worth while to differentiate between the behavior, i.e. discrimination behavior, that is observable in experiments employing the methods of constant stimuli, single stimuli, limits, and sense distances, and the behavior observable in the method of adjustment, i.e. "matching" behavior. Such differentiation would be precise, but in what follows we shall not always make the distinction.

It may be argued that any given adjustment, under the method of adjustment, involves a serialized set of discriminations involving different responses and changing stimuli. This is a theoretical position and calls for specification of the response components of the adjustment. No data on the problem exist at present, and an answer can be reached only by direct observation of a subject in the psychophysical experiment.

stimuli are specified in terms of a system (e.g. physics) that has little or no reference to the response elicited; the light may be described whether or not a subject is present. However, reference to response enters as soon as we consider the determination of stimulus values that have response parameters (e.g. thresholds).†

At another level of stimulus specification, measurement of the stimulus may be made in terms that have direct or indirect reference to response. For example, in measuring thresholds of stereoscopic vision, we make use of a difference in visual angles η as our primary stimulus datum. The use of η is based upon a theory of how stimulation of "disparate points" influences response; it is, as it were, a "second-order" measurement, given in terms of some mathematical concepts appropriate to a psychological theory.

At more complex levels physical specification of stimuli may not, at present, be especially significant. For example, the physical characteristics of sound waves that constitute words are not closely related to response; a subject may give the same response to a whisper as to a shout. In such a case the basis of stimulus classification must reside in adequate psychological theory rather than in physical measurement.

Our discussion makes it clear that the observable variables of the psychophysical experiment are response on the one hand and stimulus operations on the other; in particular the data describe how differential restricted responses relate to such stimulus operations as the presentation of objects, words, and energies. Such data are discrimination data (Graham, 1950).‡ When pro-

† In determining thresholds, theory may dictate the particular function of the stimulus variable to plot on the abscissa axis of a psychophysical curve. In such cases the plot may involve a numerical transformation of a measured energy. On problems that occur with the use of numerical transformations, see Mueller (1949).

‡ For different approaches to problems of perception see Brunswik's account of the "representative" experiment (1947) and Thurstone's description of his factor analysis investigations (1944).

cedures other than the psychophysical methods are used, and, in particular, when responses are not restricted, the data are in terms of "introspective" reports and are neither easily interpretable quantitatively nor classifiable at a level higher than social conversation.

In what follows, a "subjective" terminology will sometimes be used, not because the terms with which it deals are unspecifiable in behavior concepts but because, in the interest of avoiding circumlocution, such words as "apparent," "perception," "see," "detect," etc., are convenient. Nevertheless it is asserted that the behavior functions of which these words are descriptive are discriminations except, possibly, in cases that involve unrestricted responses.*

VISUAL SPACE PERCEPTION

Many of the concepts and measures of space perception are based on elaborate theoretical considerations. Even such a seemingly simple measure of stimulus as visual angle may involve a complex theory of the eye as an optical instrument.

Historically (Carr, 1935; Hering, 1861-64; Helmholtz, 1924) the specification of stimulus conditions for space perception has been formalized in terms of so-called cues, and these cues, in turn, have been divided into two types: monocular and binocular. Mo-

* The present discussion does not attempt to differentiate between "sensation" and "perception." From the point of view of analysis of consciousness, sensation is an irreducible element; perception is an aggregate of sensations. From the point of view of behavior, a specification of what a subject does when he analyzes "sensation" and what he does when he "perceives" is not now available and probably will not be available for a long time. In any case it is doubtful if such specialized behavior would be of great interest. Other attempts to differentiate sensation and perception on the basis of physiological and psychological mechanisms seem unfruitful. In general, it seems that the term sensation has been applied to those discussions for which some relevant sense organ theory exists, and the term perception to those for which no such theory exists. No basis for differentiation exists in the psychological functions obtained.

nocular cues are those that elicit spatial discriminations on the basis of vision with a single eye. Binocular cues require the coordinated activity of the two eyes.

The monocular cues are the following:

1. *Relative size.* Our discrimination of distances is dependent on the size of the retinal image provided by an object and by our past experience with objects of the same class. A small retinal image provided by a member of a class of objects called automobiles results in the response, "Distant automobile."

2. *Interposition.* The cue of interposition occurs when an overlapping object is said to be nearer than an overlapped object. The cue that exists in these circumstances is based on the fact that the contour line of the overlapping object does not change its direction discontinuously at a point where it joins the contour of the overlapped object. On the other hand, the contour line of the overlapped object does change direction discontinuously at the same point. The discrimination of continuity of contour change from discontinuity of contour change is the essential cue.

3. *Linear perspective.* The stimulus condition for this cue is determined by the fact that a constant distance between points subtends a smaller and smaller angle at the eye as the points recede from the subject. A subject reports that lines formed by car tracks, telephone wires, etc., seem to approach each other in the distance.

4. *Aerial perspective.* When surface details of an object do not provide conditions for requisite visual contrasts, a subject reports that the object seems far off.

5. *Monocular movement parallax.* When a subject's eyes move with respect to the environment, or when the environment moves with respect to a subject's eyes, a differential angular velocity exists between the line of sight to a fixated object and the line of sight to any other object in the visual field. This condition of differential angular velocity leads to such discriminations as are

concerned with the response that *near* objects move *against* the direction of movement and *far* objects move *with* the direction of movement (of the head or environment).

6. *Light and shade.* Various combinations of shadow and highlight are reported as objects having various dimensions and lying at different distances.

7. *Accommodation.* Differential aspects of "blur circles" in a retinal image may elicit spatial discriminations, although probably not for objects at distances greater than a few yards.

The two binocular cues are convergence and stereoscopic vision.

1. *Convergence.* When an object is at a great distance, lines of fixation to the object are parallel. When the object is near at hand, the subject's eyes are turned in a coordinated manner so that the lines of fixation converge on the object. Convergence may serve as a cue for depth responses. A large amount of convergence may lead to the response "nearby object," and slight convergence may lead to the response "far-off object." Convergence cues cannot be differentially effective for objects at distances greater than about 20 yards.*

2. *Stereoscopic vision.* When a subject regards an object in space, the retinal image in the right eye is different from the retinal image in the left eye. The difference in retinal images serves as the basis for many spatial discriminations. Theoretically the essential stimulus condition for stereoscopic vision is a difference in convergence angles between (a) lines of sight from the two eyes that converge at a fixated object point, and (b) those that converge at another object

* It might be argued that, since the subject cannot report on his condition of convergence (Ludvigh, 1936), convergence is not a cue for space. It is true, however, that convergence enters as a parameter of other space discriminations (see e.g. Matsubayashi, 1938*d*). Thus, in the sense that it is an influencing variable, convergence is, in fact, a cue. The requirement that a cue be capable of eliciting a verbal report is unnecessary.

point. (Note that the term *convergence angles* does not imply the response of convergence. It is used in a geometrical sense.)

Of the visual cues for space, relative size, linear perspective, monocular movement parallax, accommodation, interposition, and stereoscopic vision are most specifiable in quantitative terms. The cues of aerial perspective, and light and shade are conveniently specifiable, at present, only in terms of the subject's response. However, some studies, such as those of Blackwell (1946) and Hardy (1946), may clarify our concepts of specifiable contrasts and other variables in aerial perspective and may indicate an approach to some problems of illumination gradients in light and shade. Finally, the reader is referred to Schlosberg's account (1941) of the very striking depth effects, dependent only on monocular cues, that may be obtained under proper conditions of monocular viewing.

Except for a very short account of some of the better known "illusions," little attention will be paid in what follows to cues classifiable on a response basis. Rather the attempt will be made to show the manner in which theoretical concepts and analysis aid in the specification of stimuli. Finally, we shall make a survey of experimental findings on controlling variables of the stimulus-response relations of space perception.†

† The mathematical analysis of binocular vision by Luneburg (1947) is of considerable interest to the present discussion. Luneburg has been concerned with finding the mathematical form of the metric of the "visual space." He concludes that the geometry of the visual space is the hyperbolic geometry of Lobachevski. Luneburg's treatment expresses the general hypothesis that, for an individual observer, the apparent size of a line element is uniquely determined by its physical coordinates; thus the judgment of visual size depends not only upon angular relations but also upon the location of the line element. On this basis Luneburg discusses such problems as the horopter problem and the alley problem.

It is to be noted that Luneburg's treatment, in a sense a sophisticated "phenomenological" account, is based upon a psychometric coordination that attempts to introduce the concept of a metric in a manifold of "sensations." From the point of view of the present discussion, Lune-

Visual Angle

Visual angle is a basic variable in experiments concerned with the cues of relative size and linear perspective; in fact it may be conveniently employed whenever visual extents and positions must be designated. Thus it is a measure applicable in one way or another to all visual experiments.

In Fig. 1 the line e represents a distance relating to some aspect of the stimulus situation (e.g. a length of line, a diameter, a separation between points, etc.). We wish to specify the visual angle subtended.

FIG. 1. Diagram representing the concept of visual angle.

For the condition that the line of regard bisects e , the visual angle β is given by

$$\tan \frac{\beta}{2} = \frac{e}{2R} \quad (1)$$

where R is the distance to e along the line of regard.

When β is small (so that $\tan \beta = \beta$, approximately)

$$\beta = \frac{e}{R} \quad (2)$$

in radians, or

$$\beta = \frac{57.3e}{R} \quad (3)$$

in degrees.

Equations 2 and 3 overestimate β by 1 per cent at a value of 10 degrees, and by 3 per cent at a value of 17 degrees. When line e is curved, so that all its points are equidistant from the reference point of the eye, equations 2 and 3 hold perfectly. If line e is tilted with respect to R , more com-

plex calculations, analogous to those used for asymmetric convergence (see section on Convergence), must be employed.

Equations 2 and 3 are probably applicable to most situations in which visual angles must be determined. Where the equations are not applicable, good experimental design would often require that conditions be changed so that they become applicable. For example, in the peripheral retina a stimulus area should be disposed at the same distance R as the fixation point. Under these conditions accommodation is the same for the test area as it is for the fixation point, and equations 2 and 3 may be used.

The distance R is most practicably measured from the front surface of the cornea. If it is desired to calculate retinal image size, the reference point at the vertex of angle β (at or in the eye) must be specified. In any event visual angle computations should be accompanied by a statement as to (1) absolute stimulus size, and (2) position of reference point (e.g. corneal surface) from which the distance R is measured. Given these two variables it is possible to recalculate the data for any other reference point (e.g. anterior principal point) dictated by the particular form of image equation applicable to the experimental conditions. The considerations that apply under various circumstances are discussed by Southall (1933).

Discrimination of sizes. It has been known for a long time (Martius, 1889) that, under certain conditions, when a subject has been instructed to adjust the size of a comparison stimulus at constant distance until it matches a standard stimulus at a variable distance, the resulting "match" is not one that would be predicted on the basis of retinal image theory. Instead the size of the comparison stimulus changes little with increase in distance of the standard. This effect has been termed "size constancy."

Holway and Boring (1941) have performed the most adequate investigation of the conditions that influence "equation settings" for size discrimination. Their method was the

burg's hypothesized coordination is the very problem for which an experimental answer is sought. Its relation to behavior requires analysis.

following: A comparison stimulus, a uniformly illuminated circular light image, was viewed by the subject at a distance of 10 feet. The image diameter S_c could be continuously varied in size by means of an iris diaphragm. The standard stimulus, which varied in distance from 10 to 120 feet from the subject's eyes, was always of a diameter S_s that subtended a visual angle of 1 degree. Brightnesses of the two stimuli were identical for any one series of measurements, but the level varied in different series.

Results were plotted on graphs showing the diameter S_c of the comparison stimulus as the ordinate, and D_s (the distance of the standard stimulus) as the abscissa. In this type of graph, performance that results in an equating of the comparison stimulus with the standard stimulus on the basis of visual angle is represented by a horizontal line (law of the visual angle).

The law of the visual angle is based on the following reasoning. The visual angle given at the eye by S_c (variable diameter) is $\arctan S_c/2D_c = \beta_c/2$; and the angle given by S_s (variable in distance) is $\arctan S_s/2D_s = \beta_s/2$. For $\beta_c = \beta_s$, $S_c/D_c = S_s/D_s$. But S_s/D_s is constant ($= 2 \tan 0.5^\circ$) and so is D_c ($= 10$ feet). Therefore, for an adjustment based on $\beta_c = \beta_s$,

$$S_c = \left(\frac{S_c}{D_s}\right) D_c = \text{Constant} \quad (4)$$

and, when S_c is plotted against D_s , the curve must be a straight line of zero slope.

For the law of size constancy, $S_c = S_s$. But $S_s = D_s(2 \tan 0.5^\circ)$, and so

$$S_c = D_s(2 \tan 0.5^\circ) \quad (5)$$

Equation 5 means that, if the law of size constancy applies to the data of Holway and Boring, S_c should be linearly related to D_s by way of a slope constant equal to $2 \tan 0.5^\circ$ and an intercept constant of zero.

Figure 2 summarizes the data of the experiment for four conditions of observation. With binocular comparison the data are found to be in accord with expectations based on the law of size constancy. (There

may even be overcompensation as shown by the fact that the data fall above the line for "constancy." Holway and Boring tentatively attribute this effect to a possible "space error.")

With monocular regard, a condition that excludes cues contributed by stereoscopic vision, the data still adhere to the law of size constancy. With monocular vision through an artificial pupil (1.8 millimeters in diam-

FIG. 2. The diameter of the comparison stimulus S_c plotted against the distance of the standard stimulus D_s for the conditions of observation in Holway and Boring's experiment (1941). The inclined dashed line represents an expectation based on size constancy. The horizontal dashed line represents an expectation based on the law of the visual angle.

eter), the slope of the experimental function is reduced and the curve lies about halfway between the curves representing the two laws; i.e. the constancy effect is reduced. Finally, when observations are made monocularly through an artificial pupil and a long dark tunnel constructed to eliminate faint extraneous reflections, the experimental function approaches the law of the visual angle even more closely.

The experiments of Holway and Boring show that constancy behavior may be expected when conditions of stimulation are "complex," a fact emphasized by Thouless (1931a, b) and by Woodworth (1938) with respect to color and brightness constancy. When stimuli are restricted to a condition that involves a minimum number of parameters, the phenomena of constancy appear in slight degree, if at all.

In a later experiment Taylor and Boring (1942a) used two subjects, each of whom was blinded in one eye. The two subjects, long experienced in making monocular discriminations, gave data that more closely approximate the law of the visual angle than do the data of temporarily monocular subjects.

Vernon (1937), Koffka (1935), and Boring (1942) give excellent discussions of experiments on size constancy, and Boring relates them to research on the geometry of after-images and the early "alley" experiments (Hillebrand, 1902; Blumenfeld, 1913). The work of Köhler (1915) on chimpanzees and Götz (1926) on chickens shows that discrimination of sizes in lower animals tends to be of the "constancy" type; that is, for the conditions examined the responses are more in accord with expectations based on the law of size constancy than on the law of the visual angle. Beyrl (1926) and Frank (1928) obtained similar findings with young children, although deviations from the law of the visual angle were not so marked with their subjects as was true in earlier experiments on adults.

Holaday (1933) examined the question of "attitude" and found that a "betting" attitude is conducive to obtaining a size constancy function. Conditions for obtaining the constancy function are improved when extraneous objects are placed between the stimuli and the subject. The experiments of Schur show that deviation from the law of the visual angle is a function of elevation of regard, and this same influence is emphasized by Boring (1943) in considering the "moon illusion" (i.e. the fact that a subject reports the moon at the horizon to be larger than the moon at the zenith). After participating in three experiments (Holway and Boring, 1940a, b; Taylor and Boring, 1942b), Boring (1943) says:

It (the moon illusion) is not due to physical causes outside the visual mechanism. It is not due to the greater brightness of the moon in elevation, when atmospheric haze

is diminished. It depends on raising or lowering the eyes. Movements of the head, neck, and body do not cause it.

Discrimination of shapes. In an extensive series of experiments dealing with various types of constancy, Thouless (1931a) studied the responses subjects made to obliquely viewed objects. In a first experiment he had subjects regard circles or squares laid on a table top at distances of 54.5, 109.0, and 163.5 centimeters from the subject's end of the table. Each square was oriented so that one diagonal was parallel to the subject's line of regard, and the figures were viewed from a point 48.5 centimeters above the table. The subject was instructed to "reproduce" each square or circle in a drawing. Such an instruction calls for a complex, serialized response, probably uncertainly specifiable on the basis of selected dimensions of the "drawing."

The results show that the ratios of the short to the long axis in the "drawings" were $1\frac{1}{3}$ to $2\frac{1}{2}$ times as large as would be predicted by the laws of retinal image theory. In other words the reproduced ellipses and squares were much closer to being true circles and squares than were the elliptical and trapezoidal retinal images of the circles and squares. When the subject was given actually elliptical disks to reproduce in direct vision, the ratios of short to long axes in the "drawings" were very close to the true ratios. Similar results were obtained by a matching method.

Thouless performed an additional experiment to discover how deviations from retinal image theory vary with the angle of object inclination. A white circular disk 29.7 centimeters in diameter was mounted on a turntable with its axis of rotation horizontal and at right angles to the subject's line of vision. Turning the turntable presented the disk to the subject at varying angles of inclination. The subject's task was to match the inclined circle to a standard ellipse. Measurement of the axes for each condition of inclination of

the circle was performed by a photographic method.

Results are presented in Fig. 3, which shows the ratio of short to long axes of comparison ellipses as a function of angle of inclination of the circle. The solid line with a slope of 45 degrees is the line relating the two variables on the basis of retinal image theory. The experimental data fall above

FIG. 3. Shape comparisons of an ellipse and a tilted circle. Adjusted axis ratio of the comparison stimulus (ellipse) is plotted as a function of axis ratio of the standard stimulus (circle) for various inclinations of the latter. Upper abscissa units give angular inclinations of the circle in degrees. The solid inclined line gives the expectation based on the law of the retinal image. (After Thouless, 1931a.)

the "image theory" line, and we see that obtained ratios of short to long axes of the comparison ellipse are generally larger than would be expected on the basis of the geometry of the retinal image.

A later experiment (Thouless, 1931b) was concerned with the elimination of cues. In general it may be said that Thouless' experiments give results analogous to those that appear in researches on size "matchings." When stimulus cues are present in addition to the presumably single discriminative stimulus, matching values are influenced by the total constellation. What the laws are that govern perception in the presence of cue constellations is a question that sets a program of research. When the constellation is

restricted, matchings are predictable on the basis of retinal image theory.

Stavrianos (1945) performed an experiment on the relation between matchings made with respect to object inclination and matchings made with respect to object shape.

The hypothesis tested predicts that changes in the accuracy with which inclination is judged will be accompanied by changes in the accuracy of shape perception such that, when the inclination of an object is accurately perceived, its apparent shape will coincide with the actual shape; when inclination is underestimated (when in the extreme case, an object appears frontal-parallel though it is actually tilted), the apparent shape will deviate from the actual in the direction of the retinal shape; and when the inclination of the object is overestimated, the apparent shape will deviate from the actual in the direction of greater than object match or overconstancy.

The experimental data are, in general, not in agreement with the hypothesis. Stavrianos says:

We may conclude from our investigation that perception of shape may be roughly related to explicit judgment of inclination. However, in order to provide a crucial test of our hypothesis, further experiments are required in which explicit judgments of inclination and shape are made with approximately the same attitude and conditions as the implicit registration of tilt and shape.

The experiment that most nearly demonstrates a relation between tilt matchings and shape matchings is Stavrianos' Experiment III, in which errors in tilt adjustments were accompanied by the expected errors in shape adjustments for some of the subjects. In this experiment the subject was required to designate which of a series of seven rectangles appeared square. The rectangles varied in altitude from rectangles "taller than wide" to rectangles "shorter than wide." Each rectangle had a base of 5 centimeters. The background on which the rectangles were placed was presented in a frontal-

parallel position and at deviations of 15, 30, 45, and 55 degrees from the frontal parallel. The subject's task was to adjust the rectangle at his right until its tilt was considered equal to that of the background containing the rectangular forms, and then to designate which of the seven rectangular forms was seen as square. Binocular vision was used.

FIG. 4. Constant errors for tilt adjustments and for judgments of squareness plotted against angular inclination of the standard stimulus. The tilt setting of the comparison stimulus deviates more and more from the tilt of the standard stimulus as the tilt of the latter increases. In addition, the constant error of shape matching increases as the degree of tilt of the standard stimulus increases. Data are from Stavrianos' Experiment III (1945).

Constant errors for tilt and shape were determined and are shown in Fig. 4. The figure shows that the tilt setting of the comparison stimulus deviates more and more (in the direction of smaller tilt) from the tilt of the standard stimulus as the tilt of the latter increases. In addition the constant error of shape matching increases as the degree of tilt of the standard stimulus increases. At a zero-degree tilt the square designated is in fact very nearly a true square (5×5 centimeters). As tilt increases, the designated square becomes a rectangle with increasing height; i.e. the rectangle must become increasingly higher to be responded to as a square.

The status of size and shape discriminations. It is no exaggeration to say that the facts of size and shape discriminations are poorly understood. The lack of understanding may be due to a number of causes. In

the first place, experiments have often been demonstrational rather than analytic. In particular a long series of researches has not resulted in those systematically determined functional relations which, as Holway and Boring (1941) say, are "wanted and wanting." In the second place, theoretical considerations have often outrun experimental data with the consequent development of a theoretical structure weak in operational specification and definition. Despite these difficulties the problems of size and shape discrimination are important and require understanding.

What can we say about the experiments on size? For one thing they clearly show that size matches are dependent on the presence or absence of stimuli other than those that may be naively considered to be the discriminative stimuli (Holaday, 1933; Holway and Boring, 1941). Second (Köhler, 1915; Götz, 1926; Beyrl, 1926), the experiments show that the constancy effect holds, within unknown limits, in children and lower animals. Third, Holaday (1933) and Sheehan (1938) have demonstrated that the form of instruction stimulus and "attitude" affect the precise form of the discrimination function. Finally, the researches by Schur and by Holway and Boring focus attention on the influence of elevation of regard.

The experiments do not bring the measure *visual angle* into question as a stimulus specification. What is brought into question is the *relation* (as in Holway and Boring's experiment) between an adjusted *diameter* of a comparison area (or calculated visual angle) and the *distance* of an object subtending a given visual angle. The slope of the function relating the two variables changes as a function of certain controlling circumstances, e.g. presence of "extraneous" stimuli. In the absence of such additional stimuli the function approximates the law of the retinal image.

The facts of shape matching may be similarly summarized. Discrimination of shapes is dependent on the presence or absence of

“additional” stimuli (Thouless, 1931*b*). The constancy effect is improved with binocular vision (Thouless, 1931*b*; Eissler, 1933). “Attitude” influences the degree of constancy shown (Klimpfinger, 1933). On the theoretical side Koffka’s contention (1935) that the relation between matched shape and matched tilt is an invariant relation of shape perception is not unequivocally supported by the work that Koffka himself describes, nor by the experiments of Stavrianos (1945).

In general it seems that an adequate basis for theorizing about size and shape can be provided only when we have accumulated analytic data, covering large-enough ranges of specifiable parameters, on conditions influencing the forms of the discrimination functions. Analyses should probably progress from conditions where certain parameters (e.g. specifiable aspects of additional stimuli) have zero value to conditions where the same variables assume values other than zero. (A new method of psychophysical treatment by Helson, 1947, may prove valuable in researches of this kind.) Thus we shall be interested in knowing how various intensities, durations, and areas of additional stimuli influence the functions. We shall be interested in knowing how angular separation and angular elevation of the comparison and standard stimuli determine the shape of the functions; and we shall probably want to examine the effect of the temporal interval between standard and comparison stimuli. From a somewhat different point of view we may wish to study the effect of presentation of the comparison and standard stimuli to different eyes, and we might consider results obtained by flicker comparisons, although this type of analysis may provide only a limiting case of the temporal interval between standard and comparison stimulus. Above all, we shall be interested in the problem of functional relations between stimulus variables and responses rather than in further demonstrational experiments on unspecified stimulus constellations.

Finally, and not least, it is probable that size and shape discriminations must be related to conditioning, learning, and concept formation (Hull, 1920; Heidebreder, 1945). For example, the response “Circle” (in the shape experiment) is the end product of a type of learning that must involve an elaborate interplay of generalization and discrimination. The response develops, as a language reaction, in situations that present circles in many positions and under conditions involving the presence or absence of other stimuli. Thus a geometric circle as a stimulus has its influence upon an already elaborated response which shows a high degree of stimulus generalization.

And so it is important that the constancies be studied in relation to conceptual learning. In the course of this program we may ask such questions as the following: Given groups with different past histories with respect to a class of figures, what are the influences of the different past histories upon the responses made to figures within the class? Is it possible to set up experimentally a training procedure whereby different groups of subjects develop different responses to the same figure? What is the influence of such training on later discriminations?

Monocular Movement Parallax

When a human being who is moving through space fixates an object that is not moving, a differential angular velocity exists between the lines of sight to the fixated object and some other stationary object. If the objects move while the observer remains motionless, the same situation of differential angular velocity exists. Further, the differential angular velocity occurs if the observer is stationary but moves his head while looking at objects that do not move. An exhaustive list of situations giving rise to monocular movement parallax is given by Tschermak (1939). The present account will consider some of the more common examples.

Circular movement. Conditions giving rise to the differential angular velocity may be readily described for a situation in which the objects move.

An object (Fig. 5) at distance R from the center of rotation of the eye C moves from m through a distance L , along the arc of the circle of radius R , at a constant velocity. Another object (farther away and not neces-

FIG. 5. Geometrical representation of monocular movement parallax for circular movement. Explanation in text.

sarily on the same visual axis as the object at distance R) is at distance $R + \delta$ from the center of rotation of the eye. At the start of the movement (which takes place at the same constant rate as in the case above) the object is at position n . (As an alternative possibility, a nearer object, at distance $R - \delta$, may move from position p through distance L at the same linear velocity as the object at distance R .) We are interested in knowing the differential angular velocity, $\omega = d\Delta\theta/dt$, which exists between the moving lines of sight to the two objects.

In Fig. 5 the object moving from m has passed through distance L in a given period of time. This distance corresponds to an angle θ given (in radians) by

$$\theta = \frac{L}{R} \quad (6)$$

On differentiating equation 6 we obtain

$$d\theta = -\frac{L}{R^2} dR \quad (7)$$

and, if we consider small values of δ , not too far from threshold δ_t , then dR may be taken equal to δ , and $d\theta$ may be considered equal to $\Delta\theta$. Thus,

$$\Delta\theta = -\frac{\delta \cdot L}{R^2} \quad (8)$$

or, from equation 6,

$$\Delta\theta = -\frac{\delta \cdot \theta}{R} \quad (9)$$

Consequently

$$\omega = \frac{d\Delta\theta}{dt} = -\frac{\delta}{R} \cdot \frac{d\theta}{dt} \quad (10)$$

For constant change of θ with time (a case of greatest interest to the psychologist)

$$\omega = -\frac{\delta}{R} \left(\frac{\theta - \theta_0}{t - t_0} \right) \quad (11)$$

where θ_0 is a reference value of θ when t equals t_0 . ω has the dimensions of radians per unit of time. Thus, if t is in seconds, ω has the dimensions of radians per second. For ω to be expressed in seconds of arc per second, the right-hand side of equation 11 must be multiplied by 206,265. At threshold,

$$\omega_t = -\frac{\delta_t}{R} \left(\frac{\theta - \theta_0}{t - t_0} \right) \quad (12)$$

Movement parallel to the interocular axis. An equally common case involves movement from m which is parallel to the line between the centers of rotation of the two eyes. Under these conditions equations must be written to represent θ , $\theta - \Delta\theta$, and $\theta + \Delta\theta$ by the appropriate arctan functions (see section on Convergence). Appropriate calculations may be carried out when the functions are expanded in series form. However, for the range where $\tan \theta$ may be taken equal to θ , equations 9, 10, 11, and 12 apply to the first approximation.

Figure 6 represents the situation in which the objects move (usually at a constant rate) from positions that fall initially on the visual axis. The figure also shows another feature. When the eye rotates to maintain fixation upon the object at distance R , the differential angular velocity occurs with reference to an unchanging line of regard; i.e. that for the fixated object. If the eye does not "fol-

FIG. 6. Geometrical conditions existing in monocular movement parallax for movement parallel to the interocular axis. (From Graham, Baker, Hecht, and Lloyd, 1948.)

low," then the differential angular velocity exists with reference to object images that pass into more and more peripheral positions on the retina.

Moving head, stationary objects. It may be shown that equations 11 and 12 may be expected to hold when the head moves and the objects remain stationary. The assumptions are made that the head movement is essentially a lateral translatory movement at constant rate, that it is small with respect to R , and that δ is also small with respect to R . Under these conditions L is the extent of head movement, θ is the angle formed by the rotation of the visual axis around point m , and $\Delta\theta$ is the angle formed at the center of rotation of the eye by the lines of sight from the two objects. $\Delta\theta$ is equal to

the difference in apex angles formed around points m and n (or m and p) by the lines of sight.

Experimental data. Graham et al. (1948) investigated some factors that influence thresholds for monocular movement parallax, i.e. differential size of comparison stimuli, intensity of illumination, rate of movement of objects, and axis of movement.

The experimental situation used was one in which the subject remains stationary while the objects move. It may be understood with the help of Fig. 7.

The subject regards, through an aperture in a screen, two needles, one above the other. The upper needle is firmly placed; the lower may be adjusted, by means of a micrometer, in a plane parallel to the principal line of sight through the apparatus (indicated by the dashed line). The needles move in a plane perpendicular to the principal line of sight at a constant rate. The subject, "following" the needle movement in monocular vision, adjusts the distance of the variable needle until the two needles are matched in the same depth plane while they move from right to left and left to right at a constant rate across the screen aperture. The needles are regarded against a uniformly illuminated background.

The method of adjustment is used, and the standard deviation of "equality" settings is taken to be δ_s of equation 12. In addition to obtaining precision of settings, it is also possible to determine the constant error. Graham et al. (1948) report that the constant error of setting did not vary systematically under their experimental conditions.

Objects of the same dimensions placed at different distances subtend different visual angles at the eye. Since in these experiments differences in visual angle are unavoidable, because of the fact that the movable needle must be placed at different distances from the subject's eye during the course of a setting, the authors examined influences that might be attributed to differential needle size.

Three different sizes of needles were used in the fixed position, the movable needle always being 0.025 inch in diameter. δ_t (the *SD* of settings) and the "equality" position for the two needles were determined under the three conditions of needle diameter.

The effect of level of illumination on ω_t is shown in Fig. 9. The curve drawn through the data indicates that, in general, $\log \omega_t$ decreases with an increase in intensity. The rate of decrease is rapid at low intensities, but the curve seems to flatten out and ap-

FIG. 7. Schematic diagram of the apparatus used by Graham, Baker, Hecht, and Lloyd (1948). The needle driven by the micrometer is adjustable in a plane parallel to the line of sight. The subject adjusts this needle until it is in the same plane as the fixed, upper needle. The moving stage, containing the needles and accessory equipment, moves in a plane perpendicular to the line of sight.

Figure 8 gives the data of the experiment on "equality" settings. The experimental values lie on a horizontal line, and not on the line that would correspond to constant visual angle. This means that, whatever the size of needle, the equality setting was always made at the same distance from the eye. The fact that the average distance of setting remained constant under the three conditions indicates that differential size of stimuli played little part in the discrimination. However, it had some influence on precision of settings, since δ_t (and hence ω_t) was found to be smallest when the fixed and movable needles had the same diameter.

proach a final level for intensities above about 100 millilamberts. The total change in $\log \omega_t$ is approximately 0.8 log unit over the range of intensities used and for a speed of needle movement of about 7 degrees per second.

The curve fitted to the data, as a first approximate description, is Hecht's intensity discrimination (1935) equation,

$$\frac{\Delta I}{I} = c \left[1 + \frac{1}{(KI)^{1/2}} \right]^2 \quad (13)$$

in which I is intensity; ΔI is the least discriminable intensity increment, and c and K are constants. $\log \omega_t$ has been set equal

to $\log \Delta I/I$; and this treatment implies that, in order to discriminate a threshold parallax, a threshold rate of separation ω_t is required, which, in a small interval, dt , allows a discriminable separation, $d\Delta\theta$, to appear between the lines of sight to the needles, each of which provides its diffraction pattern on

of sight) in radians per second. $\log \omega_t$ increases with increase in the rate of movement of the stimulus needles. The curve is negatively accelerated and appears to be approaching an asymptote for rates greater

FIG. 8. Distance of setting of the movable needle as a function of the diameter of the stationary needle. The stationary needle was at a distance 9.75 inches from the eyepiece lens. The oblique line (marked Size) represents the theoretically expected curve for settings made on the basis of visual angle. The horizontal line (marked Distance) is the experimentally obtained curve for discriminations made on the basis of distance of the stationary needle. (From Graham, Baker, Hecht, and Lloyd, 1948.)

the retina. The small difference, $d\Delta\theta$, is required before a differential diffraction pattern may be established to signal a threshold parallax. Thus ω_t becomes a measure of a difference in diffraction exposures which, in a given short time, provides a ΔI that is discriminated against a general illumination I . Much more work, based on this analysis, must be carried out.

Figure 10 represents the data of an experiment on rate of needle movement. It shows the threshold for differential angular velocity in seconds of arc per second ($\log \omega_t$) as a function of rate of movement of the needles (in a line perpendicular to the principal line

FIG. 9. Threshold values of the differential angular velocity ω_t , in seconds of arc per second, as a function of intensity. The threshold for monocular movement parallax is high for low intensities and decreases as intensity increases. (From Graham, Baker, Hecht, and Lloyd, 1948.)

than about 0.35 radian per second. On the logarithmic scale the overall change in $\log \omega_t$ is about half a log unit, corresponding to a factor of about 3.

FIG. 10. Threshold values ω_t as a function of the rate of movement of the stimulus needles. The threshold for monocular movement parallax is low for slow rates of needle movement and increases as the rate of the needle movement increases. Data for different subjects are indicated by different symbols. (From Graham, Baker, Hecht, and Lloyd, 1948.)

A final experiment of the report is concerned with the influence of the axis of movement on ω_t . An eyepiece, with artificial pupil of 3-millimeter diameter and holding a Dove prism, was substituted for the

eyepiece of the previous experiments. Rotation of the Dove prism allowed for any desired rotation of the axis of movement. Determinations were made for axes, separated by steps of 30 degrees, through a 360-degree rotation of the field.

The experimental data are given in Fig. 11. The curve through the data shows that, when the axis of movement is horizontal (zero or 180 degrees), ω_t is at a minimum. When the axis of movement is vertical (90 or 270 degrees), ω_t is at a maximum. For

FIG. 11. Threshold values of ω_t as a function of axis of movement. Thresholds for monocular movement parallax are least for horizontal movement and greatest for vertical movement. (From Graham, Baker, Hecht, and Lloyd, 1948.)

axes of movement between the horizontal and vertical, ω_t assumes intermediate values.

When appropriate corrections are made for different viewing distances, the δ_t values obtained by Tschermak (1939) in his experiment employing unknown rates of head movement are found to be of the same order of magnitude as those of Graham et al. (1948). Thus both experiments substantiate the view that the thresholds for monocular movement parallax are smaller for the horizontal axis of movement than for the vertical. The difference in thresholds may be due to differences in the effectiveness of eye muscle pairs which control the various axial movements, or it may be due to differences in retinal gradients of cone densities along the various foveal-peripheral axes.

Zegers (1948) has been concerned with the influence on ω_t of the following parameters: (1) rate of movement of stimuli; (2) size of visual field in which the moving

stimuli appear; (3) amount of "offset" (defined as the instantaneous visual angle of separation, $\Delta\theta$, existing between the comparison and variable stimuli); and (4) conditions of fixation.

Zegers finds, as was true in the earlier experiment of Graham et al. (1948), that δ_t and ω_t increase with an increase in the rate of stimulus movement up to a limiting rate. He interprets this result to mean (1) that high rates of stimulus movement interfere with proper "following" of the stimuli by the eye, and (2) that, at high speeds, intensity effects in individual cones are decreased.

When conditions are provided to allow for good "pickup" of the stimuli as they emerge in the visual field, and for improved visual pursuit of the stimuli, the size of the visual field has little or no influence on ω_t .

In another series of experiments Zegers found that a constant visual field, providing a stimulus excursion of 3.58 degrees, and placed at increasing angular displacements from the principal line of sight, gave values of ω_t according to the rule: the greater the angular displacement, the lower the threshold for differential angular velocity. Calculations of the threshold "offset" $\Delta\theta$ in these experiments lead to the conclusion that threshold of monocular movement parallax is determined when, for a given rate of movement, $\Delta\theta$ reaches a critical value. This means that the threshold is determined for monocular movement parallax when a threshold value of visual angle separates the comparison and test stimuli. The critical value of $\Delta\theta$ varies as a function of the rate of stimulus movement, and this fact leads one to consider the reciprocal relations of time and intensity factors, relations reminiscent of those implied by the Bunsen-Roscoe law.

Accommodation

When the eye is fixated on a point in space, that point is sharply focused on the retina. All points nearer or farther than the fixated point are blurred. The blur cir-

cles formed for points not in focus have diameters that vary as a function of pupil size. They also vary as a function of the distance between the fixated point and the point not fixated (Southall, 1933, 1937).

The discrimination of the clearly focused image from the blurred image probably serves as a distance cue, although the process of discriminating must be quite complex and certainly has never been adequately investigated. Presumably such factors as the discrimination of detail and retinal image size combine with the subjects' reactions to the accommodation performance itself to provide the cue.

Interposition

Interposition is often defined as the cue for the discrimination of the relative distances of two objects that results when one object partially obscures or overlaps the outline of another object. The overlapping object is reported as nearer. As Ratoosh (1949) points out, such a definition is not satisfying, for it appeals to an unspecified factor: the basis for discriminating between the object that obscures and the object that is obscured. Helmholtz (1924) describes the cue when he says "the mere fact that the contour line of the covering object does not change its direction where it joins the contour of the one behind it, will generally enable us to decide which [object] is which."

Helmholtz's statement is not precise and is improved by Ratoosh.

Consider a projection of figures onto a plane perpendicular to the visual axis such that the nodal point of the eye is the point of projection. In such a perspective transformation all objects will be represented by simple closed curves. (Without any loss in generality only two figures will be treated here; the same reasoning may be extended to apply to any number of objects.)

A necessary condition for interposition to become effective as a cue is that the curves of the two objects in the plane of projection have a common boundary. A point at which the boundaries of the curves meet will be

called a point of intersection. Clearly there will be two points of intersection for a common boundary.

Helmholtz's specification implies that the behavior of the functions represented by the closed curves at the points of intersection alone determines which object will be seen as nearer. More specifically Helmholtz's assertion may be taken to indicate that continuity of the first derivative of the object's contour at the points of intersection is the sole determiner of relative distance. (A first derivative, $f'(x)$, of a function, $f(x)$, is continuous at a point p if and only if for any $\epsilon > 0$, there exists a δ such that $|f'(x) - f'(p)| < \epsilon$ in the interval $|x - p| < \delta$.)*

This formulation predicts that what happens at one point of intersection is independent of what happens at the other. That is to say, both points of intersection may give the same cue, both may offer no cue, only one may give a cue, or each may provide a cue which contradicts the other. If, at a point of intersection, the contours of both objects are the same with respect to continuity of their first derivatives, no cue will be provided at that point of intersection; if this occurs at both points of intersection, interposition will afford no cue for the relative distances of the two objects.

Some examples of interposition are shown in Fig. 12.

In Fig. 12A, one boundary's first derivative is continuous at both points of intersection. The other boundary has a discontinuous intersection at both points of intersection. The figure whose boundary has a continuous first derivative at the point of intersection, i.e. the left-hand figure, is seen as nearer; the figure whose boundary has a discontinuous first derivative, i.e. the right-hand figure, is seen as farther away. The same cue is provided at both points of intersection.

In Fig. 12B, one function possesses a continuous first derivative at one point of inter-

* To be continuous at a point, the first derivative must be defined at that point. Accordingly, in the examples given in Fig. 12, the coordinate axes must be taken in such a way that neither is parallel to the sides of the figures containing a point of intersection.

section and a discontinuous one at the other, whereas the other function's first derivative is discontinuous at both points of intersection. No cue is given at point *a* where both first derivatives are discontinuous. At point *b*, however, the outline of the right-hand figure has a discontinuous first derivative and the outline of the left-hand figure has a

FIG. 12. Examples of interposition as a cue for the perception of relative distance. *A* and *B* give obvious cues; *C* gives conflicting cues. (From Ratoosh, 1949.)

continuous first derivative. Thus the left-hand figure is seen in front of the right-hand figure.

Figure 12C gives a complex case: a cue is provided at each of the two points of intersection, but the two cues contradict each other; the point of intersection at *c* indicates that the right-hand figure is nearer, whereas that at *d* indicates that the left-hand figure is nearer. This situation results because the first derivative of each function is continuous at one point of intersection and discontinuous at the other, and each derivative is continuous at that point of intersection at which the other is discontinuous.

Convergence

Symmetric convergence (Southall, 1937). The angle of convergence is represented as angle α in the diagram of Fig. 13, and *a* is the distance between the centers of rotation

FIG. 13. Angular relations in symmetric convergence. Explanation in text.

of the two eyes (equal to the interpupillary distance). When, as is often the case (symmetric convergence), the two lines of fixation intersect each other at a point in the median plane perpendicular to *a*,

$$\tan \frac{\alpha}{2} = \frac{a}{2R} \tag{14}$$

In this equation *R* represents the distance along the perpendicular bisector of *a* to the point of intersection of the lines of fixation. For small angles of α the relation of equation 14 is given approximately, in radians, by

$$\alpha = \frac{a}{R} \tag{15}$$

or, in degrees, by

$$\alpha = \frac{57.3a}{R} \tag{16}$$

α is overestimated by equations 15 and 16 in the same manner as is β by equations 2 and 3. For large angles and accurate determinations of α , computations based on equation 14 should be used.

Asymmetric convergence. Suppose that we are not dealing with the case of symmetric convergence but rather with the situation represented in Fig. 14 (asymmetric convergence). We wish to obtain an expression for α .

Let $a (= Z_1Z_2)$ be the distance between the centers of rotation of the two eyes, and PM the perpendicular bisector of a . Draw $P'L$ perpendicular to the extension LZ_1 of Z_1Z_2 . Let $(LZ_1 + Z_1M)$ equal s , and let $P'L$ equal R . Finally, let $b = a/2 (= Z_1M = MZ_2)$. Note that θ' is the angle that may be used to designate the angular position of P with respect to PM .

FIG. 14. Angular relations in asymmetric convergence.

In Fig. 14 it may be seen that $P'P = LM = s$; $Z_1M = MZ_2 = b$; and $MP = LP' = R$. Also, $\psi = \arctan (s + b)/R$; $\phi = \arctan (s - b)/R$; and $\alpha = \psi - \phi = \arctan (s + b)/R - \arctan (s - b)/R$.

The expansion of the difference $\psi - \phi$ by Maclaurin's series is [for $(s + b) < R$]

$$\alpha = \frac{2b}{R} - \frac{2b(3s^2 + b^2)}{3R^3} + \frac{2b(5s^4 + 10s^2b^2 + b^4)}{5R^5} - \dots \quad (17)$$

On dropping all terms but the first and recognizing that $a = 2b$, we obtain

$$\alpha = \frac{a}{R} \quad (18)$$

as an approximate statement of the value of α (in radians).

For an alternating convergent series such as equation 17, the remainder for one term

is less than the second term; i.e. remainder $< \left| \frac{2b(3s^2 + b^2)}{3R^3} \right|$, and the error is $\frac{\text{remainder}}{\text{preceding term}} < \frac{3s^2 + b^2}{3R^2}$. Thus, equation 18 overestimates

α by 1 per cent when

$$\frac{3s^2 + b^2}{3R^2} = 0.01$$

Other percentage errors may be calculated. When necessary, terms beyond the first in equation 17 may be used for more accurate estimation of α .

Stereoscopic Vision

Single vision and the horopter. Singleness and doubleness of vision with two eyes are best understood in terms of a geometrical construct, the horopter (Southall, 1937; Boring, 1942; Helmholtz, 1924; Hering, 1861-64; Luneburg, 1947).

Johannes Müller (1826) was not the first to consider the facts of single binocular vision — Vieth anticipated him — but he discussed the problem so thoroughly that his name is inseparably associated with early theoretical developments.

According to Müller, singleness of object vision occurs when the object lies at the point of intersection (in the external field) of a pair of straight lines drawn through the nodal point of each eye, *provided* the lines meet the retinas at a pair of corresponding points. If the lines do not meet the retinas at corresponding points, (1) the object will be seen as double if the disparity between points is great enough, or (2) if the disparity is not great, the object will be seen as single but as nearer or farther away than a fixated object.

Theoretically, corresponding points are those retinal points that would be coincident if one retina could be placed over the other with vertical and horizontal axes through the fovea superimposed. We know that such a hypothetical construction is an approximation at best. Nevertheless it provides a basis for systematization not otherwise available.

The locus of points giving rise to single vision for a given attitude of the two eyes is called the horopter. As shown in Fig. 15 the horopter, for one particular case, is a circle, the Vieth-Müller horopter circle.

It may be proved that the Vieth-Müller construction is a circle in the following manner. The points o and o' are the centers of rotation of the two eyes. (The centers may

FIG. 15. The Vieth-Müller horopter circle. Only if the points P , Q , and R lie on a circle will their images fall on corresponding points in the two retinas. The proof is given in the text. (From Boring, 1942.)

be considered nearly coincident with the nodal points.) The eyes fixate P and form images on corresponding points p and p' . Let Q form images on corresponding points q and q' ; and similarly let R form images on corresponding points r and r' . Under these conditions, angle $qop = \text{angle } q'o'p'$, and angle $rop = \text{angle } r'o'p'$.

Consider angles qop and $q'o'p'$. Angle $qop = \angle QoP$ and angle $q'o'p' = \angle Qo'P$. Therefore angle $QoP = \text{angle } Qo'P$. But the opposite angles at m are also equal. Therefore triangles Pmo and Qmo' are similar, and angles oPo' and oQo' are equal.

For the condition that two triangles Poo' and Qoo' have a common side oo' opposite equal angles, it is necessary that the points at the vertices of the equal angles lie on a

circle. (All triangles erected upon a chord of a circle to a point on the circumference have equal angles opposite the chord.) Thus points P and Q lie on a circle. A similar proof would demonstrate that R falls on the same circle, and so would any other point whose images fall on corresponding points. If conditions of fixation change, the size of the circle also changes.

The Vieth-Müller horopter circle is based on the notion that, with the fovea centralis of each eye as origin, corresponding points occur at equal distances along radii rotated about the origin through equal angles from the horizontal. A generalized horopter drawn on the basis of this concept is a sphere generated by the revolution of the Vieth-Müller circle around one of its diameters.

We know that this conception of the horopter is oversimplified, and Helmholtz (1924) and Hering (1861-64) worked out the form of a general horopter which appears in Fig. 16. This horopter contains the Vieth-Müller circles as a special case; i.e. for horizontal regard. Work by Hering and Hillebrand showed that the horopter varies with different conditions of fixation, being much less curved than the Vieth-Müller circle for strong convergence. For weak convergence (fixation at about 2 meters), the curve becomes a straight line perpendicular to the median plane; and for fixation distances greater than about 2 meters, the horopter curve becomes slightly convex towards the face (Southall, 1937). For a more detailed historical summary, see Glanville (1933).

When an object is fixated, another object, not lying on the horopter of the fixated object, is discriminated as double, provided that it lies far enough from the horopter of the fixated object so that the degree of non-correspondence of the retinal images exceeds the range for binocular fusion. If the object lies beyond the point of fixation, a condition known as "uncrossed" retinal images obtains; i.e. with his left eye open, a subject says

that the object lies to the left of the fixated object. With his right eye open, the subject says that the object lies to the right of the fixated object. When the object lies nearer than the point of fixation, the retinal images

FIG. 16. The generalized horopter line, according to Helmholtz and Hering. The general horopter is a curve, symmetrical above and below, plotted on the surface of a cylinder. The curve is asymptotic to the line LMN . The eyes, with their optical centers at o and o' , are represented by the dashed circles at the back of the cylinder. The horopter line is $ABCDE$. The part of the line that passes through the eyes is dotted, BCD , and defines a region of invisibility. In a limiting case, horizontal regard, this horopter becomes the Vieth-Müller horopter circle, $CKMJ$. (From Boring, 1942.)

are "crossed"; i.e. the subject, with his left eye open, reports that the object lies to the right of the fixation object. With his right eye open, he reports that the object lies to the left of the fixated object. The geometry of crossing and lack of crossing of the retinal images is readily deducible from geometric theory (Southall, 1937).

A subject reports on the direction of an object, responded to as single in binocular

vision, as if the object were on a line drawn from the point of fixation to the point midway between the two eyes. Hering (1942), in particular, has been interested in this problem, and the reader is referred to his book for a more detailed account than can be given here.

Objects viewed in space with the unaided eyes. Suppose that a subject regards, with the left eye alone, the scene represented in the left side of Fig. 17; i.e. two flagpoles

FIG. 17. The left-eye view and the right-eye view of two flagpoles behind a stone wall. The lateral separation of the flagpoles is seen as smaller in the right-eye view than in the left-eye view.

behind a stone wall. For vision with the left eye alone the subject cannot tell which of the two flagpoles is nearer. After looking with the left eye, the subject closes that eye and regards the flagpoles with the right eye. The "right-eye view" is shown in the right side of the same figure. Although the subject may state that the lateral separation of the flagpoles seems smaller in the right-eye view than in the left, neither type of monocular viewing allows him to state which flagpole is nearer.

After regarding the scene with each eye alone, the subject looks at the scene with both eyes and can immediately state that the right-hand flagpole is nearer than the left-hand flagpole. The binocular discrimination of difference in distance is brought about by one of the well-known cues for depth perception, retinal disparity (Helmholtz, 1924; von Kries, 1924; Southall, 1937; Graham, 1943), and the geometric consider-

ations that underlie the concept are represented in Fig. 18.

In Fig. 18, a represents the interocular distance, and F (the left-hand flagpole) is the object fixated. F' represents the right-hand object. R is the distance to F along a perpendicular to the interocular axis, and δ is the difference in distance along this perpendicular between F and F' . Angle θ_2 is the visual angle formed by the lines of sight

FIG. 18. The geometry of the binocular perception resulting from stimulation as in Fig. 17. The left-hand flagpole is farther from the subject than the right-hand flagpole.

to the two objects in the left eye, and angle θ_1 is the angle between the lines of sight in the right eye. Angle α_2 is the apex angle for the intersection of the lines of sight from the two eyes to F , and angle α_1 is a similar angle for the lines of sight to F' .

It may be observed that $\theta_2 - \theta_1$ is a difference in visual angles subtended in the two eyes by the lines of sight to the two objects; hence, $\theta_2 - \theta_1$ is (ideally) a measure of the retinal separation of the two object images in angular measure.

In Fig. 18,

$$\theta_2 - \theta_1 = \alpha_1 - \alpha_2 \tag{19}$$

that is, the difference in visual angles is the difference in convergence angles with changed sign.

The determination of α_1 and α_2 is, for the general case, similar to the determination of α

in the case of asymmetric convergence (see equation 17) and requires a calculation based on a series expansion for the appropriate α and its corresponding ψ and ϕ . However, in the great majority of cases, where R is many times greater than either a or δ , and where F' is not too far from the perpendicular to a on which F lies,

$$\alpha_2 = \frac{a}{R} \tag{20}$$

and

$$\alpha_1 = \frac{a}{R \pm \delta} \tag{21}$$

in radians. Therefore, if we call

$$\alpha_2 - \alpha_1 = \theta_1 - \theta_2 = \eta \tag{22}$$

then

$$\eta = \frac{a\delta}{R^2} \tag{23}$$

an expression in which a term $(R \pm \delta)$ is considered equal to R . For calculations in seconds of arc, the radian values must be multiplied by 206,265.

At threshold one measures η_t which is determined on the basis of δ_t , i.e. $\eta_t = a\delta_t/R^2$. The term δ_t may be determined, e.g. in the Howard-Dolman apparatus (Howard, 1919), as an average of two threshold differences in the settings of two sticks (one the standard, and the other the comparison), and for settings made toward the subject and away from the subject.

The telestereoscope. In a telestereoscopic viewing system, the distance a is effectively increased by providing a system that reflects the images of the objects viewed from mirrors placed farther apart than the distance between the two eyes (Graham, 1943). The distance between the two mirrors is called the baselength B . Since a , as previously discussed, is a special case of baselength, the interpupillary distance, equation 23 may be rewritten in more general form for lines of sight converging on an object from any baselength. The resulting equation is

$$\eta = \frac{B\delta}{R^2} \tag{24}$$

When there is magnification M it multiplies (in the ideal case) the right side of equation 24, which then becomes

$$\eta = \frac{BM\delta}{R^2} \tag{25}$$

Many factors serve to diminish the influence of M at high magnifications (Riggs, Mueller, Graham, and Mote, 1947).

The limit of stereoscopic vision. The limiting range, R_{lim} , of stereoscopic vision is the greatest distance at which an object can be just detected as nearer than an object at infinity. Suppose that α_1 is the apex angle for the object at infinity; i.e. $\alpha_1 = 0$. Then, if we take the least discriminable difference, η_t as 30 seconds of arc (a large figure), we find, by equation 22, that $\alpha_2 = 30/206,265$ radians. On substituting this value of α_2 in equation 20 and assuming an average value of a to be 0.072 yard (65 millimeters), we find R_{lim} to be 495 yards. Of course, the computation of R_{lim} varies with the value of η_t taken, as well as with the interpupillary distance assumed. Nevertheless the calculation emphasizes the fact that stereoscopic vision acts as a space cue through a considerable range of distance.

Binocular vision in the stereoscope. In looking into a stereoscope, we look with the left eye at a presentation (e.g. a photograph) which is different from the one for the right eye.

Consider two stereograms, one the left view in Fig. 17 and the other the right view in the same figure. They are mounted together in the stereoscope in such a way that the right view is presented to the right eye and the left view to the left eye. Under these conditions, the two flagpoles F and F' are designated F_L and F'_L for the left eye and F_R and F'_R for the right eye. The geometrical theory of binocular vision that applies to these circumstances can be made out with the help of Fig. 19.

The angular disparity in the separation of the two flagpole images is $\theta_2 - \theta_1 = \eta$. Now, in radians,

$$\theta_2 = \frac{\overline{F_L F'_L}}{R} \tag{26}$$

and

$$\theta_1 = \frac{\overline{F_R F'_R}}{R} \tag{27}$$

Therefore

$$\eta = \frac{\overline{F_L F'_L} - \overline{F_R F'_R}}{R} = \frac{g}{R} \tag{28}$$

in radians; and for threshold, the quantities η and g are η_t and g_t , i.e. $\eta_t = g_t/R$. Where θ_2 and θ_1 are large, it is necessary to use the

FIG. 19. Geometrical relations existing for the flagpole scenes as presented in stereograms, one to the left eye and the other to the right. Theoretical considerations are discussed in the text.

appropriate arctan functions as discussed in the section on convergence.

When, in the stereoscope, the attempt is made to line up a "target" with a fiducial line, the fiducial lines F_L and F_R in the two views are "fused" and the variability of setting [in terms of lateral movement of F'_L (or F'_R) in the plane at distance R] is taken to be g_t , a datum that accords with a conventionally determined just noticeable difference.

When the eyes are accommodated for infinity by a lens in each eye piece, R is taken as the focal length of the lens.

Experimental data. Howard (1919) has performed a well-known research on the determination of the threshold difference angle, η_t . The apparatus he used has become known as the Howard-Dolman apparatus, although it is essentially similar to the earlier one of James (1908).

The apparatus presents two vertical rods, one stationary and the other movable. The subject looks through a rectangular aperture (20×12 centimeters) in a screen at the two rods (each 1 centimeter in diameter) which may be seen side by side in uniform illumination. The viewing distance is usually 6 meters, a distance great enough to minimize effects due to convergence and accommodation.

One design of the Howard-Dolman apparatus allows the subject to move the adjustable rod toward him or away from him by means of strings. In the original experiment Howard set the variable rod at various positions and determined η_t on the basis of a least depth difference δ_t that could be discriminated 75 per cent of the time. The values of η_t varied from subject to subject over a wide range of stereoscopic acuity. Of 106 subjects tested, the 14 with the best stereoscopic acuity had values of η_t lying between 1.8 and 2.07 seconds; the 24 with the worst acuity had values between 10.6 and 136.2 seconds.

It is clear that, as the variable rod is moved back and forth in space, the size of its retinal image varies. The difference in retinal image size might account for the depth discrimination, and so Howard performed an additional experiment to determine the influence of this factor. The method involved monocular viewing, which, of course, eliminated all cues but size difference. Nine subjects gave an average depth difference value, δ_t , in the binocular experiments of 14.4 millimeters, and, in the monocular experiments, 285 millimeters. In other words, a least depth difference discriminated on the basis of image size is, for a viewing distance of 6 meters, about twenty

times as great as one discriminated on the basis of stereoscopic vision.

Woodburne (1934) has made a careful determination of η_t under conditions where retinal image size is invariable. He presented the subject with two illuminated slits, one stationary and the other variable with respect to distance. By means of an ingenious apparatus, it was so arranged that, as the distance of the variable slit increased, the actual size of the slit also increased, the visual angle for length and width remaining the same in all positions. The viewing distance was 2 meters and single observations were restricted to exposures of 1.5 seconds. The method of constant stimuli was used, and by this method η_t turned out to be 2.12 seconds for the averaged "near" and "far" thresholds for 7 subjects. This value is similar to the one found by Howard for his best subjects.

Matsubayashi (1937, 1938) published a series of papers in Japanese (abstracts in German) on factors that influence stereoscopic acuity. He used a two-rod and a three-rod apparatus in various experiments. The three-rod apparatus had a movable middle rod and two stationary outer rods.

One important factor that influences the magnitude of the threshold difference angle η_t is the distance (or visual angle) separating the stationary and variable rods in the three-rod and the two-rod apparatuses (1937*b*). As the outer rods vary in angular separation from the variable rod, η_t becomes larger and larger as shown in Fig. 20, which presents a graph of Matsubayashi's data. The constant error of setting may also be influenced by angular separation. Matsubayashi says that it may be opposite in sign for some separations as contrasted with others.

In other experiments Matsubayashi examined influences due to length of rods and thickness of rods. With a decrease in length of rod from 2.5 degrees to 38 minutes η_t increases slowly, until with further decrease

to 17 minutes η_t increases rapidly (1938a). A thickness of about 2.4 minutes gives the lowest values of η_t (1938b).

Distance of observation, with its associated conditions of convergence, also seems to influence η_t (1938d). η_t is greater for an observation distance of 2.5 meters than it is for 15 meters. For example, with a 30-minute lateral separation of rods, η_t , determined by the method of constant stimuli,

FIG. 20. Data from Matsubayashi (1937b) on the threshold difference angle for stereoscopic vision (η_t in seconds of arc) as it is influenced by the visual angle (in minutes of arc) separating the stationary and variable rods. Curve *L* presents data obtained, by the method of limits, with the 2-rod apparatus. Curve *C* represents data obtained, by the method of constant stimuli, with the 3-rod apparatus.

is 3.86 seconds at 2.5 meters and 2.51 seconds at 15 meters. These data are averages for 6 subjects.

Artificial visual defect, produced by placing a gelatin filter over one eye, seems to have little influence on the threshold difference angle η_t until the acuity of the covered eye is very low (1938e). With acuity normal in one eye at 1.2 and reduced to 0.3 in the other eye, η_t is slightly increased. Further reduction of acuity in the eye covered by the filter to 0.2 causes a great increase in η_t . With a decrease in acuity of the covered eye to 0.1, depth perception becomes impossible.

A number of interesting experiments were performed by Langlands (1926) and his report presents a good survey of earlier investigations.

Langlands obtained stereoscopic acuity values comparable to those obtained by other investigators; i.e. values ranging from about 2 to 40 seconds of arc, depending on the conditions of experimentation. He found that good space discriminations may be made for differently shaped objects in continuous illumination, η_t for his subjects being of the order of 1.5 to 6.0 seconds. With short flashes of light produced by a spark of about 10^{-5} second's duration, objects were spatially discriminated when η_t varied, for two well-trained subjects, from about 20 to 40 seconds. Discrimination was better with an 8-degree field than with a 1-degree field.

Langland's results do not mean that the discrimination is made in the short period of the flash. Obviously the duration of flash simply determines amounts of retinal initiating processes, and discrimination may be based on events that last for a time after the flash has ceased. Langlands maintains that the discriminations of his subjects were not based on the positive after image.

A series of exploratory experiments on stereoscopic acuity at 2 degrees from the fovea demonstrate that the probability of detection of a spatial difference is lower for this location than it is for the center of the fovea.

In addition to making observations in the "real depth" situation, Langlands determined η_t in a stereoscope, where η_t , as found with exposure by an electric spark, was slightly higher than that found in "real depth," but, as Langlands says, "I have no doubt that with improved apparatus and greater practice finer binocular acuities could be reached."

Mueller and Lloyd (1948) determined the influence of illumination on η_t for observations with a stereoscope. The stereoscope they used provided movement of a vertical line in the right-eye field while a comparable line in the left-eye field remained stationary. The "fused" line that resulted was compared spatially with three short "fused" fiducial lines, produced by paired vertical lines in

the right and left fields. Mueller and Lloyd found, for observations lasting from 5 to 10 seconds, that η_t is small (i.e. discrimination is "good") at high photopic illuminations and increases with a decrease in illumination to cone threshold. Figure 21 gives the data. Cone threshold is taken to occur at the discontinuity of the curve. It will be observed that η_t is nearly constant over much of the range of photopic illumination and rises as

FIG. 21. The threshold for stereoscopic vision (η_t in seconds of arc) as a function of intensity of illumination. Determinations were made with the stereoscope. Thresholds are high for low illuminations and decrease as illumination increases. (From Mueller and Lloyd, 1948.)

intensities decrease to cone threshold. Below the cone threshold, space discrimination is still maintained, presumably by the rods, but in a relatively ineffective way, as shown by the high values of η_t .

Mueller and Lloyd's results for the stereoscope are similar to some obtained by Berry, Riggs, and Duncan (1950), Holway (1947), and Ludvigh (1947) in experimental conditions involving a comparison of object distances in "real depth" (e.g. as in the Howard-Dolman apparatus). η_t is high at low intensities, decreases as intensity increases, and finally approaches a low limiting value at high illuminations.

The observations of Matsubayashi on the effect of lateral distance between rods have been verified for the stereoscope by Graham, Riggs, Mueller, and Solomon (1949). Observations were made in an apparatus comparable to that used by Mueller and Lloyd, and

η_t was determined as it is influenced by the separation of the variable line from a constant reference line. η_t increases when the lateral distance between reference line and variable line increases in the frontal plane.

Berry compared threshold acuities for vernier, real-depth, and stereoscopic tasks under similar conditions (1948). Two black cylindrical rods, one above the other in the median vertical visual plane, were viewed through an aperture. Under the vernier condition the subjects were required to tell whether the bottom rod was to the right or left of the upper one (i.e. the subjects had to discriminate an "offset"). In the real-depth situation the discrimination was based on the bottom rod's being behind or in front of the upper rod. In the third condition, stereoscopic depth, two sets of vernier objects were viewed through right angle prisms, the view of each set being restricted to a single eye. The method of constant stimuli was employed. An essential question concerned the manner in which the three types of acuity vary as a function of the vertical separation between the rods. The separations employed varied between 3.6 and 891 seconds.

The results show that, for a small rod separation, vernier acuity is best. However, as the vertical separation is increased to more than 135 seconds, stereoscopic-depth acuity and real-depth acuity become superior to vernier acuity.

Many factors in daily life must influence the effectiveness of stereoscopic vision. For example: a condition of asymmetric convergence means that the retinal image in one eye must be different in size from the retinal image in the other eye, due to the fact that one eye is farther removed from the observed object than the other. Ogle (1939) has shown that the expected size difference does not produce anomalous stereoscopic effects. He assumes that some sort of compensatory effect must occur to offset the difference in distance from the object to the eyes in asymmetric convergence.

It is obvious that if size differences exist between the two images, complex stereoscopic effects will ensue, because the points along contours do not lie on corresponding points. This problem has engaged the attention of workers at the Dartmouth Eye Institute (Ames, 1946; Ogle, 1939), and many elaborate and useful studies have been made upon phenomena resulting from aniseikonia, the condition under which the two retinal images are different in size. There is an excellent theoretical account of aniseikonia by Ogle and Boeder (1948). Their discussion relates aniseikonia to a geometrical theory of space perception in a convincing manner.

Effects due to size difference show up in such manifestations as an apparent horizontal rotation of the visual field around a vertical axis at the point of fixation. If the relative shapes of the two ocular images are distorted, the visual field, instead of being rotated, will appear concave or convex. Differences in size of about 0.25 per cent may be distinguished (Ames, Gliddon, and Ogle, 1932).

Differences in the size and shape of the two retinal images may be introduced by two sources: by a change in the dioptric image, and by a change in the anatomical positioning of the retinal elements. Differential effects due to both sources may be expected in the two eyes. For example, (1) differential conditions of accommodation may produce aniseikonia; (2) there is a change in the asymmetric distribution of corresponding retinal points from distant to near vision (Hering-Hillebrand horopter deviation); (3) there seems to be a disparity of corresponding points in certain abnormal conditions of the eyes associated with phoria; and, finally, (4) there is some evidence that ocular images change in size when one looks left or right of the median plane (Ames, Gliddon, and Ogle, 1932).

An interesting effect, called the induced size effect (Ogle, 1940), occurs when a difference in the vertical dimensions of the

images occurs. The effect appears as an apparent rotation of the observed object about the point of fixation and is opposite in direction to the rotation introduced by a difference in the horizontal dimensions of the retinal images. Complex effects may also be introduced when the aniseikonia involves an oblique axis (Burian and Ogle, 1945), and an instrument, the space eikonometer (Ogle, 1946), has been developed to measure the declination error between the images in the two eyes as well as image size differences in the vertical and horizontal meridians.

Graham, Hammer, Mueller, and Mote (1949) have shown theoretically that, under certain conditions of varying convergence, a stereoscopic observer may align a target with a reticle at more than a single value of apparent range. Theory predicts that multiple alignments may occur when the visual angle, $\Delta\beta$, existing between adjacent, equally spaced reticle marks is sufficiently small. If we designate the angular difference existing between a given alignment setting and the "true" alignment setting as η , then the condition for alignment is fulfilled when $\eta = n\Delta\beta$, where n , an integral number, represents the degree of "false" fusion. The effect described is, of course, the "wallpaper" effect discussed by Woodworth (1938). Experimental data are in accord with theory.

Conditions of attitude of the eyes may be expected to influence stereoscopic vision. For example, certain torsional effects (Hermans, 1943; Ogle and Ellerbrock, 1946) may occur due to the manner in which the muscles of the eyes are attached to the eyeball. The net result of such effects would be to make the upper part of a vertical line appear farther from the observer in stereoscopic vision than the lower part of the line. Undoubtedly, many other factors are important in stereoscopic vision, and some may influence our behavior in everyday life.

The Pulfrich effect. If a subject with a not-too-dense filter in front of one eye regards an object oscillating in simple harmonic motion in the frontal plane, the physi-

cally rectilinear movement of the object is reported as generating a curve, not unlike an ellipse, whose plane is perpendicular to the frontal plane and parallel to the floor. Best results are obtained when fixation is maintained in the median plane.

The phenomenon is explained in the following way by Pulfrich (1922) who uses a suggestion by Fertsch: Stimulation of a given point on the retina is signaled after a latent period that varies as a function of light intensity. Now the latency of visual effect for the uncovered eye is shorter than for the eye covered by a filter, and so the covered eye signals a position of the moving object that "lags" behind the position signaled by the uncovered eye. Thus at any moment the reaction of a subject is based on stimulations from noncorresponding points, and the discriminated position of the object at any time is dependent on the amount and sign of the retinal disparity. Banister (1932), Liang and Piéron (1947), and Lit (1949) have made quantitative measures of the effect and on the basis of their results have computed the difference in latencies for the two eyes as a function of intensity differences. For a good summary of the history of the Pulfrich effect and related phenomena, see Lit (1949).

Binocular Rivalry

When two figures, different according to some system of classification, are presented, one to one eye and the other to the other eye, in a stereoscope, the subject reports that now one and now the other figure appears in alternating sequence. Sometimes, when the two stimuli are not "incompatible," the subject reports that they present a view that is a combination of both. For example, under certain circumstances the figure of a fence presented to one eye and a figure of a pony presented to the other results in the report of a pony jumping over the fence. The rivalry of binocular color mixture is well known and has played a role in the development of color theory (Hecht, 1928).

Illusions

"Illusions" of reversible perspective have been known since Euclid's time. Boring (1942) ascribes to Necker (1832) the first scientific observation on reversible perspective, and Necker's well-known cube is shown in Fig. 22. Schröder's staircase (1858) and Sinsteden's windmill (1860) are other famil-

FIG. 22. Necker's cube as an example of reversible perspective. Fixation of *M* gives one perspective; fixation of *N*, the reverse. (From Boring, 1942.)

iar reversible figures; both are presented in Boring (1942). Rubin (1921) studied a number of "ambiguous" configurations and on the basis of his analysis formulated the Gestalt principle of "figure and ground." The reader is referred to Boring's discussion for a fuller treatment of these interesting but unexplained phenomena.

Papers on illusions are not as numerous as they once were, but occasionally one appears. Finger and Spelt (1947), for example, analyzed the effects due to the bisection of a line in a figure that shows the horizontal-vertical illusion.

The overestimation of verticals with respect to horizontals was, together with the illusion of interrupted extents, the first to be studied. Wundt (1862) called attention to the tendency to overestimate the vertical as compared to the horizontal, and Oppel (1854-55) showed that interrupted extents are reported as greater than "empty" extents.

The Poggendorff figure was described by Zöllner (1860), and his modification of the illusion provided a more striking effect.

Hering (1861-64) presented the figure that bears his name, and a companion figure

was published by Wundt (1898). All these figures are reproduced in Boring (1942).

By far the most famous geometrical illusion of all is the Müller-Lyer figure (1896) shown in Fig. 23. The Müller-Lyer figure has been used to test almost all the theories of illusions that have been advanced, and it, together with other common designs, has been presented over and over in the psychological texts of the past fifty years.

FIG. 23. Müller-Lyer figure. The horizontal line segment appears longer when the arrows point out. (From Boring, 1942.)

Theories concerning the mode of action of the various figures have been inconclusive. As Boring (1942) says, "The problem of the geometrical illusions is not a special problem of space perception. When the general laws are known, the illusions will also be understood."

PERCEPTION OF MOVEMENT

The field of movement perception includes studies of real and apparent movement. An adequate theory of movement perception must include both topics, but at present we are in a position to do little more than systematize and summarize experimental results. For this reason, in what follows we shall consider the two types of movement independently.

Real movement. Experiments on real movement involve a stimulus that moves through a distance s at a rate ds/dt . Theoretically, thresholds for changing velocity may be determined, but, in fact, the literature on real movement is almost entirely restricted to the examination of constant, or nearly constant, speeds.

Two types of threshold have been of primary concern: (1) the rate threshold, for

which a threshold value of ds/dt is determined while s remains constant, and (2) the displacement threshold (Gordon, 1947), for which a threshold value of s is determined while ds/dt remains constant.

Aubert (1886) determined the lower threshold for rate under several conditions. He found that when the threshold for moving objects, such as the fine lines of millimeter paper, a long vertical line, etc., was determined with fixation on the moving object and in the presence of clearly seen stationary parts of the apparatus, the threshold turned out to be of the order of 1 to 2 minutes of arc per second. When the stationary parts of the apparatus were screened from view, the movement threshold rose to about ten times this figure, that is, to 10 to 20 minutes per second.

Bourdon (1902) verified these observations, and Grim's data (1910), obtained under conditions similar to Aubert's "screening" experiments and with circular movement, are in accord with the figures of Aubert.

The threshold for peripheral movement is higher than the threshold for central vision; for example, in one of Aubert's experiments the threshold for movement at 9 degrees in the periphery turned out to be 18 minutes of arc per second, whereas the threshold for central vision was 54 seconds per second. As for the discriminable difference between two different basic rates, Aubert interpreted it to be of the order of 1 to 2 minutes per second, a figure that resulted from a rejection of data for high speeds.

The results of Graham et al. (1948) on monocular movement parallax may be thought of as rate discrimination data and hence may be compared with Aubert's results. The discriminable difference rate (about 30 seconds of arc per second) found by Graham et al. (1948) for low speeds is lower than the figures given by Aubert. The difference threshold, about 100 seconds per second, obtained at high velocities, is near Aubert's figure and holds for much higher

velocities (about 17 degrees per second) than he used. Presumably, differential rate thresholds obtained in the experiments on monocular movement parallax are not complicated at high speeds by factors that may have appeared in Aubert's double drum arrangement.

An experiment by Basler (1906) is representative of research on the minimum discriminable extent of movement—the displacement threshold. Basler found the displacement threshold to be of the order of 20 seconds of visual angle in photopic illuminations. Such a small angle is less than the angle required for the resolution of two acuity objects. (See also the earlier date of Exner, 1875, for peripheral vision.) In contrast to Basler, Stern (1894) and Gordon (1947), working in dim illumination, found that the displacement and acuity thresholds are similar; and Stratton (1902) determined that the displacement threshold is no smaller in foveal vision than the threshold for vernier (“offset”) acuity. In view of the fact that the threshold is a function of rate of stimulus movement (Basler, 1906), the question of the relation between acuity and displacement threshold becomes meaningless in the absence of a rate specification.

Basler's experiments were neither systematic nor exhaustive; for example, he did not provide satisfactory measures and controls of rate and illumination. Nevertheless we may probably accept his qualitative results as showing an influence on threshold of the following variables: (1) Illumination: the displacement threshold is lower for high illuminations than for dim illuminations. (2) Rate of movement: the displacement threshold is low for high rates (probably not too high) and increases as rate decreases. (3) Retinal position: peripheral thresholds are higher than foveal thresholds. Data on the latter variable are now relatively satisfactory in comparison with results on rate and illumination. For example, Gordon (1947) has shown that the displacement threshold in-

creases systematically with increase in the peripheral angle of regard.

Some experiments by Brown (1931) are important because they specify several types of movement threshold and demonstrate the influence of certain variables on the thresholds.

Brown used small black squares pasted at 20-centimeter intervals on an endless white paper band, the spaces appearing in a diaphragm opening of dimensions varying from 15×2 centimeters to 3.75×1.25 centimeters. A fixation point was provided in the center of each field.

Brown found that, as the physical velocity of the moving square is increased continuously from zero to 200 centimeters per second, the following thresholds are ascertainable: (1) just discriminable movement; (2) movement reported as a reversed movement; e.g. when a square moves to the top of the field, disappears, and the succeeding square appears at the bottom of the field; (3) movement reported as equivalent to movement of two or more squares; (4) movement reported as equivalent to a continuous gray band (i.e. at “stimulus fusion”).

Brown determined the threshold rate for each of these aspects of movement. He found a lower threshold for just discriminable movement (threshold 1) which ranges from 0.11 to 0.30 centimeter per second, depending on field dimensions. These figures correspond to angular velocities of about 2 to 6 minutes of arc per second.

It may be observed that Brown's lower figure is equal to Aubert's upper figures, previously discussed. Length and width of field of view enter as important parameters to determine threshold magnitude, as do size and, presumably, distance between objects. These variables affect not only the lower threshold, but all other thresholds that Brown determined.

As for the other thresholds: the threshold for reversed movement (threshold 2), which Brown refers to as a threshold for a phi movement, varies from 10 to 30 centimeters

per second (about 3 to 9 degrees per second) depending upon field dimensions, size of stimulus objects, and distance between stimulus objects. Threshold 3, for increase in the number of moving objects, varies under different conditions from about 25 to 50 centimeters per second (7 to 15 degrees per second). Threshold 4, for "fusion," varies with different conditions from about 50 to 115 centimeters per second (12 to 32 degrees per second). Another specification of these results, which emphasizes the fact of repeated stimulation, is in terms of critical fusion frequency; this turns out to be about 6 to 8 stimulations per second.

All the thresholds determined by Brown show an effect of field dimensions and stimulus dimension parameters. Thresholds are low for small fields, small stimulus objects, and small separations between stimulus objects. More extensive analyses of these factors are needed.

Brown's investigation of "band" movement (threshold 4) followed an earlier research by Cermak and Koffka (1922) on the effects of illumination and field size on "band" movement threshold. Cermak and Koffka caused a narrow line of light, 35 millimeters in length, to rotate behind a screen containing an open sector which was variable in angular size. The authors determined, for each sector width, the speed of rotation of the line of light that was required just to cause an equivalent "band" discrimination. Under these conditions threshold speed of rotation was found to vary as a function of sector angle (or arc) according to the approximate empirical description $v = (KB)^{1/2}$, where v is speed of rotation, B is length of arc; and K is a parameter depending on line illumination. In examining the influence of illumination on traversal time, $e (= B/v)$, Cermak and Koffka obtained results that may be described by the empirical expression $e = b - a \log I$, where b and a are parameters representing influences that include size of exposure opening.

Data on the effects of intensity on movement discrimination are sparse and unsystematic. Crook (1937) determined the intensity threshold for the detection of direction of movement with rate of movement and width of stimulus grating bars as parameters. Crook's data show that the intensity threshold for the discrimination of the direction of movement passes through a minimum for fairly slow rates and then increases as rate increases. Intensity thresholds decrease as the width of the grating bar increases.

Our cursory survey of data on real movement shows that our knowledge of the relevant parameters is at an elementary stage of analysis. Complete functional descriptions of the relevant relations are badly needed, as are careful considerations of variables. In studying movement thresholds, we must take care that parameters are not confounded, a danger that arises only too readily from the fact that velocity itself involves the variables of distance and time. In any given experiment the variables of time, distance, interval between stimuli, and cycle of repetition of stimuli must be clearly analyzed before we can be confident that unequivocal data may be obtained.

Apparent movement. The most important type of apparent movement* arises under the following conditions. A given stimulus (a dot, a line, an illuminated area, etc.) is presented to the subject for a duration extending from a few milliseconds up to about

* Presumably the study of apparent movement involves the determination of the critical values of the variables that determine the conditions under which a subject's response will be equivalent to one made in the presence of real movement. Apparent movement, then, is a problem in response equivalence for various conditions of stimulation. Conversely, if the responses are restricted by instructions, the problem becomes one of determining thresholds, based on contrasting responses, for given variables in the presence of a given instruction stimulus.

A discussion of "apparent" movement in terms of behavior does not involve insurmountable difficulties. It is clear, however, that an agreed-upon vocabulary would be valuable in specifying the stimulus and response relations in the various kinds of perception experiments.

400 milliseconds. Then a second stimulus, similar to or different from the first, follows after a pause and in a new location. The length of the pause p may be varied as well as: (1) the duration d_1 of the first stimulus; (2) the duration d_2 of the second stimulus; (3) the intensities i_1 and i_2 of the respective stimuli; (4) the spatial interval s between the two stimuli; (5) the shapes and sizes of the two stimuli; (6) the wavelength distributions of the two stimuli, and (7) the conditions of instruction. (See Koffka, 1931, for a detailed discussion of variables.)

The determinations of greatest interest are those made under an instruction to perceive "optimal movement" (Wertheimer, 1912) where, presumably, the problem is to determine conditions that lead to a response equivalent to one produced by "real" movement (Neuhaus, 1930).

Under certain conditions it is also possible to determine thresholds of p for a report of simultaneity of stimuli and succession of stimuli. The report of simultaneity occurs with pauses p that are shorter than those holding for "optimal" movement. Reports of stimulus succession appear with pauses longer than those providing optimal movement. In addition, Wertheimer maintained that he was able to demonstrate the existence of what he called phi movement. The pause threshold for phi movement lies between the threshold for optimal movement and for succession. Phi movement is reported under an ill-defined class of instructions to the subject to respond to "pure" movement, i.e. "movement that does not involve object movement."

It will be impossible in this short review to give a thorough account of the confused, sprawling literature on apparent movement. Good reviews by Higginson (1926), Koffka (1931), Neff (1936), and Boring (1942) are available. It is sufficient to say that, although several stroboscopic devices had been perfected before 1835 by Faraday, Plateau, Stampfer, and Horner (cf. Boring, 1942), it was not until 1875 that Exner's experiments

showed the relevance of apparent movement to psychological theory.

Exner presented an analysis in which he claimed that movement, because of its irreducible nature, is a true "sensation"; and thus began a long series of papers by various authors. In the next few years Exner's view was supported by Vierordt (1876) and Aubert (1886), but Stern (1894) vigorously combated Exner's assertion and treated movement as a complex of psychological processes. Marbe (1898) presented an analysis of movement in terms of peripheral and central physiological mechanisms, and a short time later Dürr (1900) attempted to get along without the central mechanisms. These men and others, for example, Linke (1918) and Schumann (cf. reference to Lasersohn, 1912, a student of Schumann's) who worked before and after Wertheimer, are of some interest for their psychological analyses. However, it was not until the appearance of Wertheimer's paper that psychologists came into possession of enough data to specify essential controlling variables for apparent movement.

Wertheimer's paper appeared in 1912. With its systematic implications—its treatment of the perception of movement as simple unanalyzable experience—we shall not deal. Nor shall we consider the implications of Wertheimer's theory of cortical activity. From the point of view of the present discussion the paper is important because it contributed to the systematization of the study of apparent movement.

Wertheimer's experimentation set the pattern for much of the later work in the field. His method consisted of the tachistoscopic presentation of two stationary stimuli in such a way that they might be made to appear as simultaneous, overlapping in time, or successive. In Wertheimer's experiments, many variables were found to determine the class of response: exposure time of stimuli, interval between stimuli, characteristics of the stimuli (form, shape, wavelength distribution, intensity, etc.), as well as influences

due to conditions of the subject (attitude, instructions, etc.).

Wertheimer paid particular attention to the influence of the temporal interval between stimuli. On the basis of his observations he specifies three types of apparent movement response which may be made as a function of stimulus interval.

With intervals up to about 30 milliseconds the two stimuli are reported as occurring simultaneously. With intervals near 60 milliseconds subjects report the appearance of "optimal movement." Stimulus succession appears at about 200 milliseconds. "Part movements" of stimuli may be reported at temporal intervals lying between those for optimal movement and for simultaneity; and phi movement appears between optimal movement and succession.

In addition to his observations on the various responses obtainable with variations in the temporal pause, Wertheimer investigated the effects of eye movements and changes in the subject's attitude and compared certain phenomena of real and apparent movement.

Immediately after Wertheimer's work, adherents of the Gestalt school, particularly workers in Koffka's laboratory, instituted a program concerned with the specification of (phenomenal) variables and the laws of movement perception. For example, Kenkel (1913), using Wertheimer's methods, examined figures of the "illusory" type, especially various forms of the Müller-Lyer illusion.

Kenkel reports that on successive presentation of the figures subjects may report three different types of movement, alpha, beta and gamma. The alpha movement is an apparent change in the size of an object under successive presentation. Beta movement is the apparent movement of an object from one position to another, the type of effect indicated by Wertheimer's "optimal movement." Gamma movement is the apparent expansion and contraction of an object as illumination is increased or decreased. (It is possible that gamma movement may

be due, in some cases, at least, to an increase and decrease in diffraction-pattern intensities.)

Finally, another type of apparent movement, delta movement, was obtained by Korte (1915), who found that under certain conditions of intensity of illumination, size of objects, distance between objects, and length of pause, a report of reversed movement can be obtained. The essential requirement is that the later stimulus be brighter than the earlier. Under these circumstances movement is reported to occur in the direction of late stimulus to early stimulus. Problems of latency have to be considered in an adequate theory of this effect.

In his experiments Korte (1915) examined beta movement as well as delta movement and, on the basis of his results, propounded the "laws" that bear his name. These laws do not express precise functional relations, and they are confusing with respect to stimulus specification. At best they are limited descriptions of trends for short ranges of stimuli.

Before considering the laws in detail, it will be well to consider one of Korte's terms that causes confusion. Korte used *i* to refer to a variable that he called *Intensität der Reiz*. This variable sometimes refers to light intensity, e.g. as it is varied by the interposition of one, two, or three sheets of white paper between the stimulus patch and the light source. In other cases *i* refers to stimulus area or shape; e.g. a stimulus of large area or one "strengthened" by "crossbeams" is said to have a higher *i* value than one having a smaller area or lacking the crossbeams. It is obvious that the term *i* is ambiguous. For a precise formulation of his results Korte required two types of laws: one that stated the relation between physically measured light intensity and other variables, and another that stated the relation between stimulus area and other variables.

And now consider the laws. Let us call s the spatial distance between stimuli; i_1 the "intensity" of the earlier stimulus, and i_2 the

"intensity" of the later; t_1 and t_2 , the exposure times of the stimuli; and p the temporal pause between stimuli. Since, for beta movement, $i_1 = i_2$ and $t_1 = t_2$, we may refer to i ($= i_1 = i_2$) and t ($= t_1 = t_2$) without subscripts, and the descriptions may be formulated in the following way:

For a report of optimal beta movement:

I. s increases as i increases; p and t remaining constant.

II. i decreases as p increases; s and t remaining constant.

III. s increases as p increases; i and t remaining constant.

IV. t decreases as p increases; i and s remaining constant.

The first variable given for each rule is to be read as the critical value of s , i , t , etc., required for the report of optimal movement. If the independent variable becomes the dependent, then the rule is restated so that the appropriate critical value of the new dependent variable is treated as a function of the formerly independent variable.

The application of these laws to delta movement is brought about by a fifth rule, in which d stands for the absolute difference between I_2 and I_1 , the respective light intensities of the two stimuli. Since i_1 does not equal i_2 , it is necessary to designate the appropriate i -variable (the intensity of the later stimulus) with a subscript. In Korte's experiments $t_1 = t_2$, and so the t -variable may be written without subscripts.

V. d increases as i_2 increases; p , s , and t remaining constant.

The fifth law refocuses attention on the confusion centering about the use of the term i . The light intensity measures I_2 and I_1 do not always have the dimensions of i_1 and i_2 , which may refer to spatial extent. Again, the need for rules concerning the effect of area is obvious.

Two more laws complete the case for delta movement:

VI. d increases as s increases; p , t , and i_2 remaining constant.

VII. d increases as p increases; s , t , and i_2 remaining constant.

The outstanding study on conditions of apparent movement was performed by Neuhaus (1930). Neuhaus felt it essential to vary stimulus conditions over large ranges of relevant variables, and his apparatus, for the first time, allowed such variation. He investigated a number of problems, many of which had been discussed and worked on by earlier investigators, and on the basis of his experiments drew the following conclusions.

(1) If exposure time t and distance between stimuli s are kept constant, a proper choice of temporal interval p is required for the report of optimal movement. There is, however, a large range of p values within which variation in p has little effect. For certain values of t and s , optimal movement may be reported over a range of 80 to 400 milliseconds. This finding destroys the generality of Wertheimer's figure of 60 milliseconds.

(2) If t is constant and p and s are varied, the spatial separation s for optimal movement increases with an increase in p . This finding is in accord with Korte's third law. Further increases in s may be made by increasing t . (3) If the distance between stimuli, s , is held constant, t increases as p decreases. This finding is in line with Korte's fourth law. In addition, if t_1 represents the exposure time of the first stimulus and t_2 the exposure time of the second, variation in t_2 has little effect. (4) Optimal movement may occur under conditions of temporal overlap of stimuli, but only if t is larger than a certain value. (5) Variation of stimulus intensity over a considerable range results in no need for change in other variables. This finding is in contradiction to Korte's first and second laws. (6) Movement may be reported with differently colored lights and with lights of different intensity.

In addition to examining stimulus conditions, Neuhaus made observations on states of the subject as they influence his reports. Unpracticed subjects, he says, report simul-

taneity or succession for temporal intervals that, for practiced subjects, result in a report of movement. With continued training, subjects give more and more consistent reports of movement.

Effect of instructions is also important. Direct instructions to see movement elicit the appropriate response in subjects who had not previously given it. Thus for Neuhaus, conditions of the subject, such as "attitude" and "set," are important influences in determining responses to movement.

Our discussion of apparent movement suggests that the field may be greatly improved by new analyses and new investigations. Early research was important for breaking new ground, but it has certainly not left us free of confusion. Where then do we stand at present? What are the generally agreed-upon conditions for the perception of apparent movement? What are the points of disagreement?

The following discussion attempts to contrast, by a topical consideration of variables, those facts that are undisputed and those problems that are foci of disagreement. Neff (1936) presented a similar discussion in his valuable review, and the present treatment makes considerable use of Neff's analyses.

1. *Length of pause between stimuli.* There is general agreement that the length of the interval is fundamental in determining apparent movement. It is certain, however, that Wertheimer's figure of 60 milliseconds for the occurrence of optimal movement is not appropriate to all conditions. Korte's laws have been shown by Neuhaus to be inadequate descriptions of the relations between length of pause and other variables.

2. *Duration of stimulus exposure.* Neuhaus presents data to demonstrate that duration of stimulus exposure is important. Certainly it must be for short exposures below a critical duration (Graham and Margaria, 1935). A change in exposure time necessitates a change in other variables for movement to appear optimal.

3. *Distance between stimuli.* Korte and Neuhaus have shown that distance between stimuli, a basic variable, must be increased as the pause between stimuli increases.

4. *Form.* Linke and others have shown that stimulus form enters as a complex determinant of apparent movement. (See Koffka, 1931, for a detailed consideration of such things as tridimensional effects.) Korte's data show that an increase in area or change in shape of the stimulus patches (see the discussion of his *i* variable) requires increase in the distance and a decrease in the pause.

5. *Relative differences in intensity.* Korte reports delta movement when the second stimulus is more intense than the first. This observation awaits confirmation.

6. *Wavelength distributions.* Movement may be obtained with stimuli of different colors. Quantitative analyses are wanting.

7. *Conditions of the subject.* States of the subject determined by past history with respect to a given stimulus (providing stimulus "insistence," "conventionality," "familiarity," etc.) operate to influence apparent movement. Attitude, self-instructions, and instructions presented by the experimenter are of fundamental importance in determining the nature of apparent movement.

In general this topic could benefit greatly from good experimentation and careful analysis. Careful exploration of the relevant variables over wide ranges of values will be required before we shall be in a position to improve the rigor of a field that has suffered from too much generalization and too little experimentation and analysis.

SPAN OF PERCEPTION

In introducing their study of the "span" of visual discrimination, Hunter and Sigler (1940) describe the theoretical interests of earlier workers in the following words.

The psychological literature contains many experimental studies on the span of visual discrimination which have been interpreted

by their authors as studies of the span either of attention or apprehension. These interpretative labels and their accompanying discussions indicate clearly that the problem was viewed as one whose investigation would illuminate such phases of mental life as the following: How many objects can be grasped in a single moment of consciousness? How many levels of clearness are there? What is the difference between attention, cognition, and apprehension? How does the span of attention vary with the instructions given the subject, with the character of the material used, and with the age and training of the subject?

So far as we can discover no investigator has viewed the experiment as one on visually controlled behavior. . . .

Hunter and Sigler do view the problem in these terms, but before we consider their work it will be profitable to give a short account of some of the earlier "span" experiments.

The history of early work on the span of attention is given in a concise manner by Whipple (1924), and Garrett and Schneck (1933) present a valuable short summary of some later investigations.

The span-of-discrimination experiment employs a variety of stimulus objects: figures, letters, nonsense syllables, dots, etc. Various numbers of objects within a given class are presented to the subject for *short* durations (of the order of 200 milliseconds and less) and the number of objects correctly responded to half the time is determined by the method of constant stimuli. Of course, the number correctly responded to may be influenced by various factors: intensity and duration of stimulus, instructional stimuli, class of objects, age of subjects, previous amount of practice, etc.

Whipple summarizes some of these influences. Age, according to Freeman's work, has some effect on the span of discrimination: children 8 to 10 years of age give correct responses to five objects 22 per cent less frequently than adults. Practice has little influence on the threshold for span of discrimi-

nation once an "habituation" period is passed. Little relation exists between span and intelligence score. Different forms and combinations of stimuli give different threshold spans.

When a series of "unrelated" objects is exposed, the threshold is of the order of 4 to 8. When objects may be "grouped" (as letters in words, part figures in larger figures, etc.), the threshold remains at 4 to 8 units of the new class of grouped stimuli. These latter findings demonstrate the great need for an adequate theory of grouping and of relatedness. Why must one specify *words* as the appropriate stimulus units in one situation and *letters* in another? Such description clearly implies a need for an understanding of behavior processes that depend on different classes of discriminative stimuli.

When durations of exposure of the order of several seconds are used, the experiment becomes the span of apprehension experiment. Presumably complex behavior, such as counting, can take place during intervals of the order of 3 seconds and longer, and it seems fairly certain that, whatever form behavior analysis must take in the future, it must reckon with complexities for the long exposures that do not exist for the short.

Durations between about 80 milliseconds and 2000 milliseconds are beyond the range where an increase in duration increases intensity effects in the visual process (Graham and Kemp, 1938). Hence it is not surprising that for durations below about 3 seconds and with many classes of stimulus materials (e.g. nonsense syllables), the span of discrimination is little better for long durations than for short. With other stimulus classes, such as words, the span approximately doubles (Whipple, 1924) for a duration of 3 seconds as contrasted with a duration of about a second. For durations of the order of 10 seconds and more it is clear that the span would be limited only by the amount of counting, verbal repetition, etc., that may be accomplished.

Whipple reports that practice has little effect on the span of apprehension for adults. Dallenbach (1914) found that a 17-week period of daily drills resulted in an increased span for children aged 7 to 10 years, with performance reaching its maximum by the seventh week.

The 1920's were the heyday of systematic theorizing about attention, particularly by workers of the Cornell and Pennsylvania laboratories, who set their findings in a context of structural psychology. Dallenbach (1920) performed an elaborate introspective analysis of levels of clearness. Fernberger (1921) emphasized the need for application of psychological methods to the "span of attention" experiment. He found himself in agreement with Whipple (1924; Fernberger refers to the 1914 edition) and Dallenbach (1914, 1920) that, since more than one degree of clearness was discriminated by subjects within the "focal consciousness," the "range of attention" experiment should rightly be called the "range of apprehension" experiment. Oberly (1924), on the basis of introspective studies, divided the conscious content of the span experiments into three characteristic processes: a first, *immediate* process; a second, *grouping* process; and a third, *counting* process. To these three processes, Oberly gave the names attention, cognition, and apprehension, respectively. Much controversial writing occurred at this time concerning the processes and the question of "clearness" (Cooper, 1928; Wever, 1928; Dallenbach, 1928).

The first study of the span of discrimination from the point of view of behavior was performed by Hunter and Sigler (1940). They determined, by the method of constant stimuli and for binocular vision, the number of dots giving a 50-per-cent correct response for a given intensity and duration of light. The dots were small black figures on an illuminated field. Psychophysical functions were determined, each for a given intensity, with duration employed as a parameter that fixed the position of each curve. The durations

of the exposures varied from 4 to 4000 milliseconds.

Hunter and Sigler's data show that, for a constant duration of exposure, the number of dots correctly responded to 50 per cent of the time increases with intensity (cf. also Schlegel, 1929). Figure 24 shows this result and also demonstrates the influence of dura-

FIG. 24. Curve showing the number of dots correctly discriminated 50 per cent of the time at different intensities. The number attached to each curve gives the duration of exposure. (After Hunter and Sigler, 1940.)

tion. The curve for the 4-millisecond duration is farthest to the right, indicating that a high illumination is required in order to discriminate the dots at this short duration. The curve for the 8-millisecond duration is to the left of the curve for 4 milliseconds; and the curves for successively longer durations, up to 4000 milliseconds, are successively shifted in the direction of lower intensities. Up to a duration of about 75 milliseconds the maximum number of dots correctly discriminated seems to be fairly constant; i.e. the maxima of the curves are similar. However, for durations greater than about 75 milliseconds the maximum becomes

greater and greater with an increase in duration.

Hunter and Sigler continued their analysis by relating their data to the Bunsen-Roscoe law. This law states that a constant photolytic effect is determined by a constant amount of energy of stimulation, which may be spread over a shorter or a longer duration of time. Specifically, $I \cdot t = C$, where I is intensity, t is duration, and C is a constant.

In visual research it is convenient to test for the Bunsen-Roscoe law by plotting $\log I \cdot t$ against $\log t$. A slope of zero on such a graph indicates that the Bunsen-Roscoe law holds; a slope of unity represents the relation $I = \text{Constant}$. In experiments on responses to short flashes of light it has been found that the equation $I \cdot t = C$ gives way to $I = \text{Constant}$ at a critical duration (Hartline, 1934; Graham and Margaria, 1935; Karn, 1936). Hartline has discussed the implications of the critical duration most adequately. He states that where a given constant response, for example a constant initial rate of nerve impulses, is determined by light stimulation, the product of intensity and time may be expected to be constant up to that critical duration at which the sensory event is completed. Any increase in time beyond this critical duration has no influence since the event in question is over. Beyond this critical point, intensity alone is the determining factor.

In Fig. 25 the data of Hunter and Sigler are plotted in terms of $\log I \cdot t$ versus $\log t$. It may be observed that the lowest curve, the curve for discrimination of a single dot, lies lowest on the graph and that, as the constant effect is taken to be 2, 4, 6, etc., dots, the total energy (product of intensity and duration) required for the discrimination increases. All the curves up to the curve for 7 dots seem to give data that fit the Bunsen-Roscoe law for short durations; i.e. the curves have zero slope. Beyond a certain duration the slope of each curve changes gradually to a slope of unity, and the equation becomes $I = \text{Constant}$.

The relations described are not obeyed by the curves for 9, 10, 12, and 14 dots. These curves have initially negative slopes, which become positive only at long exposure times.

On this problem Hunter and Sigler say:

The construction of the graph is such that a negative slope indicates that time is a more important factor in determining span

FIG. 25. Curves showing the total energy ($I \cdot t$) required for the discrimination of various numbers of dots as a function of exposure duration. On this graph a horizontal line would represent the Bunsen-Roscoe law. A line with a slope of unity would represent the relation $I = \text{Constant}$. The curves are derived from those of Fig. 24. (After Hunter and Sigler, 1940.)

than is intensity. Since we are certain that the discrimination of a large number of dots, let us say 12, involves counting and therefore that time is an important factor, we are led to infer that even the span of 8 dots has taken us over the boundary of a single discriminatory event and into the counting area because its curve also has a negative slope. In spans of 8 dots and over we have not left the field of sensory determination of response as indicated by the role of the Bunsen-Roscoe law, but we have obscured that rôle by dealing with more than one event at a time. [P. 177.]

Hunter and Sigler summarize the implications of their work in the following terms:

These results are interpreted to mean that where the span is a single discriminatory event (1-7 dots) as opposed to several such

events, as in the necessary counting of more than 7 dots, the Bunsen-Roscoe law holds up to that duration at which the sensory contribution is complete. Stating this in other words, we may say: the span of a single discriminative event may vary from 1-7 dots depending upon the intensity and duration of the stimulation; and up to the duration at which the sensory contribution is completed, a constant amount of sensory energy is required to produce the event. Beyond that critical duration, intensity is more important than time. The 'span of attention' thus resolves itself into a span of discrimination, a form of behavior which in the field of vision is controlled on the receptor side by time and intensity factors.

In a later analysis of the Hunter-Sigler data Schlosberg (1948) was concerned with the problem of why the number of dots correctly responded to increases with the energy of the stimulus. Schlosberg sets forth the hypothesis that, in a response to a given configuration of dots, the contribution of each dot to the discrimination is an independent event, so that, for example, the probability of seeing 2 dots at a given energy is less than the probability of seeing either alone. Schlosberg attempted to fit the psychophysical functions of Fig. 24 by a theory based on the simple formulation that the probability of seeing N dots is the N th power of the probability of seeing a single dot at the same light value. This simple formulation fits the data for low intensities quite well but does not fit the data for the higher intensities.

For a more precise formulation Schlosberg attempted to compound the probabilities by assuming that the binocular data of the Hunter-Sigler experiment are the end product of events taking place in the two eyes. The Hunter-Sigler data are fitted by the resulting equation for 2 to 3 dots. However, when the curve passes to 5 or 6 dots, the deviation of data from theory is considerable.

Because of the failure of the simple formulations Schlosberg developed two some-

what more complex hypotheses: (1) Any dot will be discriminated if it stimulates either eye. On this assumption the resulting probability expression is mathematically similar to one of the simple formulations. (2) Two or more dots will be discriminated *only* if they all stimulate the same eye. On this assumption lower frequencies of correct response are predicted than by hypothesis 1.

When the curves given by the mathematical treatments of (1) and (2) are applied to the Hunter-Sigler data, it is found that treatment 1 fits the data for 1, 2, or 3 dots, but that treatment (2) fits the data for 4, 5, 6, and 7 dots. (Schlosberg is not interested in applying the theory to more than 7 dots. He says that the "span of apprehension," with new controlling events, enters beyond this number.)

Taken at face value, Schlosberg's treatment may imply that the subject "can interpret two or three dots, even though they stimulate different eyes." However, "five or six dots must *all* stimulate the same eye if they are to be perceived."

Undoubtedly other hypotheses might account for the data as well as or better than those employed by Schlosberg. Nevertheless his analysis is interesting, and its further application may elucidate data in an informative way. Already, in fact, Casperson and Schlosberg (to be published) have found that Schlosberg's simplest formulation fits new data for the *monocular* viewing of dots.

Hunter and Sigler's experiments and Schlosberg's analysis signal new approaches to the old span experiments. The points of view and the methods exemplified in their work may stimulate a new approach to this old problem.

FLUCTUATIONS OF PERCEPTION

If a subject regards a weak light, under instructions to report when the light is visible and when it is not, his behavior shows an alternating character: positive responses

("The light is visible") alternate with negative ("The light is not visible"). Oscillating behavior of this sort, traditionally called "fluctuations of attention," may continue in a more or less rhythmical way for many cycles. Fluctuations of behavior occur not only to weak visual stimuli but to weak stimuli in the other senses. Guilford (1927) gives an excellent summary, not only for the field of vision, but for other senses as well.

Münsterberg (1889) was not the first to work on the problem of fluctuations but he formulated it in terms that led to later work; hence, he is probably the most important of the early investigators. On the side of analysis his work is significant chiefly because of his conclusion that fluctuations to visual stimuli are due to changes in accommodation and fixation.

Münsterberg's theory was soon brought into question by Pace (1893) who treated one eye of a subject with atropine and found just as frequent fluctuations in that eye as in the untreated eye. Slaughter (1901) used an aphakic subject (one without a lens) and found fluctuations of normal period. Ferree (1913) also found normal fluctuations in aphakic subjects.

The experiments of Pace, Slaughter, and Ferree indicate that accommodation changes do not account for the oscillations. Pace introduced the concept of light adaptation as a determinant of fluctuations, and Hammer (1905) and, later, Ferree (1913) added eye movements as complementary influences. Presumably eye movements, in causing stimulation to shift to new portions of the retina, operate to restore sensitivity, which, in turn, is diminished by adaptation.

As against the eye movement theory, Liddell (1919) failed to show any relation between eye movements and fluctuations, a fact that was later verified by Guilford (1927). Troland (1921) suggested that the fluctuations might be connected with changes in pupil size, but the suggestion has not yet received experimental verification. At present we must regard as untenable theories

that emphasize eye movements and changes in accommodation.

Early in the present century considerable interest was shown in the problem of how fluctuations of response relate to the various bodily rhythms. Slaughter (1901), on the basis of some inconclusive data, reported relations among fluctuations of response, breathing rate, and the Traube-Hering waves of blood-pressure change. Bonser (1903) interpreted some of his results as substantiating the Traube-Hering relation, and Griffiths and Gordon (1924) concluded that visibility of a light occurs during the trough and upward slope of the Traube-Hering waves.

Guilford criticized the work of Griffiths and Gordon on the grounds that they did not correlate the response period with the Traube-Hering period. At present it seems that any theory that interprets response fluctuations as correlates of bodily rhythms will have to be decisively bolstered before it can be accepted with confidence.

In the most adequate study of oscillating visual discrimination, Guilford (1927) showed that fluctuations of response are phenomena associated with the visual threshold. First, he demonstrated that the percentage of time a weak light is discriminable varies with the light intensity in a manner comparable to the "frequency of seeing" function obtained by the method of constant stimuli. Second, he showed that the stimulus value that is visible 50 per cent of the time is near the threshold value found in the usual manner when allowances are made for adaptation occurring with long stimulus exposures. Like thresholds themselves, fluctuations of response to weak visual stimulation are a matter of "probability of seeing."

FIGURAL AFTER-EFFECTS

In 1933 Gibson reported the interesting observation that, when we look steadily at a curved line, the line seems to become progressively less curved. In addition, when a straight line is presented immediately after

exposure to the curved line, the straight line seems to be curved in a direction opposite to the original curvature. Quantitative measurement gave an indication of the degree of curvature imposed on a straight line, in order for it to be seen as straight, after pre-

a straight line, moderately tilted from the horizontal or vertical, and then regard a horizontal or vertical line, the position of the objectively horizontal or vertical line is reported to be tilted in a direction opposite to the tilt of the original line. Gibson and

FIG. 26. Inspection configurations used by Köhler and Wallach (1944) to demonstrate displacement effects. Regard the fixation cross of *A* at a distance of about 18 inches for 40 seconds, and then look at the fixation cross of *B*. After *A* has been observed, the right-hand squares of *B* appear nearer the central horizontal axis of this figure than do the left-hand squares. Inspection of the left-hand *I*-figure in *A* causes the left-hand squares of *B* to move apart vertically; and inspection of the right-hand *I*-figures of *A* causes the right-hand squares of *B* to move together. Test figures are displaced away from previous inspection figures.

ceding stimulation by a curved line. (See also Bales and Follansbee, 1935.)

In another series of experiments Gibson examined straight lines that joined at the vertex of an obtuse angle. When, after stimulation by such a bent line, the subjects regard a straight line, they report that the straight line appears bent into lines whose contained angle is opposite in sign to the angle of the original bent figure.

A further effect was observed by Gibson (1937), M. D. Vernon (1934), and Gibson and Radner (1937). When subjects inspect

Gibson and Radner interpreted the tilted-line effect as due to the deviation of inspected objects from vertical and horizontal "norms" (Gibson and Mowrer, 1938).

Köhler and Wallach (1944), on the other hand, have demonstrated that a displacement effect is basic to an understanding of figural after-effects.

Consider the design shown in Fig. 26A. The solid rectangles, marked *I*, are presented to the subject, together with their fixation cross, on a separate card. After a period of regard lasting about 40 seconds,

the inspection objects are withdrawn and the subject is confronted with the test objects shown in *B*. The subject is instructed to report on the heights of the right-hand squares relative to the left-hand squares. The almost universal response under these conditions is that the upper right-hand square is lower than its paired left-hand square, and the lower right-hand square is higher than its paired left-hand square.

On the basis of many related experiments, Köhler and Wallach demonstrated that, in general, subjects report that test objects are seen as displaced in space from the positions of previously viewed inspection objects. In the experiment under consideration, the shift of each right-hand *T*-object toward the center of the field is a displacement away from the associated *I*-object; and the movement of each left-hand *T*-object away from the center of the field is also a displacement away from the associated *I*-object.

It is clear that any adequate theory of the displacement effect requires a description of the manner in which displacement varies as a function of the distance that separates the inspection and the test object. Köhler and Wallach performed such an experiment. Their method is described as follows:

Our *T*-objects were two outline squares which lay at equal distances on the left and on the right side of a fixation mark. On the right side—and in one experiment on both sides—an *I*-figure was first shown which affected the relative height of the two squares. The position of one *T*-square was varied in a random order and the subjects reported in each case which square, if any, appeared higher. From a table of such judgments the most probable equivalence point was inferred.

One experiment done under these conditions gave the results shown in Table 1. (The *I*-figure was a single solid oblong placed at various distances above the right-hand test square.)

It will be observed in the table that when the *T*-square is separated from the *I*-oblong

TABLE 1

DISTANCE THROUGH WHICH THE SUBJECTS MOVED THE LEFT-HAND TEST SQUARE DOWN SO THAT IT APPEARED AT THE SAME HEIGHT AS THE RIGHT-HAND SQUARE. *I*-OBJECT IS A SOLID OBLONG ABOVE THE RIGHT-HAND SQUARE

by $\frac{5}{20}$ inch, the displacement of the *T*-square with respect to the comparison square is greatest. When the *T*-square is separated from the *I*-object by $\frac{2}{20}$ inch, the displacement is less, and, when it is at a distance of $\frac{3}{20}$ inch, the displacement is again small. This means that displacement is a function of the distance separating the *T*-object and the *I*-object. The displacement function passes through a maximum at intermediate distances and has low values at small and great distances.

Observations on the displacement function are important and only in terms of it can many of Köhler and Wallach's results be explained. The reader is referred to their account for a full treatment.

It will be recalled that Gibson (1937) and Gibson and Radner (1937) had explained certain tilted-line effects as due to deviations from vertical and horizontal "norms." (See also Gibson and Mowrer, 1938.) Köhler and Wallach disagree with this interpretation and believe that tilted-line effects can be explained as special cases of the displacement principle without resort to the concept of norms.

Their method was as follows:

An *I*-line was inspected in a given orientation, and then a *T*-line was shown in an-

other orientation, so that a small angle lay between the two lines. Parallel to this *T*-line there were on both sides and at some distance two other lines which served as comparison objects. The position of the *T*-line in the middle was not actually constant. As one inspection period followed another this line was shown in slightly varying positions, and in each case the subject compared its direction with that of the fixed lines. The method of constant stimuli was used throughout.

FIG. 27. The *T*-line used by Köhler and Wallach (1944) in one of their tilted-line experiments. The *I*-object (not shown) is a straight line (with fixation point) which may be presented to the subject on any retinal axis.

Figure 27 represents the test figures shown to the subject. The line marked *T* can be rotated about the point of fixation, and the whole configuration can be presented so that the two outer lines fall on any one of a number of chosen retinal axes. The *I*-object was a straight line (with fixation point) that could be presented to the subject on any retinal axis, the only consideration being that the *I*-line varied 10 degrees (plus or minus) from the orientation of the succeeding *T*-line.

Table 2 gives the averaged data of the experiment; they "indicate by what angle the *T*-line had to deviate from the direction of the standards if the *T*-line was to appear parallel to them; i.e., if compensation for the after-effect was to be obtained horizontally

TABLE 2

NECESSARY ROTATION OF THE *T*-LINE AT VARIOUS ORIENTATIONS OF THE *I*-LINE IN ORDER FOR THE *T*-LINE TO APPEAR PARALLEL TO THE OUTER COMPARISON LINES. ORIENTATION OF THE *I*-LINE AND INITIAL ORIENTATION OF *T*-LINES ARE GIVEN IN TERMS OF ANGLES MEASURED COUNTERCLOCKWISE FROM HORIZONTAL. AVERAGE OF THREE SUBJECTS

Orientations of <i>I</i> - and <i>T</i> - Lines in Degrees		Rotation of <i>T</i> -Line in Degrees
<i>I</i>	<i>T</i>	
10	0	1.22
0	10	1.27
35	45	2.73
100	90	1.34
85	95	1.46
90	100	1.46

the *T*-line had to be turned toward the direction of the *I*-line" by the amounts given in the table. In other words, the presence of the *I*-line caused the later *T*-line to appear out of parallel with the standard lines, and the subjects then had to rotate the *T*-line by the amounts indicated.

Köhler and Wallach interpret the results of Table 2 to mean that Gibson and Radner's account of visual after-effects in terms of deviations from horizontal or vertical norms is invalid. Angular displacements comparable to those of Table 2 may presumably occur for any visual axis; in fact, they are greatest in Table 2 for the 45-degree axis. Thus there is no need to consider norms; the tilted-line effect is a special case of displacement.

Hammer (1949) studied some temporal aspects of frontal plane after-effects: (1) their development during the inspection period and (2) their disappearance after the inspection period. Specifically she examined the way in which figural displacements vary as functions of (1) the time interval between inspection and test periods and (2) the duration of inspection period.

Her procedure consisted in having her subjects, during the test period, make a vertical alignment of a short upper black com-

parison line with a lower black test line. Prior to each alignment (i.e. during the inspection period) an inspection line had been presented to the left or right of the position of the subsequently presented lower test line. The measure of the after-effect produced was the deviation of a setting of the upper line from a zero point (i.e. a point of "subjective" equality based on alignment set-

inspection period, increase with increase in the duration of the inspection period to a maximum at approximately 1 minute. With further increase in inspection time, displacements remain relatively constant.

Köhler and Wallach present an exhaustive theoretical account of figural after-effects, an account that seems to follow from Köhler's earlier "brain field" theory (Köhler, 1920). (See also Ségal, 1939.) To what extent the theory may be important in producing a rational account of figural after-effects must remain a question until many more experiments are directed at estimating magnitudes of essential variables. For some important criticisms of the theory, see Smith (1948).

In a later research Köhler and Emery (1947) investigated figural after-effects in the third dimension. They demonstrated that tilted-line effects occur in the third dimension as well as in the frontal plane.

FIG. 28. The disappearance of figural after-effects as a function of time after inspection. Positive angular displacements are to the subject's right of the zero point; negative, to the left. Curves have been fitted by inspection. (From Hammer, 1949.)

tings made in the absence of prior stimulation by the inspection lines).

Hammer's experiment shows that, as regards the time course of disappearance of figural after-effects, such effects are at a maximum immediately after the inspection period and decrease rapidly with increase of time after inspection, reaching zero at approximately 90 seconds, and remaining constant with further increases in time after inspection. The experimental data are presented in Fig. 28. Displacements from zero are a function of the position of the *I*-figure with respect to the *T*-figure. When the *I*-figure is to the right of the *T*-figure (solid circles), the displacement is to the left; when the *I*-figure is to the left of the *T*-figure, the displacement is to the right (open circles).

The time course of development of figural after-effects is presented in Fig. 29. Figural after-effects, tested immediately after the

FIG. 29. Angular displacement as a function of inspection time. Signs of displacement and symbols have the same significance as in Fig. 28. (From Hammer, 1949.)

One of their experiments consisted in presenting an inspection line tilted at 20 degrees to the frontal plane. When a later test line was shown in the frontal plane, subjects reported that they saw it tilted in a direction opposite to the tilt of the original inspection line. Several other experiments have demonstrated that tilted-line effects occur even more strikingly in the third dimension than in the frontal plane.

Displacements also occur for objects in the third dimension, a fact that may be demonstrated in the following manner. A subject is instructed to inspect a white square placed in front of the homogeneous background provided by a large black screen. After removal of the inspection object a similarly sized test object (white screen) is placed in front of the location of the now absent inspection object, and the subject is instructed to compare its distance with the distance of another white screen, placed to the left of the test object but physically at the same distance from the eye. Under these conditions subjects report that the test object appears nearer than the left-hand "neutral" comparison object.

If the test object is placed farther away than the inspection object, the subject reports that it seems at a greater distance than a neutral object physically at the same distance. Köhler and Emery combine both demonstrations; and the subject sees a test object nearer than the previous inspection object as closer to him than its associated neutral object, whereas a test object farther away than the previous inspection object appears to be at a greater distance than its neutral object.

Thus the same rule holds for the third dimension as for the frontal plane: subjects report that a test object appears displaced from a previous inspection object. Quantitative experiments show that the displacement is at a maximum for a medium distance in space and becomes less for great and small distances.

Another series of experiments was concerned with displacements as related to conditions of fixation. In one of the experiments a subject regarded, during the inspection period, a fixation point in the same frontal plane as the inspection object. After the inspection period the inspection object served as test object, and a neutral comparison object, at the same distance as the test object (previously the inspection object) was inserted in the field. The subject had

been instructed to change fixation, after the inspection period, to a mark either in front of or behind the fixation point of the inspection figure and to report on the position of the test figure with reference to the neutral figure.

Under these circumstances it was found that, when fixation is changed, after the inspection period, to a point nearer the subject, the subject reports that the test object is seen as farther away than the "neutral" object. If fixation changes to a point farther away than the fixation point of the inspection period, the test object appears nearer than the neutral object. In other words the direction of apparent spatial displacement of a given test object depends on the relation between fixation distances in the inspection and test periods, and the subject's report is made with reference to the geometry of the horopter.

Köhler and Emery do not relate their results immediately to a theory of space perception. They describe some interesting experiments on "stereoscopic distortions" and conclude that contours are important determiners of space perceptions. It is probable that some of these latter phenomena have much in common with problems investigated by workers on aniseikonia.

PERCEPTION AND CONDITIONS OF THE ORGANISM

It has been known for a long time that discriminations are influenced by the condition of the organism at the time the discriminations are made. The multitude of experiments on attention, apperception, Einstellung, and preparatory set attest the universal appreciation of this fact. On the side of psychological theory, many writers, e.g. Woodworth (1945) and Dashiell (1937), reserve an important central position for factors of this sort in their systematic presentations. In a similar vein, in our earlier dis-

cussion of size and shape, we pointed out that a subject's responses are determined not only by the stimuli present at a given moment but also by the nature of the subject's history of past stimulation. The present chapter is not the place to consider a de-

of language, or, as they say, by "those processes of the organism that are initiated by language." A set of twelve relatively ambiguous figures was prepared, seven of which are shown in Fig. 30. Two names were assigned to each of the figures. The same

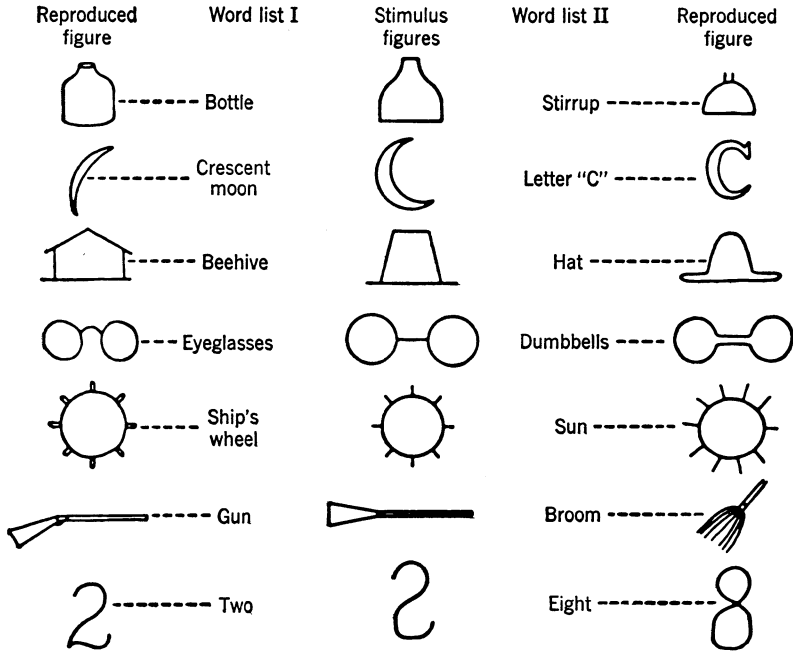

FIG. 30. Figures used by Carmichael, Hogan, and Walter (1932) in their experiment on the influence of speech upon perception. The stimulus figures appearing in the middle column were presented to one group of subjects with the associated words of word list I and to another group with the associated words of word list II. The reproduced figures given by the two groups are shown in the two outer columns. Differences in the drawings for each stimulus figure may be attributed to differences in conditions set up within the subjects by the different words announced. (From Dashiell, 1937.)

tailed treatment of this topic, but it does seem necessary to indicate its relation to perception in more than a passing way.

Experimental facts, as they exist, do little more than set the problem. It has often been shown that different conditions of the organism, aroused in many different ways, lead to different responses to similar stimuli. Experiments on reproduced forms are of interest here (cf. e.g. Wulf, 1921; Gibson, 1929).

Carmichael, Hogan, and Walter (1932) attempted to control reproduction by means

visual figures were presented to all subjects, but one list of names (word list I) was given when the figures were presented to the 48 subjects of group I, and the other list of names (word list II) was given when the figures were presented to the 38 subjects of group II. Each subject was instructed that he must draw the figures as accurately as possible after the series was over. Just before each figure was presented, the experimenter said, "The next figure resembles . . ." (giving one of the two names of the figure).

The figures as reproduced were judged, without consultation, by two of the authors, and the drawings were rated upon a 5-point scale. Drawings rated 5 "included figures which were almost completely changed from the original." All the analyses of the report were performed on drawings of this grade.

Based on the ratings of the two judges, 74 per cent of the figures that had been named by word list I were found to be similar to "what may be termed the visual representation of the figure named in List I." Seventy-three per cent of the figures named by word list II "were like the visual representations of the figure named in List II."

In summarizing their experiment, Carmichael, Hogan, and Walter make the following statement:

It seems that if a subject has just heard, for example, the word "eyeglass," certain processes in his organism have been started that initiate certain processes which are possible because of the past experience of that individual with *eyeglasses* as words and as objects. If, while these processes are in progress, a figure of two visual circles connected by a line is presented to the subject, this figure may later be reproduced in a manner (different from what would be the case) if the processes present in the individual at the time of the same visual presentation had been evoked by the word "dumb-bell." In other words, without recourse to any elaborate theory, one who wishes to make an empirical statement of fact may say: If a verbal stimulus-form and a visual stimulus-form are presented to a subject in certain temporal relationships, the processes in question may be modified, or rather a new total process may result, which is in certain respects unlike either of the previous sets of processes. On subsequent arousal by any "part" stimulus the "reproduction" is thus a complexly determined total, and not either of its component processes.

Specification of such a "complexly determined total" and conditions of which it is representative is, of course, fundamental to a science of psychology.

Sherif (1935, 1936) performed a widely known experiment on the influence of social factors in perception. Subjects were brought into a dark room and instructed to regard a small stationary spot of light. Under such circumstances an effect called the autokinetic phenomenon occurs; i.e. the subject reports that the stationary spot seems to move erratically in all directions.

Sherif studied the reported extent of the autokinetic effect with subjects tested singly and in groups. Among single subjects, as might be expected, the estimates of movement showed wide variation from subject to subject. But, when the individual subjects were grouped in two's and three's, the data for each individual tended to approach the average of the group. In other words, "social factors," deriving from the fact of grouping, influenced individual subjects to make estimates in line with those of their fellows.

Sherif (1936) relates these findings to a concept of social norms.

The experiments, then, constitute a study of the formation of a norm in a simple laboratory situation. They show in a simple way the basic psychological process involved in the establishment of social norms. They are an extension into the social field of a general psychological phenomenon that we found in perception and in many other psychological fields; namely, that our experience is organized around or modified by frames of reference participating as factors in any given stimulus situation. [See also an experiment by Schonbar, 1945.]

A number of experiments have tested the influences of reward and punishment upon discrimination. Proshansky and Murphy (1942) rewarded subjects for estimating the weights of objects or lengths of line with a given bias, the subjects showing significant response shifts in the rewarded direction. Reward may also influence responses to "figure" and "ground" relations (Schafer and Murphy, 1943). Frequency and extent of movement of the autokinetic phenomenon in

a given reported direction is increased by "reinforcement," by "active participation" by the subject, and by instructions that the light would move (Haggard and Rose, 1944). Ellson's experiments (1941*a, b*) on "sensory conditioning," in which subjects were conditioned to "hear" a tone on the presentation of a light, are also of considerable interest.

The experiments of Bruner and Goodman (1947) show the influence on discrimination of conditions presumably set up by "economic deprivation." Groups of "rich" and "poor" children were instructed to set the area of a variable circular aperture equal to the area of a simultaneously presented penny, nickel, dime, quarter, or half-dollar. The subjects also made matches against cardboard disks equal in size to the various coins.

In the matches made against the cardboard disks the subjects showed only slight error in the adjustment of the diaphragm aperture; but with the coins the error increased with coin denomination to a maximum for the twenty-five-cent piece. The error was in the direction of overestimating coin size and rose to 35 per cent for the quarters.

When the data were broken down (Fig. 31) into scores for the "rich" and "poor" groups, it was found that the "poor" children overestimated in much higher degree than did the "rich" children. (The children were described as 10-year-olds of "normal intelligence." One would like data on the intelligence scores of the two groups.)

Bruner and Goodman interpret their results as affirming the hypothesis that perceptual behavior deviates from "physiologically determined behavior" as a function of subjective need for socially valued objects. Thus the greater overestimation of the "poor" children is a manifestation of habits relating to money, conditioned by "economic" factors in the lifetime of the subject. In an experiment with similar orientation, Ansbacher (1937) found that, in matching a variable number of stamps or coins with respect to a standard number, the number

required to make a match depends upon the values of the stamps and coins.

The problem with which we have been concerned in the present section is the following: How are discriminations influenced by different conditions of the organism? The correlated question of how the conditions may be specified is probably a more

FIG. 31. Size adjustments made by "rich" and by "poor" 10-year-old subjects for various coin denominations. Note that the poor children overestimated coin size more than did the well-to-do. (From Bruner and Goodman, 1947.)

important one; it is certainly more important as soon as we progress beyond the stage of demonstrating that various conditions cause different discriminations. Without operational or theoretical specification of "conditions" it is unlikely that we can give a satisfying answer to the first question. Although it may be true that specification of the organism's state as love, pain, attentive set, need, anxiety, joy, etc., may, at the conversational level, establish the existence of a problem, we hope to develop behavioral theory to the point where these unknown conditions may be described in such form that their quantitative influences on behavior are predictable. One of our first duties is probably to see that definitions of the vari-

ous "conditions" are anchored to definable antecedents and consequents.*

CONCLUDING REMARKS

The present account has considered the problem of specification of variables in considerable detail but has said little about theory. This emphasis is justifiable at the present time, for it is probably true enough that significant theory cannot exist in the absence of proper specification. Nevertheless the search for adequate theory must remain an overshadowing endeavor of the scientist; and, as regards the field of perceptual discrimination, the need for useful theory is great. This is not to say that the field has lacked theorists in the past. It has had plenty of theorists but little adequate theory. Exceptions to this statement, of course, come to mind, notably the brilliant but limited systematization available in the geometrical theory of space perception.

Close examination of the many theories advanced reveals that they do not usually specify test operations and that, very often, the number of facts explained is no greater than the number of assumptions made. Theories exhibiting these deficiencies may be of interest for other reasons, but they are not a satisfactory stopping place in a scientific program.

It would probably be unprofitable to attempt an a priori judgment on the nature of theories that might advance the field of visual perception. In general terms, however, it would seem that an ultimately adequate theory must make specific the general relations implied in the equation

$$R = f(a, b, c, d \cdots n \cdots t \cdots x, y, z) \quad (29)$$

The first letters of the alphabet (*a, b, c*, etc.) refer to properly specified aspects of stimuli; the last letters ($\cdots x, y, z$), to properly

* A number of articles dealing with the topic of perception as influenced by conditions of the subject has appeared since this account was written. Pastore (*J. Psychol.*, 1949, 28, 457-475) presents a critical review of some of the later work.

specified conditions of the organism; *R*, to response; *n*, to number of presentations; and *t*, to time.

In a program of research that might eventually explicate these relations, it can be foreseen that theories of vision (Hecht, 1937; Granit, 1947), which tell something of initiating events and limiting conditions, will be desirable; and behavior theories (Hull, 1943; Skinner, 1938), which can describe conditions of the organism, will clearly be advantageous.

Psychologists have sometimes reacted against theories couched in terms of physiological mechanisms. There can be little doubt that a theory that uses a physiological vocabulary adds nothing to a theory using a psychological vocabulary if the former theory specifies no test beyond what may be specified by the latter.

On the other hand, there is no reason why well-established phenomena, describable by a physiological vocabulary and demonstrating functional dependencies of the sort required by a necessary inferred variable, may not be used for a quantitative account when due attention is paid to transformation relations; in fact, the joining of vocabularies may result in an increased number of testable statements. (The need for attention to transformation relations is not unique to a transition from a physiological to a psychological vocabulary. The same consideration applies to generalization of results obtained in a particular behavior situation to principles presumably applicable to a class of situations.) On the practical side, the existence of ready-made physiological models may lead, in the hands of some workers, to a more rapid adoption of appropriate inferred variables. Generalization beyond this point is probably unwarranted; the essential point is that variables related in the context of a given vocabulary need not be excluded from the systematic considerations of another vocabulary.

Finally a statement may be made concerning the general field of perception. The study

of perception has, since its beginnings, come a long way. It still has a long way to go. Improved experimentation, performed with attention to problems of specification and designed to provide a broad base for theory, will hasten the day when psychology will be provided with an inclusive system of relations to define and explain the phenomena of this important field.

The Psychophysiology of Vision

S. HOWARD BARTLEY

Michigan State College

The psychophysiology of vision may be thought of as the study of the mechanisms whereby the discriminative reactions of vision are brought about. Obviously, since these mechanisms are means to ends, both structure and function are involved, and we are faced with anatomical as well as with physiological problems.

Vision involves at least five major kinds of mechanisms: (1) optical, (2) anatomical, (3) photochemical, (4) neurophysiological, and (5) oculomotor. This division of the subject of vision into topics on the basis of mechanisms is different from a classification on the basis of primary functions, such as adaptation, brightness discrimination, visual acuity, etc. These functions will be discussed in several places in this chapter, i.e. at as many places as there are different mechanisms crucially involved.

OPTICAL MECHANISMS

Optical mechanisms fall into three subgroups those having to do with image formation, those that pertain to the relations between the object, the image, and the sensory end result, and those that produce stray light within the eye.

Image formation has to do with clearness of vision, with visual acuity, with the size of the retinal area stimulated, and (when the two eyes are considered in relation to each other) with the apparent localization of objects. Not so long ago small differences in the sizes of the retinal images of the two

eyes had no more than academic interest. But, since it has been shown that these small differences have a marked effect on spatial localization, retinal image size has become a matter of importance.

The human eye may evidence refractive error (become ametropic) in at least two, if not three, ways: (1) by a change in the axial length of the eyeball, (2) by a change in the power of the dioptric system through alterations in the curvature of the cornea or lens surfaces, through shifts in the separation between cornea and lens, or through changes in the indices of refraction of the several ocular media, and (3) through some change in the innervation that alters the power of the lens. The first type of defect, or ametropia, is called *axial*; the second, *refractive*; and the third, *accommodative* or *functional*. Although the first two are taken for granted by most investigators, the third is still controversial.

The retinal image size in the corrected axially ametropic eye remains unchanged by the application of spectacles and is the same as though the eye were normal. In the refractive ametropic eye the image after "correction" is different from that of the normal or emmetropic eye, so that if the experimenter wishes to deal with precise values he must take steps to determine the effect of the corrections used.

Image Formation

A point source of light used as an "object" is not focused on the retina as a point.

TABLE 1

RETINAL LIGHT DISTRIBUTION FOR A POINT AND A LINE (FROM HARTRIDGE, 1947)

Distance from Center of Image in Microns	Distance in Cone Units	Relative Intensity		Color	
		(a) Point	(b) Line	(a) Point	(b) Line
0	0	∞	∞	Yellow	Yellow
1.8	0.5	34.0	40.0	Yellow	Yellowish white
3.6	1.1	13.0	15.0	Yellow	Cream
5.4	1.6	5.3	8.0	Yellow	Cream
7.2	2.1	2.3	4.5	Yellow	Cream
8.9	2.7	1.0	2.0	Yellowish white	White
10.7	3.2	0.4	0.8	Greenish white	White
12.5	3.7	0.2	0.5	Greenish white	White
14.3	4.3	0.1	0.2	Greenish white	Greenish white
16.1	4.8	0.1	Bluish white	Bluish white
18.0	5.4	Purple	Purple
19.5	5.8	Purple	Purple
21.5	6.4	Blue	Blue
25.0	7.5	Blue	Blue

TABLE 2

EDGE OF A BRIGHT AREA ON A DARK SURROUND (FROM HARTRIDGE, 1947)

	Distance from Edge of Image in Microns	Distance in Cone Units	Relative Intensity	Color
Outside edge (blue)	10	3.0	Black
	9	2.7	0.2	Deep violet
	8	2.4	0.4	Deep violet
	7	2.1	1.1	Dark blue
	6	1.8	2.3	Dark blue
	5	1.5	3.9	Dark blue
	4	1.2	6.2	Blue
	3	0.9	9.6	Blue
	2	0.6	13.9	Blue
	1	0.3	28.0	White
Edge	0	0.0	50.0	Yellow
Inside edge (yellow)	1	0.3	72.0	Yellow
	2	0.6	86.1	Yellow
	3	0.9	90.4	Yellow
	4	1.2	93.8	Pale yellow
	5	1.5	96.1	Pale yellow
	6	1.8	97.7	Pale yellow
	7	2.1	98.9	Cream
	8	2.4	99.6	Cream
	9	2.7	99.8	Cream
White	10	3.0	100.0	White

Although it is true that actual point sources are never points in the mathematical sense, they may be very restricted in area. Ideally such a point source would focus in a restricted and sharply defined area on the retina. Table 1 (from Hartridge, 1947) gives the retinal effect of a point source and a 4-millimeter pupil. The first column indicates various distances from the center of the retinal image in microns. The same information is given in the second column, but in cone units. The cone unit is approximately 3 microns. In the third and fourth columns are the relative intensities of the image at the various indicated distances from the center of the image for a point (*a*) and for a line (*b*). The fifth and sixth columns indicate the color of the light at various distances from the image center for a point (*a*) and for a line (*b*).

Table 1 shows that there are differences between the image of a point source and the image of a line source: (1) the intensity of the line does not decline so rapidly as a function of distance on the retina, and (2) more white light is present in the central parts of the line image, owing to overlap between the yellow and the blue disks.

The image of an extended test object or source differs from that of a narrow line and a point source in that it is composed largely of white light. Color fringes are found only near its edges. The dimensions of such fringes are given in Table 2 for a 4-millimeter pupil.

The characteristics of the image of a black dot on a bright surround is the negative of a bright point source on a dark ground (Table 3). The image of a bright point source on a black ground is an intense yellow center surrounded by a dark blue-violet annulus. The image of a black point source on a bright ground is a blue center surrounded by a pale pinkish yellow annulus. Images of black lines of various widths also manifest the expected differences from white lines.

TABLE 3

THE RETINAL LIGHT DISTRIBUTION OF A BLACK POINT ON A LIGHTED GROUND (FROM HART-
RIDGE, 1947)

Distance from Image Center in Microns	Distance in Cone Units	Relative Intensity	Color
0	0	0	Blue
1.8	0.5	66.0	Blue
3.6	1.1	87.0	Pale blue
5.4	1.6	94.7	Pale blue
7.2	2.1	97.7	Bluish white
8.9	2.7	99.0	Bluish white

Relation to illumination. In strong illumination many individuals adjust monocular optical instruments to a negative focus. Instruments whose focus can be adjusted are usually calibrated in both directions from a zero point. The zero point indicates the adjustment that ought to function for an accommodation for infinity or supposedly for an emmetropic (normal) eye. A negative adjustment indicates that the individual using the instrument is acting as though he needed lenses of negative power (concave) in order to see. It appears that, whether or not the individual is visually abnormal, he tends to accommodate in order to achieve maximum visual acuity. Accordingly, he compensates for his accommodation by adjusting the instrument. Within the 4- or 5-diopter range of the usual instrument, the average setting is 1 to 2 diopters more negative than the refractive corrections of the observers themselves. In view of this fact, fixed focus instruments often incorporate corrections of -0.5 to -1.5 diopters.

With binocular instruments the tendency to focus negatively is usually absent. In both binocular and monocular settings, however, there is a tendency to set instruments negatively under *low* illumination.

Wald states that a change of about -0.4 diopter is justifiable on the basis of the chromatic aberration of the eye and the Purkinje shift. Furthermore the deviation from optimal setting can be this large without producing a marked functional detriment.

subtend the same visual angle at the eye as some other object differently oriented with relation to the eye. Figure 1, for example indicates that there is an infinite number of surfaces, differently oriented with reference to the line of regard, that may produce a

FIG. 1. A diagram to show that a number of objects may subtend the same visual angle at *A* as does square 1 and therefore may be perceived as a square when collateral cues are absent. (Bartley and Chute, 1947.)

Object, image, and sensory end result. Even when the optical properties of the eye as an image-forming system are known, the relations between the geometry of the object, the image on the retina, and the sensory end result are not directly deducible. Although the relations between the three are lawful, they are not always discoverable without experiment.

First of all, there is some degree of ambiguity or "freedom" between the shapes of objects and the shapes of the retinal images cast on the eye. An object of one shape may

retinal image of the same shape. This and related problems are discussed in Chapter 23.

Entoptic Stray Light

Another optical fact about the eye is that stray light reaches the retina (Bartley, 1941). Were the amount of this light trivial relative to that falling on the retinal image, mention of it would be of little interest. It happens, however, that the slight stimulation of the myriads of receptors in the retina outside the image may sum up to a greater recordable electric effect than the receptor activity

in the image itself, except when the image is very large. Seldom is retinal stimulation confined to a small area. Either the image covers a part of the retina and is accompanied by stray light over the whole retina, or else the image is large and covers the retina, in which case the whole retina receives both focused and unfocused light.

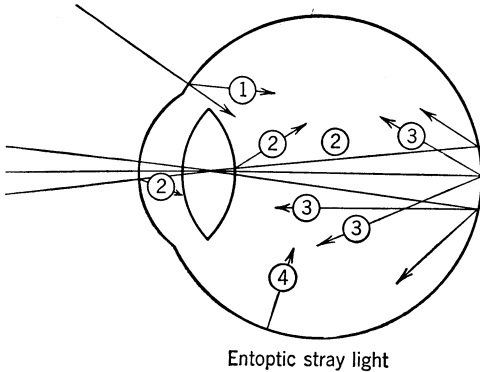

FIG. 2. Diagram of eye to indicate the sources of stray light within. The stray light that falls on any specific part of the retina comes initially either through the pupillary aperture or through the coats of the eyewall. However, it is helpful to classify the sources into four: (1) the passage of diffuse light through the eyewall; (2) diffraction and scattering in the media, particularly the boundaries between the cornea and the humor, and the lens and the humor; (3) reflection from the retinal image; and (4) reflection from one portion of the retina to another.

The sources of internal (entoptic) stray light are indicated in Fig. 2.

The existence of a considerable amount of stray light on the retina may be observed in an excised eye of an albino rabbit. When the image of a disk of intense light (the surrounding field being dark) is thrown upon the retina, not only is the disklike image seen through the coats of the eye, but the whole eye becomes an internally illuminated globe. One set of measurements on the rabbit's eye indicated that with an artificial pupil 5 millimeters in diameter a test object whose brightness was 342 candles per square foot formed an image whose brightness,

through the coats of the eye, was 9.5 candles per square foot. The average brightness of the area not covered by the image was 0.266 candles per square foot or close to $\frac{1}{36}$ the value of the image.

When the pupil of the eye was masked by an opaque disk, the light falling on the eyeball from a 7-degree test object whose brightness was 1500 candles per square foot provided a noticeable illumination of the retina. This shows how much the eye may be illuminated by light passing through its relatively opaque walls.

Several other means have been used to demonstrate or to measure entoptic stray light. The *first* of these is the measurement of the effect upon the differential threshold at the fovea, induced by a light whose image falls on the periphery of the retina. The *second* is the measurement of the critical flicker frequency of the visual field surrounding the intermittently illuminated test object. When the flicker of the field to one side of the test object is measured, the critical flicker frequency (cff) * is found to be lower than that of the test object. Checks to determine whether this critical flicker frequency is caused by neural spread from the test object or by stray light shows that it is attributable to stray light.

The *third* method is electrophysiological. The electric effect of the light in the image is compared with that of light falling outside it. In one experiment equivalent electroretinograms were produced by two different stimuli, (1) a small but intense spot of intermittent light, and (2) a homogeneous whole-field illumination applied intermittently. The size and intensity of the spot was set to provide stray-light illumination of the retina equal to the whole-field illumination. The two conditions, in yielding the same-sized electroretinograms, indicated that

* Critical flicker frequency (cff) is the lowest rate of stimulus intermittency required to produce a sensation of uniform illumination.

the retinal field outside the image produced virtually the whole response, even in the presence of an intense image.

The *fourth* method also utilizes the electroretinogram as an indicator. In this experi-

single disk, the major factor producing the electroretinogram is fluctuation in stray light. When the stray light is constant, the conditions for producing a series of waves in the electroretinogram are absent.

FIG. 3. The structure of the primate retina. The numbers and letters at the left indicate various layers and zones. The other letters indicate elements as follows: *c*, horizontal cell; *a*, mop bipolar; *e*, brush bipolar; *f*, flat bipolar; *h*, midget bipolar; *i*, centrifugal bipolar (amacrine cell); *l*, internal association cell (amacrine cell); *m*, *o*, and *p*, diffuse ganglion cells; *n*, short ganglion cell; *s*, midget ganglion cell; *u*, "radial fibers" of Müller. (Polyak, 1941.)

ment disks of light in different positions alternate with each other. As one disappears, the other appears, thereby providing a constant level of stray light in the retina. Under conditions of slow alternation—in which one would expect a series of responses if the images were the effective cause—no responses occur. This indicates that, with a

Stray light measured in the human eye by the first of these four methods has indicated that a peripheral light, 5 degrees from the test object, produces 0.00408 troland of retinal stray light per candle per square foot of brightness per millisteradian (unit of solid visual angle) per square millimeter of pupillary aperture.

ANATOMICAL MECHANISMS

The vertebrate eye handles light by means of a focusing mechanism, which forms an image of an external pattern upon the sensitive carpet called the retina. The compound eyes of certain subvertebrate forms use mainly unfocused light. The compound eye is composed of a number of tubelike cells (ommatidia) closely packed together and arranged so as to present their distal ends in the form of a spherical grid. The light that penetrates to the proximal or sensitive ends of the tubes reaches there primarily by virtue of its being in line with the axis of the

tube. Hence a light source moving across the animal's visual field strikes some of these elements earlier than others.

The photoreceptors of the compound eye are functionally separate. The fiber processes leading from them form a bundle that does not reach a synapsing center until it arrives at the animal's nerve axis, some distance from the eye. Electrodes can therefore be placed on the fiber bundle, and pre-synaptic effects can be recorded. Furthermore separate fibers can, in some cases, be teased out so that the activity of single receptors can be studied.

FIG. 4. The grouping of the primate retinal cells into functional systems. (For the identification of elements, see Fig. 3.) A, rod system; B, rod system with a single intermediate link (mop bipolar); C, rod system with only the brush or flat bipolar as the next link; D, cone system; E, pure cone system with midget bipolar as intermediate link; F, cone with mop bipolar as intermediate link; G, cone system with either the brush or flat bipolar cell as intermediate link; H, common rod-and-cone system. (Polyak, 1941.)

Some vertebrates possess one kind of photoreceptor (cones), some another (rods), and still others possess both kinds. Some animal forms have two kinds of cones. Because of their peculiarities and differences these sev-

ately connected and compact tissue system (see Figs 3 and 4).

According to Polyak (1941), the *rod system* consists of three links: (1) the rods, (2) mop bipolars, and some brush bipolars

FIG. 5. A schema of the essential elements of the primate retina with their connections. The schema indicates the direction of propagation of impulses from the receptors to other elements in the retina, to the brain, and back to the retina. For identifications, see Fig. 3. (Polyak, 1941.)

eral animal forms provide a means for the analysis of receptor function not otherwise available.

In the human retina there are two kinds of receptors (rods and cones). The rods and cones differ in their functions and in their interconnections with each other, with the other elements of the neuroretina, and with the brain centers. Notwithstanding their difference in function, they form an intim-

and flat bipolars, and (3) all varieties of ganglion cells. The rod system does not involve the midget bipolars, the association cells, or the amacrine cells.

The *cones* may synapse with all types of centripetal bipolars, which may in turn synapse with all types of ganglion cells. Just as in the rod system, the cone receptors are not completely separate from one another, owing to the overlapping of the bipolar and gan-

glion cells. Only in the fovea where the "pure" cone system exists are there no diffuse ganglion cells. There the mop bipolars are also absent, and the cone impulse is conducted to a midjet bipolar, then to a midjet ganglion cell, without lateral or transverse overlapping (convergence and divergence). This is the old "private line" system of the cones according to the classical description.

retinal system, consisting of the horizontal cells, the centrifugal bipolars, and presumably the amacrine cells.

Figure 5 indicates the direction of the propagation of impulses through the retina, according to Polyak. Discharges from receptors *a* and *b* reach the horizontal cells and are carried to the surrounding receptors. The discharges from the receptors reach also

FIG. 6. Diagram to show the number of receptors (cones and rods) at various distances from the fovea. The number of cones drops rapidly with increasing distance from the fovea, and the rod density rises. (Østerberg, 1935.)

There is also the *mixed rod-and-cone* type of system. It involves as the first link both rods and cones, as the second link all kinds of bipolars, and as the third all types of ganglion cells. In such a system each diffuse bipolar is associated with a densely packed group of receptors. These groups, of course, fuse with one another, owing to the overlapping of the dendrites of the various bipolar and ganglion cells. Even the midjet bipolars, which form a part of the pure cone conduction at the fovea, are constituents in this mixed system. The mixed system is active at levels of illumination where rods and cones are both activated.

In addition to the "line" conduction from receptor to brain, there is a definite intra-

the bipolars (*d, e, f, h*) which act as analyzers. Thence the impulses pass to all types of ganglion cells which in turn discharge into their axons, the optic nerve fibers. Impulses from the bipolar and ganglion cells also reach the centrifugal bipolar cell (*i*) which sends impulses to the receptors. This cell connects with afferent fibers in the optic nerve and acts as the main link in the conduction path carrying impulses from the brain to the receptors. The amacrine cells (*l*) presumably receive impulses from the bipolars and "diverge" them among ganglion cells (*m, n, o, p, s*).

The distribution of the rods and cones across the human retina is obviously a matter of functional importance. Figure 6 indi-

ates their distribution across the horizontal meridian of the human retina, according to Østerberg.

The Stiles-Crawford Effect

Stiles and Crawford (1933) showed that rays passing through the edge of the pupil

be laid to the retina itself. Figure 7 indicates the loss in effectiveness as we pass from the center nasalward, and templeward. It was found that the effect appears only in the light-adapted eye. It is definitely related to cone vision, for it is found at all levels of adaptation when measurements are re-

FIG. 7. The Stiles-Crawford effect. Light falling on different parts of the pupil is not equally effective in producing a sensory end result, even though the light reaches the same point on the retina. The data are those for B. H. Crawford's eye. (Stiles and Crawford, 1933.)

stimulate the retina less than those passing through the center of the pupil. To a very small extent this reduction in the effect of peripheral rays may arise from losses at the margins of the refracting media. Rays entering the edge of the pupil and those passing through its center do not encounter equivalent conditions along their paths to a given point on the retina. The greater part of the Stiles-Crawford effect, however, must

be restricted to the fovea. The effect is also found in any part of the retina when the illumination is deep red. Thus it is apparent that, in order to obtain the effect, the response must be predominantly that of the cones.

Of the exact origin of the Stiles-Crawford effect, we are not sure. Several authorities ascribe it either to the shape of the cones or to the direction in which they point. O'Brien

says that the total internal reflection within the conical part of the cones may be responsible for a concentration of the light in the outer segments. If the cone pigment is concentrated largely in the outer segments, and if the refractive index of the cones is higher than that of their surrounds, the Stiles-Crawford effect would necessarily follow. The fact that the Stiles-Crawford effect does not occur in pure rod vision is then to be ascribed to differences between cones and rods in shape, in refractive index, and in distribution of the photoreceptive pigments. The diameters of the rods are almost constant throughout their lengths, and this alone might account for the absence of the effect were it not for the morphological similarity of the rods and the *foveal* cones. Moon and Spencer (1944) have calculated in detail the quantitative features of the Stiles-Crawford effect.

Factors in Visual Resolution

The retina contains a layer of light-sensitive elements (the receptors) that form a *mosaic*. In order for objects (areas of different luminance in the visual field) to be differentially responded to, they must produce images of varying intensity on the retina. The ability of the individual to see two portions of the visual field (let us say, two dark bars on a light ground) as spatially separated is called visual acuity, and it is based, in part, upon the resolving ability of the retinal mosaic.

The two major hypotheses advanced to account for the limits of visual acuity concern (1) geometrical factors and (2) diffraction patterns. These hypotheses have to do with the way the anatomical and the sensitivity features of the retinal mosaic function to provide for fine resolution. In order for spatial distinctions to be perceived, the geometrical hypothesis would insist that the retinal image must not possess a fineness of detail exceeding the diameter of individual retinal receptors. The second hypothesis relies upon the gradients in the diffraction pat-

tern of the image. The diffraction pattern must not taper so slowly that it fails to excite adjacent receptors differentially.

The necessary precision of perception, as it relates to visual acuity, can be accounted for if it is assumed that small differences in light intensity are reacted to by adjacent receptors. It first seemed as though the intensity difference to be accounted for was not less than 10 per cent. But Hecht and Mintz found that a single line on a homogeneous background of considerable extent could be resolved when it subtended a visual angle of only 0.5 second of arc. This necessitated a revision downward, to 5 per cent, in the magnitude of the difference between the stimulation of neighboring receptors.

The relation between cross-section sizes of the receptors and the sizes of the retinal images of fine wires is indicated in Fig. 8. The taper of the images can be seen to involve not one row of receptors, but several, although with unequal intensities of light. The finest detectable wire actually subtends a visual angle covering less than a single cone. Since the breadth of its image covers several cones, some sort of a differential response between rows of cones is necessary in order to explain how a fine wire is seen in contoured form.

There are four primary factors limiting visual acuity: (1) diffraction of light at the pupil, (2) aberrations of the eye, (3) fineness of the retinal mosaic, and (4) ability of the nervous mechanism, from the receptor onward, to utilize differences in excitation. Of these the first two are optical, the third is anatomical, and the fourth is neural. Factors 1 and 2 are to some extent interrelated: diffraction results in image deterioration, especially with small pupils, and aberrations induce deterioration, especially with large pupils. Accordingly, between the limits of large and small pupils definition is maximum. Factors 3 and 4 are not obviously interrelated. With a grating test object, resolution might be inadequate for one of two different reasons: (1) because the light

and dark bars are too nearly alike in shade of gray, or (2) because the bars are so close together that the entire width of two adjacent bars falls on a single receptor. In this event all receptors would be stimulated equally.

The following methods can, as Hartridge (1947) points out, be used to determine

if they were initially low. This would be expected to increase the fineness of the retinal mosaic.

4. Finally, if visual acuity is low on account of too little difference between the light and dark parts of the test object, it can be improved by increasing these differences.

FIG. 8. Diagram to indicate the relation of the retinal mosaic (cones, in this case) to the retinal images of three narrow lines (diameters indicated by black bars at bottom). The cones are shown at the top of the diagram. It will be seen that more than single rows of cones are involved in the illumination pattern and that adjacent rows are not equally intensely illuminated. The differential in this illumination is presumed to be a crucial factor in accounting for the perception of a sharp line. (Modified from Hecht and Mintz, 1939.)

which of the four determiners of acuity is operating:

1. If diffraction underlies the failure of resolution, matters will be improved by enlarging the pupil, or by using light of shorter wavelength.

2. If aberration is the cause, acuity will be improved by substituting monochromatic light for white light.

3. If the retinal mosaic is responsible, it might be expected that the use of monochromatic light would reduce visual acuity, for, according to current theories, monochromatic light would activate fewer receptors. This would coarsen the retinal mosaic. A procedure for increasing visual acuity would be to increase the stimulus intensity, especially if

Shlaer concluded that the limiting factor in the visual resolution of a grating is the diameter of the pupil when it is less than 2.3 millimeters, and the size of the cones when the pupil is larger than this. Hartridge disagrees.

Other patterns that have been used in the laboratory to study visual acuity are broken circles (Landolt C's) and paired bars. The width of such bars is a critical factor in the visual resolution of the space between them. Fry and Cobb (1935) used two sets of paired bright bars on a dark field. The angle subtended by the width of the bars in the narrower set was 168 seconds; in the broader, 1000 seconds. The length of the bars in both cases subtended 2000 seconds.

As the intensity of the narrow bars was increased from a low value up to 3 candles per square foot, visual acuity increased rapidly at first, but finally declined again. For the broad bars the initial rapid rise was followed by a maintained slow ascent. To explain this these authors utilized the principle previously announced by Fry and Bartley, namely, that parallel borders interfere with each other's formation. The sides of the bars are parallel to each other, and, the broader the bars, the less the borders interfere. Hence the adjacent borders of two broad bars can come closer together before they cease being neurally "resolvable."

The Visual Pathway

The main bundle of optic tract fibers invades the medial and posterior surfaces of the ventral nucleus of the geniculate body and envelops the ventral and posterior surfaces of the dorsal nucleus. When the optic radiation fibers passing to the visual cortex leave the lateral and anterior surfaces of the nucleus, they are structured as a 3-layered S-shaped sheet. The part of the optic tract just described as entering the geniculate contains most of the largest fibers as well as some of the smaller fibers of the optic nerve.

The tract not entering the geniculate consists of medium-sized fibers and many more small fibers than are contained in the tract to the dorsal nucleus. There are indications that, in general, the smaller fibers pass toward the colliculus before synapsing. Between the tract fibers entering the geniculate and the small fibers passing toward the colliculus are the medium-sized fibers that seem to supply various structures such as the pulvinor, the lentiform nucleus, and the pretectal area.

Pathways for Pupillary Response

The central nervous connections for the various pupillary reflexes are not completely known. The two arcs, the sphincter (constrictor) and the dilator, are under control of the parasympathetic and sympathetic seg-

ments of the autonomic nervous system, respectively (see Fig. 9).

The fibers mediating the light reflex of the pupil by-pass the geniculate and hence do not synapse there as do optic fibers passing to the occipital cortex. These pupillomotor fibers pass through the superior colliculus to

FIG. 9. The pathways for dilatation and constriction of the pupil. FL is the frontal lobe of the cerebrum; VC, the visual cortex; Sup Col is the superior colliculus; Lat Gen is the lateral geniculate body, through which the sensory arc passes and synapses; OcMot Nu is the oculomotor nucleus; Pret is the pretectal area; Ed-Wes is the Edinger-Westphal center of the oculomotor nucleus; III N is the third or oculomotor nerve; Cil G is the ciliary ganglion from which the short ciliary nerves reach the eye; Cil-Sp G is the cilio-spinal ganglion; Sup Cer S G is the superior cervical sympathetic ganglion. The two kinds of fibers in the ciliary muscles are the radial (dilator) and the annular (sphincter).

the pretectal region. After synapsing there, the pathway divides. One part passes through the anterior commissure to the opposite side of the nervous system. The other part passes around and ventral to the cerebral aqueduct. Here it divides again, one fraction entering the oculomotor nucleus of the same side, the other going to the oculomotor nucleus on the other side.

The efferent part of the pupillomotor pathway consists of two parts, the sphincter and the dilator arcs. The sphincter arc is as follows: From a part of the oculomotor nucleus called the Edinger-Westphal center the path passes along the oculomotor nerve

to the ciliary ganglion behind the eyeball, and from there through the short ciliary nerves to the sphincter muscle fibers of the iris. Cortical influences on pupil constriction are mediated by cerebral connection with the Edinger-Westphal center.

The dilator arc is more complex. Both the frontal cortex and the visual cortex may initiate the reflex through a midbrain center close to the Edinger-Westphal center in the

visible spectrum, and its limits depend upon the intensity of the radiation involved. Near the middle of the visible spectrum the wavelengths are most effective in eliciting a visual response. The efficacy of the various wavelengths diminishes as the limits of the visible spectrum are approached. The curve representing this phenomenon is called a *visibility curve*, or a *luminosity curve*. It is obtained by a method of comparison in

FIG. 10. Luminosity curves for scotopic (rod) and photopic (cone) vision. Since the maxima are arbitrarily set at 100, these curves give no information about the relative sensitivity of the rods and cones. The vertical line indicates the place at which a common red filter cuts off. It transmits $\frac{1}{10}$ of the light involved in the cone curve, and $\frac{1}{100}$ of that in the rod curve. (Hecht and Yun Hsia, 1945.)

oculomotor nucleus. The dilator pathway leads to the inferior ciliospinal center in the constrictor arc. The pathway passes next to the superior cervical sympathetic ganglion, the homologue of the ciliary ganglion of the constrictor arc. It is thought possible that these two ganglia have some connecting pathway, though its existence and function are unknown. The pathway from the superior cervical sympathetic ganglion passes to the radial muscle fibers of the iris.

PHOTOCHEMICAL MECHANISMS

The human eye is sensitive only to the limited spectral band of radiation that has been called light. This band is spoken of as

which the visible brightnesses of the various wavelengths in the spectrum are matched by adjusting their intensities. In Fig. 10 two luminosity curves are plotted. One is for moderate levels of illumination at which the cones are definitely functioning. It is called a photopic luminosity curve, and its maximum is at 554 $m\mu$. The other curve is for levels at which only rods are functioning. It is called a scotopic luminosity curve. Its maximum lies more toward the blue end of the spectrum, at about 511 $m\mu$. It is believed that luminosity curves bear some relation to the absorption spectra of the pigments found in the eye. A pigment called visual purple is found in the rods, and it possesses an absorption spectrum similar to the scotopic luminosity curve.

Wavelengths shorter than those at the violet end of the spectrum are spoken of as ultraviolet. Wavelengths longer than those at the red end of the visible spectrum are known as infrared. Questions regarding the more precise effects of both ultraviolet and infrared are still being raised and studied.

Sensitivity to Infrared Radiation

Although it is customary to specify the limits of the visible spectrum as lying between 400 and 750 $m\mu$, it has been shown by Griffin, Hubbard, and Wald (1947) that with sufficient energy the eye can be stimulated well beyond these limits.

The most recent measurements of the infrared extend to 1050 $m\mu$ (Fig. 11). In the visible range from 550 to 700 $m\mu$, the rods decline in sensitivity faster than the cones. In the far red the fovea is the most sensitive area of the retina. However, at still longer wavelengths this relation is reversed. Beyond 800 $m\mu$, under the conditions used by Griffin, Hubbard, and Wald, the rods are considerably more sensitive than the cones. At the threshold of the dark-adapted eye infrared radiation is seen only with the peripheral retina and is colorless. It should be noted that in Fig. 11 the foveal and peripheral functions coincide between 675 and 740 $m\mu$. This is an apparent contradiction to the statement that in the extreme red the fovea is more sensitive than the periphery (by about 0.2 log unit). The difference is occasioned by the fact that the exposure time in the earlier experiments was 0.04 second, and in the later measurements, 1 second.

Although the customary limits assigned to the visible spectrum have been extended by increasing the energy of the stimulus, this does not mean that the range is limitless. At some point, the eye would cease to function as a specialized visual sense organ and be no more sensitive to radiant energy than is the body surface in general. The human skin can respond to radiation both visible and infrared. The sensation is that of

warmth. For example, the threshold for the skin to radiant energy varies from 0.019 g-cal/cm²/sec for a small area (0.2 square centimeter on the forehead) to 0.00015 g-cal/cm²/sec for a large area (the whole dorsal surface). It has been shown that the threshold for rods at 510 $m\mu$ is 1.85×10^{-16} g-cal/cm²/sec.

FIG. 11. The relative spectral sensitivity of the dark-adapted fovea and the peripheral retina. The curves represent 1-degree test objects either fixated or placed 8 degrees above fixation, and exposed for 1 second. (From Griffin, Hubbard, and Wald, 1947.)

It is to be noted from Fig. 11 that at 1050 $m\mu$ the retina is 125 decibels or 3.3×10^{12} less sensitive than it is at 510 $m\mu$. At 1050 $m\mu$ the threshold is 0.00061 g-cal/cm²/sec, which is a little higher than the value for the whole dorsal body surface, but definitely lower than for small cutaneous areas. An additional factor working in favor of the skin is the absorption spectrum of water. It is negligible below 950 $m\mu$, but at 1150 $m\mu$ all but about 16 per cent of the radiation entering the eye is absorbed by the water in the various media before it reaches the retina. At 1200 $m\mu$ even less

reaches the retina (about 8 per cent). It would be expected that 1150 to 1200 $m\mu$ would mark the limit at which radiant energy would cease to be seen and would be more readily felt as heat.

The effect of wavelengths in the ultraviolet region will be discussed in the section on dark adaptation. Exposure to ultraviolet radiation apparently produces effects on the visual system that have been detected in the form of raised thresholds of dark adaptation.

Cone Function and Color Response

While we are on the subject of the selective sensitivity of the receptors (particularly the cones) let us consider the matter of color vision. Many theories regarding the mechanism of color vision have cluttered up our textbooks for several generations (see Chapter 22), but it is only now that we are beginning to lay an experimental foundation for dealing with the problem. Even now not too much can be said. There have long been two contending hypotheses regarding the functioning of foveal cones: (1) the single receptor theory, and (2) the triple receptor theory. According to theory 1, all receptors are able to respond to all parts of the spectrum. According to theory 2, the receptors belong to one of three groups: they may be sensitive to red, green, or blue. In addition to these two hypotheses, two others have emerged, namely, (3) the polychromatic hypotheses of Granit and of Hartridge, and (4) the cluster hypothesis of Hartridge.

According to Granit (1945), there are not three groups of receptors, there are many groups, each sensitive to a band of frequencies. At present it is thought that one group of receptors, the "dominators," is activated by white light, whereas the other groups, the "modulators," are activated by light near the wavelengths 600, 580, 520, 500, 460, and 430 $m\mu$. Using a microelectrical recording technique, Granit found evidence for this variety of receptors in the retinas of a number of animals. Thus far

these techniques have not been applied to man.

Hartridge (1947) points out that his cluster hypothesis does not conflict with any of the first three hypotheses. It adds, rather, an important feature to either the triple-receptor idea or the polychromatic idea. Were the single-receptor hypothesis proved, the cluster hypothesis would be unnecessary.

According to the cluster hypothesis, receptors of a given variety tend to group together. Hence at one retinal point there may be a cluster of "dominators"; at another point, some blue-sensitive receptors; and at still another, some green-sensitive receptors. This nonuniform distribution would function as follows: Let the test object be a broken circle (C). When red light is used, the fixation of the test object is such that the image of a critical portion is caused, by an appropriate adjustment of the extrinsic eye muscles, to coincide with the red fixation point. This implies that there are several possible fixation points, an idea for which Hartridge feels he has some evidence.

Granit found two types of receptor in the light-adapted eyes of such animals as frogs and snakes: (1) receptors with restricted spectral response, and (2) those with broad response. The former he called "modulators," and the latter he called "dominators." It was found that the luminosity curve of the dominator was quite like, if not identical with, the luminosity curve of the light-adapted human eye. Dominators were not found in the eyes of those animals devoid of cones, such as rats and guinea pigs. This led to the idea that cones are essential in the dominator response.

Granit also found that the dominator can be split into the individual modulators of which it consists, provided selective adaptation is used. He also synthesized the human photopic luminosity curve on the basis of three fundamental sensation curves, red, green, and blue. (The red is made up of two modulators, *MY* and *MR*.) This concept that the dominator is a complex of sev-

eral modulators connected with the same nerve fiber is consistent with Polyak's finding that both rods and cones converge on the same optic nerve fiber. Granit found all dominators to be identical in their response curves. Hence he concluded that they must be similarly constituted. All of them must be made up of four modulators: one blue, one green, and two red.

Visual acuity based on dominator action must be grosser than that provided for by a modulator, since the former is a cluster of receptors acting together as a physiological unit. Accordingly, were dominators to be present in large numbers, visual acuity would suffer. Since it is firmly believed that visual acuity in the human fovea can be accounted for only if each receptor is connected to its own nerve fiber, few, if any, of Granit's dominators can exist in the human fovea.

Hartridge, on the other hand, came to the revolutionary conclusion that all foveal cones give the "white" or dominator response. This is to say that every cone is a dominator. This concept implies that the same receptor may be at one time a modulator and at another a dominator. It is a dominator when the light reaching it is weak and covers a small visual angle. It becomes a modulator, able to differentiate parts of the spectrum, when the stimulated retinal area is larger and the light more intense. This idea will require considerable investigation in order to verify it. If it is proved, then in some way the retinal receptors would seem to be under a control by which, at one time, they can respond equally to all wavelengths of light, and at other times they can respond quite critically to some restricted portion of the spectrum.

Hartridge's (1948) polychromatic theory postulates two kinds of units in addition to the tricolor unit of the single receptor theory. One of these is called the *Y-B* unit and possesses receptors most vigorously responsive to wavelengths for yellow and blue. The other unit he labels *R-BG-R*. It contains two kinds of receptors responding most vig-

orously to wavelengths in the red and blue-green parts of the spectrum. The "red" receptors also have a secondary characteristic of being sensitive in the extreme violet part of the spectrum. This he indicates by the extra *R* in the symbol for the unit. There is also the conventional tricolor unit. Thus according to this theory there are three response units, with a total of seven types of receptor. Since the one type displays a secondary curve of sensitivity, there is a total of eight response curves that may be activated in any one of several combinations. There are, then, different responses for high, medium, and low intensity ranges of stimulation, and for the fovea and periphery, which, of course, differ in behavior. Whereas Granit developed his theory from electrical recording from the retina with micro-electrodes, Hartridge obtained most of his evidence from the sensory impressions that occurred when he used the fovea, the periphery, and several levels of illumination as variables. It would seem, however, that Hartridge was considerably influenced by Granit's findings.

In the fovea, according to Hartridge, all seven types of units may be brought into action, depending upon intensity and kind of stimulation. All these units function when white light is used. If the intensity is very high, only the *Y-B* unit functions. If the intensity of the white light is low, or the visual angle very small, only the *R-BG-R* unit functions. In the periphery the *Y-B* unit is all that ever functions.

When colored light (a restricted band of the spectrum) is used, the receptors activated depend upon the response curves that correspond to the portion of the spectrum used. Hartridge gives the example of what would happen for stimulation by the wavelength of 650 $m\mu$. Certain receptors in each of the three units would be activated, namely, the long wavelength receptor of the tricolor unit, the red receptor of the *R-BG-R* unit, and the yellow receptor of the *Y-B* unit.

Here again, if the intensities are very high, only the *Y-B* unit is activated. The result is a sensation of yellow. If moderate intensities are used, all three receptors just mentioned are activated, the combined effect giving a sensation of orange-red. When

to rods and cones through polysynaptic ganglion cells and bipolar neurons. Others make connections to cones through midnet ganglion and bipolars. Some cones are connected to both types of fibers. These connections are indicated in Fig. 12.

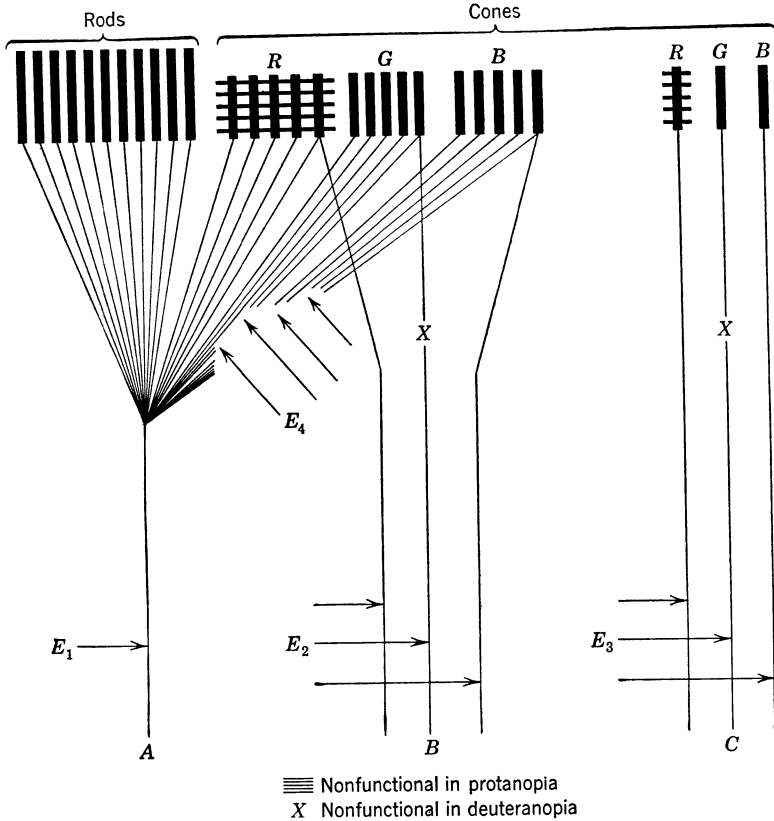

FIG. 12. A diagram to represent the supposed neural connections between modulators, dominators, and rods. Points marked E_1 , E_2 , E_3 , and E_4 are recording positions. *R*, *G*, and *B* stand for red, green, and blue. (Jahn, 1946a.)

low intensities are used, only the *R-BG-R* unit is involved, and it provides for the sensation of purplish crimson, owing to the involvement of both the primary and secondary response curves.

Jahn (1946b) combines Granit's data and what is known about synaptic connections in the retina to form a very simple account of the mechanism of color vision and its defects. Some fibers in the optic nerve are connected

Jahn proceeds from the premise that modulators and dominators refer to ganglionic axons rather than to types of cones. Accordingly the fibers of the polysynaptic ganglion cells are the dominators. Modulators are then of six or seven kinds, which for convenience are divided into three groups, red, green, and blue. The algebraic summation of the modulator sensitivity curves is equivalent to the dominator curve. On this

account, the dominator fiber can be considered to be connected to the receptors as in *A* of Fig. 12, and the dominator response would be obtained from a recording electrode at E_1 . Modulator fibers may be connected with cones as in *C*, or with certain cones that are connected with the dominator as in *B*. In such cases the modulator responses would be experimentally recorded at E_3 and E_2 , respectively. A sensitivity curve recorded from a set of fibers as in E_4 could be identical to a modulator curve.

Jahn (1946*b*) also assumes that the usual luminosity curve is the overall effect of dominator and modulators, rather than simply the dominator curve as Granit proposed. Jahn also assumes that hue discrimination is determined by modulators alone.

Though it is not the purpose of this section to deal at length with color vision and its defects, the kind of explanation given deuteranopia will indicate one of the possibilities of Jahn's version of the polychromatic theory. In deuteranopia red-green hue discrimination is poor, although the luminosity curve is almost normal. There could exist a deficiency in the "green" modulator units (midget bipolars or midget ganglion cells) or in the "green" cones connected with them. In either case the pathways indicated by *X* in the figure would become nonfunctional, whereas pathways between some of the "green" cones and their dominator fibers would still be functional. This would account for a decided decrease in hue discrimination associated with only a small shift in spectral sensitivity, such as actually occurs. The fact that nerve fiber degeneration may result in deuteranopia but not in protanopia is also cited by Jahn in support of this theory.

Photoreceptor Processes

The processes that occur in the photoreceptor have for some time been assumed to determine the quantitative features of processes further along in the optic pathway.

Certain features of photochemistry are known and others have been postulated to account for the known sensory end results. Hecht (1934), whom we shall follow in the first part of this section, points out that we know three things regarding the *primary* photochemical process: (1) that certain material is decomposed by light falling on it, (2) that some of the resulting products are transported from the site of action, so that the full photochemical result is never utilized, and (3) that the initial sensitive material is replenished in the dark and supposedly even in the light. It would appear that this synthesis occurs from two other substances that disappear in the process.

In addition to the primary or light process, there is a *secondary* or "dark" process intimately related to it. The secondary process is unable to initiate the nerve impulse until the primary process has, through the action of light, produced the necessary products. The rate of the secondary reaction is proportional to the concentration of these products.

The situation may be represented by a pseudoreversible reaction as follows:

in which *B* is a product of the primary reaction, and *C* is a substance developed in excess and supplying the means for recombination of *A* and *P*. Hecht puts it as follows.

Imagine light falling on *S*. Through its decomposition its original concentration *a* will be changed to concentration *a* - *x* (*x* equaling the concentration of *S* changed into *P*). The rate of this process may be written as

$$v_1 = k_1 I(a - x) \quad (2)$$

in which k_1 is the velocity constant including the absorption coefficient. This rate is proportional to the concentrations of the already-mentioned substances, *P*, *A*, *B* (and possibly others, with reactions x , x^2 , or x^n , depending upon the number of photolytic products).

Then

$$v_2 = k_2 x^n \quad (3)$$

must be subtracted from the velocity of the primary reaction in order to describe the actual velocity

$$\frac{x}{t} = k_1 I(a - x) - k_2 x^n \quad (4)$$

with which the products accumulate in the receptor. The equation may be rearranged so as to indicate more directly the relation between intensity of light, the time it acts, and the production of a given amount x of photochemical products, in which case we have

$$It = \frac{x}{k_1(a - x)} + \frac{k_2 x^n}{k_1(a - x)} t \quad (5)$$

Since x is presumed to be constant, $(a - x)$ is constant, and equation 5 may be simplified to

$$It = C + Dt \quad (6)$$

D , representing k_2 , becomes negligible for threshold values of the x and for short exposure times, so that the equation reduces to

$$It = C \quad (6a)$$

which is the Bunsen-Roscoe law. Despite the occurrence of the extra reaction removing P , the relation between *time* and *intensity* follows the simple equation 6a for short exposures, and the slightly more complex equation 6 for more extended exposures.

When intensity is the limiting factor determining a threshold reaction, $t \rightarrow \infty$, and $S \rightleftharpoons P + A$ reaches a stationary state. Then the velocity $dx/dt = 0$, and equation 4 becomes

$$\frac{k_1}{k_2} I = \frac{x^2}{(a - x)} \quad (7)$$

in which time is eliminated. The equation also describes the concentration in the photosensory system when adaptation to I has occurred. Exposure to an additional momentary illumination subjects the system to the sum of I and I_s (the adapting and the stimu-

lating intensities). The stationary state then no longer exists, and additional S is decomposed with a velocity represented by

$$\frac{dx}{dt} = k_1(I + I_s)(a - x) - k_2 x^2 \quad (8)$$

If the intensity is reduced to some fraction of its original value, the following will result:

$$\frac{k_1}{k_2} \cdot \frac{I}{p} = \frac{x_p^2}{a - x_p} \quad (9)$$

Here x_p indicates a particular value of x in equation 7 determined by I/p . Whereas the total effect of I is reduced by a reduction in its intensity, its effectiveness may also be reduced by shortening the time of action, e.g. by means of a sector disk. When such a disk is used, the photosensory system is subjected to alternate periods of light and darkness. Figure 13 will aid in picturing what happens. During the light period (light fraction of the cycle) the velocity of the process is represented by equation 4, and during this time the concentration of x rises. During the dark phase of the cycle only the "dark" reaction occurs. Its velocity is given by equation 3. If the alternation is continued, a pseudostationary state is maintained. In it the light phase and the dark phase produce equal but opposite effects, and the concentration of x fluctuates equally above and below a mean value. The more rapid the alternation, the smaller is the fluctuation of x , until at last a point is reached at which the fluctuation is no longer sufficient to produce physiological effects leading to a sensation of flicker. That is to say, Δx becomes too small to be effective.

During the short light phase the velocity of the light reaction is

$$\frac{\Delta x}{\Delta t} = k_1 I(a - x) - k_2 x^2 \quad (10)$$

and the speed of the "dark" reaction during the short interval $(p - 1) \Delta t$ is

$$\frac{\Delta x}{(p - 1) \Delta t} = k_2 x^2 \quad (11)$$

which may be rearranged so that

$$\frac{\Delta x}{\Delta t} = (p - 1)k_2x^2 \quad (12)$$

and since this may be equated with equation 10 the result becomes

$$k_1I(a - x) - k_2x^2 = (p - 1)k_2x^2 \quad (13)$$

which becomes

$$\frac{k_1}{k_2} \cdot \frac{I}{p} = \frac{x^2}{a - x}$$

which is equation 9. This means that a reduction in exposure time by the fraction $1/p$, obtained by rapid alternations of light and dark periods, is equivalent to a reduction, by the same fraction, of the intensity of a steady illumination. This, of course, is Talbot's law.

The situation is not so simple, however, as the derivation indicates. First of all, observed flicker rates and rates of stimulus

FIG. 13. Diagrammatic derivation of Talbot's law. The upper two curves represent the course of light adaptation and of dark adaptation. Dark adaptation is in reality many times slower than light adaptation. The two processes are here made roughly alike for diagrammatic purposes, since the actual values do not enter into the derivation of Talbot's law as given in Hecht's equations. In the lower graph the alternation of light and dark periods is such that the light period is given by the small time Δt , the total cycle of light and dark by $p\Delta t$, and the dark period by $(p - 1) \Delta t$. The fluctuation in concentration Δx in the stationary state is quite small in relation to the concentration x , and is incapable of producing sensory fluctuations. (Hecht, 1932.)

intermittency ("flash" rates) do not, under all conditions, coincide. Second, subjective uniformity (the steady state) may be reached by the use of short light intervals and long dark intervals, or vice versa, at nearly the same critical flicker frequencies. The explanation of the first fact involves certain intrinsic properties of ganglion cells; the second fact involves specifically the off-effect in retinal discharge. These effects will be discussed in the section on neurophysiological considerations.

Hecht derives an equation for critical flicker frequency as follows. Since the concentration of the photo products is x , the rate of the secondary dark reaction is

$$\left(\frac{\Delta x}{\Delta t}\right) \text{secondary} = k_3 x \quad (14)$$

where k_3 is a velocity constant. At the disappearance point of flicker he supposes that $\Delta x = c'$, i.e. that the change Δx in the dark time Δt is constant at a value just too small to induce a physiological change sufficient to cause a change in the sensation of brightness. Let the critical fusion frequency F be defined as the number of light-and-dark cycles per second. Let $F = 1/2 \Delta t$. Substituting for Δx and Δt in equation 14, the result is

$$F = cx \quad (15)$$

where $c = k_3/2c'$. This means that the critical flicker frequency is directly proportional to the concentration of the photo products in the stationary state represented by

$$\frac{k_1 I}{k_2 p} = x^2(a - x) \quad (16)$$

Since in equation 15 F is a linear function of x , F may be substituted for it in the equilibrium equation, where at the same time F_{\max} may be exchanged for a . We let m and n indicate the order of the reaction of $S \rightarrow P + A$ and $P + A \rightarrow S$, respectively. Equation 16 then becomes

$$\frac{k_1 I}{k_2 p} = \frac{F^n}{(F_{\max} - F)^m} \quad (17)$$

or, by rearrangement,

$$F = \left[\frac{k_1 I}{k_2 p} (F_{\max} - F)^m \right]^{1/n} \quad (18)$$

or, by shifting the absolute value of k_2 ,

$$F = \frac{1}{p k_2} (k_1 I)^{1/n} (F_{\max} - F)^{m/n} \quad (19)$$

Jahn (1946a) has pointed out that several difficulties arise in the use of equation 19 to account for the relation between fusion frequency F and intensity I . (1) When the temperature is changed in lower animals the effect is opposite to prediction. (2) The effect of a change in the light-dark ratio (LDR) is opposite to prediction. (3) It is necessary to assume that the photochemical reaction is bimolecular in order for the data on human observations to fit the equation. This is contrary to the chemical evidence we have. (4) The flicker results for certain animals do not fit equation 14; (e.g. *Pseudemys*, *Sphaerodactylus*, and the low illumination results for *Asellus*). (5) On a purely logical basis, it is taken as probable that the concentration of S , instead of the concentration of $P + A$, directly determines critical flicker frequency.

It is thought that the amount of "new" $P + A$ needed for excitation at threshold is the same for all frequencies and intensities. The quantity of light needed for a given small photochemical result is inversely proportional to the concentration of S . Thus if the amount of photosensitive material is increased, as for instance by raising temperature, or by increasing time in the dark, critical flicker frequency should rise, and the intensity of light needed for a given eff should drop. This is what actually occurs. The eff equations of Hecht appear to be open to criticism mainly because the concentration of the active catalyst ("new" $P + A$), the direct antecedent of stimulation, is not taken into account. "Old" $P + A$, indicated by x , has no active part in stimulation, and it is possible that the observed correlation between F and x is fortuitous. On account of

the difficulties listed, equations 17 to 19 require modification.

Two assumptions may be made in modifying the formulations: (1) that F varies as the reciprocal of light phase needed to produce a given critical catalytic effect of "new" $P + A$ (an amount just too small to be effective in ultimate sensation); and (2) that the maximum F is determined by some factor outside the sense cell (which is not affected by temperature) rather than by photochemical changes in the sense cell itself.

Whereas P and A represent "old" or inactive substances, active materials may be denoted by E whose concentration is w . Accordingly the photochemical cycle becomes $S \rightarrow E \rightarrow P + A \rightarrow S \dots$. The reaction resulting in nerve stimulation is determined by the concentration of E , whereas the process of dark adaptation depends on the concentration of P and A .

It is supposed that the formation of E varies with intensity I , with the amount of S present, i.e. $(a - x)$, and with the duration of illumination t . The amount of E formed by a single light period ("flash") is thus

$$k_1 I(a - x)t \quad (20)$$

It is assumed that, with some exceptions, E is small relative to $a - x$. The secondary reaction ($L \rightarrow T$) depends upon the concentration of E , and of L (denoted by l) and the velocity constant k_4 of the catalyzed reaction. Accordingly the rate of the reaction is $k_4 lw$, and the amount of L changed to T is approximated by $k_4 lwt$. It may be assumed that for critical flicker frequency either this or $k_4 lw$ is a constant and may be represented by C . Since $L \rightarrow T$ is either cyclic or reversible, it may be assumed that its rate must attain a threshold value ($k_4 lw = C$). Thus

$$C = k_4 l k_1 I(a - x)t \quad (21)$$

For any chosen value of p (light fraction of the cycle), the critical flicker frequency F should vary as the reciprocal of the time needed to produce the required constant physiological effect. Thus F varies as $1/t$.

$$\frac{1}{t} = \frac{k_4 l}{C} [k_1 I(a - x)] \quad (22)$$

Assuming $L \rightarrow T$ to be any kind of change resulting in nerve stimulation, we may assume that the concentration of L varies considerably during a light-dark cycle, decreasing during the light phase and increasing during darkness. At the start of the light phase, the available l varies as a function of the duration of the previous dark period ($l = fp$). As a first approximation, l may be considered a linear function of p . As a consequence, p may replace l in equation 22. The proportionality constant C , now C' , may also be included.

$$\frac{1}{t} = \frac{k_4 p}{C'} [k_1 I(a - x)] \quad (23)$$

The equation for flicker frequency may be written thus:

$$F = \frac{k_4 p}{C'} [k_1 I(a - x)] \cdot f(F) \quad (24)$$

In this equation $f(F)$ does not have to do with the chemical process by which the receptor is stimulated, but rather with the mechanism by which the experience of flicker approaches the fusion frequency when the frequency of intermittent stimulation is increased. The critical process for this phenomenon may (as far as the equation is concerned) lie anywhere in the chain of events from the sense organ process to the central nervous effects. One simple expression for this function may be $(F_{\max} - F)^r$. Consequently one form of equation 24 is

$$F = \frac{k_4 p}{C'} [k_1 I(a - x)] q (F_{\max} - F)^r \quad (25)$$

where q probably pertains to the mechanism by which photo product E is used in the sense cells.

Jahn (1946a) points out that the data for *Pseudemys*, *Sphaerodactylus*, and *Acellus* which are not well fitted by Hecht's equation 17 can, because of the flexibility of equation 25, be fitted reasonably well by it. Equation 25 also predicts the shift observed when the LDR is changed.

In order to explain brightness discrimination, Jahn has set up the following equations: In the photochemical cycle $S \rightarrow E \rightarrow P + A \rightarrow S \dots$, the concentration of E is denoted by w , the concentration of P and A by x , and the concentration of S by $a - w - x$.

In the stationary state the rates of the three reactions implied above are equal, so that

$$k_1 I(a - w - x) = k_2 w = k_3 x^2 \quad (26)$$

where k_1 , k_2 , and k_3 are velocity constants. The outcome is that

$$\Delta I = \frac{(C/k_4 l)^{1/q} - w}{k_1(a - w - x)t} \quad (27)$$

which becomes, on dividing by I ,

$$\frac{\Delta I}{I} = \frac{(C/k_4 l)^{1/q} - w}{k_1 I(a - w - x)t} \quad (28)$$

But since in equation 26 $k_1 I(a - w - x) = k_3 x^2$

$$\frac{\Delta I}{I} = \frac{(C k_4 l)^{1/q} - w}{k_3 x^2 t} \quad (29)$$

And since from equation 26 $w = k_3 x^2 / k_2$

$$\frac{\Delta I}{I} = \frac{(C/k_4 l)^{1/q} - 1}{k_3 x^2 t} - \frac{1}{k_2 t} \quad (30)$$

Since the minimum visual angle α varies as $\Delta I/I$, the form of the present equation for visual acuity is

$$\alpha = C_1 \frac{(C/k_4 l)^{1/q} - w}{k_3 x^2 t} \quad (31)$$

in which C_1 is a proportionality constant. This equation fits all the data that can be fitted by Hecht's (1935) equivalent formula

$$\frac{\Delta I}{I} = C \left[1 + \frac{1}{(kI)^{1/2}} \right]^2 \quad (32)$$

Response of a Single Receptor

Jahn's modification (1946a, c) of Hecht's equations for the activity of the photoreceptor has been applied by Fry and Alpern to the response of the dark-adapted receptor of the Limulus (horseshoe crab) to a flash of light. From it they derive equations for predicting the sequence of impulses. Accord-

ing to Jahn's proposal the initiation of an impulse depends upon the presence of the catalyst E . Thus, to predict the sequence of impulses elicited by a flash of light, the changes in the concentrations of E and the original photosubstance S must be known. Equations for the course of these changes at various times after the onset of the flash were derived. It is assumed that the secondary reaction ($L \rightarrow T$) is produced in one part of the photoreceptor and must diffuse to another part before it can produce nerve impulses. This takes time, and there is a lag between the production of T and its arrival at the point of effectiveness. In order to account for the failure of low intensities of light to produce a response regardless of duration, it must be supposed that T is constantly being dissipated. It must also be supposed that a fixed quantity of T must be accumulated before the photoreceptor can initiate a nerve impulse. When the receptor discharges, all the accumulated T is consumed. Fry and Alpern derive an equation for the frequency of impulses

$$F = \frac{1}{\Delta t}$$

where Δt is the time required for the concentration of T at the point of nerve stimulation to rise from zero to threshold value. In general the frequency is proportional to the rate of accumulation of T at the point of nerve stimulation.

Fry and Alpern also account for the initial burst of impulses in the receptor and the subsequent "silent period." They explain why reaction time lengthens when the duration of the stimulus is shortened to within the critical value, and they explain the relation between the peak of the curve for concentration of E and the instant at which the maximum frequency of impulses is produced. Their formulations deal also with light and dark adaptation and with the effects of a brief increase in light intensity.

Dark Adaptation

The ability of the human eye to become more sensitive during a stay in the dark is known as dark adaptation. Its readjustment when it returns to high illumination levels is

millilambert, its threshold after a few minutes in bright light is 0.005 millilambert, a diminution in sensitivity equal to 37 decibels, or a reduction to $\frac{1}{37000}$ of the previous sensitivity.

FIG. 14. Diagram indicating the extreme range of light intensities that the human eye confronts and the relation between the levels of cone and rod vision. The scale on the right shows that the range of visible intensities covers approximately 100 decibels, or a ratio of intensities equal to 10 billion to 1.

known as light adaptation. It is obvious from Fig. 14 that there is an enormous range between the threshold level of sensitivity and the brightness of snow in noonday sun. The range is actually something like 1 to 10 billions, or close to 100 decibels (10 logarithmic units). Whereas the threshold of the eye after 10 to 12 hours in darkness is 0.000001

Figure 15 indicates the relation between log luminance in microfoot-lamberts (1 foot-lambert = 0.929 millilambert) and the angular relation of the sun to the horizon. The curve was constructed from readings made at four different times of the year. For the latitude (42.5 degrees) at which the readings were made, the light reflected from a test

object not in shadow is definitely related to the angular elevation of the sun.

Figure 16 shows both the decline of outdoor brightness during twilight and the dark-adaptation curves for rods and cones. The adaptation curves are thresholds obtained under the usual condition of complete dark-

The distribution of the rods and cones for 25 degrees on either side of the fovea, along the horizontal meridian, was previously indicated in Fig. 6. Figure 17 shows the dark-adaptation curves obtained with centrally fixated fields of various sizes from 2 to 20 degrees. It will be noted that the centrally

FIG. 15. The intensity (luminance) of a test object as a function of angular height of the sun at different times of the year. (Beebe-Center, Carmichael, and Mead, 1944.)

ness between readings. Hence dark adaptation induced by gradually declining illumination may not be so rapid as pictured. Nevertheless it is thought to be as rapid as the normal decline in daylight illumination, if not more so.

Owing to the difference in the distribution of the rods and cones over the retina, dark-adaptation threshold curves vary in shape in accordance with the area of the test object and, if small, with its location on the retina. The dark-adaptation curve also depends on the intensity level of preadaptation, the duration of preadaptation, and the portion of the spectrum used.

fixated 2-degree test object indicates little adaptation aside from the initial cone effect which is complete within the first few minutes. Progressively larger test objects involve a relatively greater proportion of rods, and the curves show greater adaptation. Figure 18 pictures the dark-adaptation curves for a test object of 2 degrees placed at various distances from the fixation point. Figure 19 shows the thresholds (reached after 30 minutes in darkness) for test objects of different diameters, and for a 2-degree test object placed at different distances from the fixation point. The behavior of the retina with regard to dark

adaptation is shown in another way in Fig. 20, which represents the effects of a 20-degree annulus test object and a 20-degree disk test object. From these results it would seem that the outcome depends more upon where

levels. A violet color was seen above threshold, whereas at threshold the light was colorless. Figure 23 shows the various rates of dark adaptation following preadaptation to

FIG. 16. Human dark adaptation compared to the decline in outdoor brightness during twilight. It must be remembered that the curves representing dark adaptation indicate rates for the eye in absolute darkness rather than in waning illumination. (Beebe-Center, Carmichael, and Mead, 1944.)

the image of the outer border of the test object falls on the retina than upon the total area involved in the image.

Figure 21 shows the rate of dark adaptation following exposures to 5-second flashes at various intensities and following exposure to the very short flash of a photoflash lamp. Figure 22 indicates the progress of dark adaptation as measured with violet light (480 $m\mu$ and below) following 2-minute exposures to preadapting intensities of various

FIG. 17. Threshold curves showing dark adaptation for centrally fixated areas of different size. (Hecht, Haig, and Wald, 1935.)

different durations of a luminance at a level of 333 millilamberts.

From both practical and theoretical points of view the effect on dark adaptation of

FIG. 18. Dark adaptation as measured with a 2-degree test object placed at various angular distances from the fixation point. (Hecht, Haig, and Wald, 1935.)

exposure to red light is of interest. In order to explain why red filters (goggles) enable a person to become dark adapted while ex-

FIG. 19. The threshold level reached in 30 minutes of dark adaptation for retinal fields of different size and location, for three different observers (each curve for a single observer). The left-hand graph shows the results for test objects coaxial with the fixation point (central field). The right-hand graph is for a 2-degree field placed at different distances from the fixation point. (Hecht, Haig, and Wald, 1935.)

posed to ordinary indoor levels of illumination, we must inspect the characteristics of rods and cones as they bear on this matter. The luminosity curves based on rod and cone

FIG. 20. A comparison between thresholds under dark adaptation for a centrally fixated 20-degree field and for a narrow 1-degree annulus, 20 degrees in diameter. (Hecht, Haig, and Wald, 1935.)

functions are effectively dissimilar (see Fig. 10). Spectral sensitivity curves plotted in terms of threshold, as in Fig. 24, express in another way the dissimilarity between rods and cones.

Were we to use exposure to red light as provided by a filter with a cutoff at about $620\text{ m}\mu$ (see Fig. 25), we should be exposing the two classes of receptors (rods and cones) to different fractions of the total spectral ranges to which they are sensitive. This is one of the principal factors involved in dark adaptation when red filters are used. To illustrate, we may again refer to the two luminosity curves (Fig. 10) where the portions of the two curves eliminated by the red filter are shown by the unshaded areas. It will be seen that a greater portion of the scotopic curve (rod) is eliminated than is taken from the photopic curve (cone). The red filter passes $\frac{1}{100}$ of the effective flux for the rods and $\frac{1}{10}$ of that for the cones. This is a 10 to 1 difference, and it means that by wearing the red filter goggles the individual reduces the effective flux of light to the rods more than to the cones. For cone vision, if white light is to be reduced in effectiveness until it is equal to the red, the light of all wavelengths must be reduced to $\frac{1}{10}$ their value. Through a red filter, then, the cones receive enough light for the individual to see to do his work, but the light to the rods is greatly reduced. By adjusting the spectrum of the light source we may further aug-

ment the 10 to 1 difference between the stimulation of the rods and cones. The difference may become as great as 50 to 1.

preadaptation and the time required in darkness for the eye to reach a threshold 0.5 log unit (5 decibels) above its final value. The

FIG. 21. Dark adaptation following short exposures to various intensities. The initial dark adaptation of the rods increases in velocity as the preadapting intensity decreases. (Wald and Clark, 1937.)

FIG. 22. The influence of light adaptation on subsequent dark adaptation of the eye. The thresholds during dark adaptation were measured with violet light following different amounts of preadaptation. (Hecht, Haig, and Chase, 1937.)

Figure 26 shows the rate of dark adaptation following preadaptation to white and red lights. It is obvious that preadaptation to red light provides for more rapid dark adaptation. Figure 27 shows the relation between the intensity of the light used for

curve for red preadaptation is about 1.5 log units to the right of the curve for white. To obtain the same dark adaptation in the same time the eye can be exposed to thirty times as much red light as white. In aviation where vision at low intensities is often

FIG. 23. Threshold curves showing dark adaptation following various lengths of exposure to a luminance of 333 millilamberts. As light adaptation proceeds, the visual threshold rises and the rate of rod adaptation declines. (Wald and Clark, 1937.)

FIG. 24. Spectral sensitivity curves for rod and cone vision, showing the relative energy required to produce a threshold response. The actual energy increment above the threshold for the appearance of color (cone function) varies for different parts of the retina. In the parafovea it is between 0.1 and 1.0 log unit. The distance between the two curves represents the *photochromatic interval*. (Hecht and Yun Hsia, 1945.)

FIG. 25. Transmission of the red plastic material commonly used in red goggles. The part of the spectrum transmitted by the material is in the right-hand side of the diagram. (Hecht and Yun Hsia, 1945.)

FIG. 26. Dark adaptation following preadaptation to white light and to red light of about equal photopic brightness. It is clear that, following white preadaptation, dark adaptation (which here is purely red) is slower than that following red preadaptation. (Hecht and Yun Hsia, 1945.)

very necessary, and where restricted areas in the visual field may at the same time intrude with higher levels of illumination, red light may be used to advantage.

Preadaptation to lights containing various amounts of ultraviolet radiation has been tested for its effect upon subsequent dark adaptation. Young chicks were used for this

FIG. 27. Relation between the brightness of the preadaptation and the subsequent dark interval required for the eye to reach a threshold 0.5 log unit above the final threshold. The curve for red is nearly 1.5 log units to the right of the curve for white. This means that, in order to secure the same dark adaptation in the same time, the eye must be exposed to thirty times as much red light as white. (Hecht and Yun Hsia, 1945.)

FIG. 28. The course of the dark adaptation of the eye of the young chick after pre-exposure to light containing different amounts of the ultraviolet spectrum. In proportion to the increase of the ultraviolet component below 365 $m\mu$, the final dark-adaptation thresholds are raised, indicating a reduction in potential dark adaptation by the ultraviolet. Wavelengths above 365 $m\mu$ do not produce such effects. Curves 1 to 9 represent the effects of filters that pass a progressively decreasing range of ultraviolet radiation. The final threshold is affected less and less. Curve 10 is for an ultraviolet filter that transmits all the ultraviolet radiation. This filter shows the greatest effect on the final threshold. (Wolf, 1945.)

study. The results are shown in Fig. 28. Apparently ultraviolet radiation below 365 $m\mu$ raises the threshold in proportion to the amount of ultraviolet involved.

Dark Adaptation of the Color Anomalous

For a long time it was held that the dark-adaptation curves for both types of dichromats, for anomalous trichromats, and for

dark-adaptation curves resulting from red, reddish-orange (Red II in the figure), yellow, and white lights are higher than are the corresponding sections of the curves for the color normal. The discrepancy decreases as one proceeds from the long to the short wavelengths. The curves for the protanopes resulting from the use of green and violet light are essentially normal.

FIG. 29. Composite data from two dark-adaptation curves for each of four protanopes, four trichromats, and three deuteranopes, using various 3-degree spectral test lights placed 7 degrees temporally in the visual field. The various types of observers are indicated by the letters, P, D, and T, and the spectral colors are designated in each case. Red_I is red, and Red_{II} is a reddish-orange. (Chapanis, 1947.)

normal individuals were similar, but, either the data for these assertions were never published, or else the experimental conditions left something to be desired. Since it is known that protanopes are less sensitive to long wavelengths than are deuteranopes or color-normal persons, it would be expected that dark-adaptation curves measured with red light would be different for the protanope.

Measurements on the dark adaptation of the color anomalous with red, reddish orange, yellow, green, violet, and white lights gave results as shown in Fig. 29. It will be seen that the dark-adaptation curves for the deuteranopes are essentially like those of the trichromats (normals). The protanopic

Brightness Discrimination

Absolute threshold. In brightness discrimination there are several major considerations, of which the relation between area and the absolute visual threshold is of first importance. One assumption is that a constant number of retinal elements must be stimulated in order for a threshold response to occur. Wald used fields placed 15 and 25 degrees above the fovea and found close agreement between his findings and the results expected from the assumption just stated.

An expression used to describe such data is the following:

$$(A - n_i)^k I = C$$

where A is area, n_t is a constant threshold number of elements, and C and k are constants. This, in its simplest form, $AI = C$, is Ricco's law, applying to foveal vision. When k chances to take the value 0.5, it becomes Piper's law, which pertains to the peripheral retina

$$I\sqrt{A} = C$$

It happens, however, that investigators who have studied the area-threshold relation throughout a large area range have found that the simple rules just stated do not hold precisely. Ricco's law holds, for both fovea and periphery, when the angular size of the test object is no greater than 10 minutes. Piper's law holds for the periphery for visual angles within the range of 2 to 7 degrees.

Graham, Brown, and Mote (1939) surveyed the area-threshold relation. In the fovea they used test objects with diameters ranging from 1.86 minutes to 1 degree. In the periphery they used test objects ranging from 1.86 minutes to 25 degrees and 6 minutes. In explaining their findings and in considering the possible mechanisms involved, they recognized the fact that, although a retinal image may be more or less uniform from its center to its periphery, the excitation of the retina by the image tapers from center to periphery. This introduces complications in formulating the relation between area and stimulus intensity for threshold response. The authors assumed that at threshold only the center of the retinal area is involved. All other parts of the retina within the image are excited subliminally, but they nevertheless make some contribution to the effect E at the center. The excitatory contribution of each elemental area away from the center will be inversely proportional to a power p of the distance from the center r . Therefore the excitatory contribution dE is proportional to I/r^p .

In the fovea the unit area of effect may be a single cone, but in the periphery it is a more complex affair. If e is a constant

intensity effect in each elemental area, e may be considered as being either (1) the photochemical effect occurring as a function of the intensity of the light in each receptor unit, or (2) the impulse frequency in the nerve fibers leading from the unit. Therefore e might be considered as

$$e = k_2 \log \frac{I}{I_0}$$

where k_2 is a proportionality constant, I_0 the constant threshold intensity of the receptor unit, and I the intensity of the light involved.

$$E = cR^{2-p} \log \frac{I}{I_0}$$

where $c = (2\pi k_1 k_2)/(2 - p)$, k_1 is a proportionality constant that was used in another equation (not given here) in connection with e , and R is the radius of the circle. The simplest assumption regarding threshold is that it is a constant, and the equation above becomes

$$\log \frac{I}{I_0} = CR^{p-2}$$

where $C = E/c$.

The constants found for this equation yield the specific expressions as follows: $\log I/I_0 = 1.61R^{-0.51}$ for the fovea when $\log I_0 = -2.9$; and $\log I/I_0 = 6.92R^{-0.54}$ for the peripheral retina whose $\log I_0 = -5.95$.

Differential thresholds. Brightness discrimination involves not only absolute thresholds but differential thresholds as well. Here the major consideration is the ratio of ΔI to I , but the area of the test object must be taken into account at the same time. Figure 30 shows the results when the angular size of the test object is varied from 23.5 minutes to 24 degrees. Figure 31 shows the values of $\Delta I/I$ for very small test objects (2 to 28 minutes) stimulating the fovea.

The differential threshold is also dependent upon the duration of stimulation. Here it may be said that the value of $\Delta I/I$ for constant intensity is highest for the shortest durations. It decreases as the duration is

extended and reaches a limiting constant value at long durations. The duration at which the limiting value is reached is a function of intensity. It shortens as intensity increases.

Holway and Hurvich plotted $\log I/\Delta I$ against the visual angle subtended by the

from the cornea and amounts to about 4 per cent. The second loss occurs in the ocular media between the outer surface of the cornea and the retina. For a wavelength of $510 \text{ m}\mu$ a loss of approximately 50 per cent is sustained in the media. The percentage of the energy reaching the retina, where it

FIG. 30. Human intensity discrimination as dependent upon illumination and size of test object. Each curve is for a separate size of test object. The visual angles subtended are indicated on the curves. (Steinhardt, 1936.)

test object and found a linear relation for intensities lying between 0.000625 and 500 millilamberts, a range of 59 decibels.

Minimum visible energy. The matter of threshold stimulation has been studied from another point of view, that of determining the absolute amount of energy needed to produce a perceptual end result. It has been demonstrated that very little energy is required to reach the absolute threshold of visual response. The amount of energy in the stimulus outside the eye is, of course, greater than the amount that reaches the retina. The first loss is due to reflection

is finally absorbed by the receptors, has been estimated to range from 4 to 20 per cent of the energy incident on the cornea. The best estimate, according to Hecht (Hecht, Schlaer, and Pirenne, 1941), is about 10 per cent. The initial 58 to 148 quanta reaching the cornea (Hecht) dwindle to a number between 5 and 14 before they actually become effective within the receptors. The estimated number of rods in the field used by Hecht was 500. It was considered improbable that any single rod would receive more than 1 quantum. It was therefore concluded that, in order to initiate a

visual sensation, only a single quantum of light needs to be absorbed by each of 5 to 14 rods.

FIG. 31. The influence of area on foveal intensity discrimination. The values on the curves give the radii of the test objects in minutes of visual angle. (Graham and Bartlett, 1940.)

Additional factors. Not only the size of the test object, but also the degree of contrast between the test object and its surrounds, is important to discrimination. A study of these relations requires that we vary both the size of the test object and the level of its surrounds, as well as the contrast between the test object and its surrounds. An extensive study of this sort was made at the Tiffany Foundation and published by Blackwell (1946). Findings from this work are shown in Figs. 32, 33, 34, and 35. Let B_0 represent the apparent brightness of the surrounds, and ΔB the increment either added to or subtracted from B_0 to form the brightness of the transient

FIG. 33. The "critical" visual angle in minutes as a function of adaptation level. The critical visual angle is the angle at which area times intensity of test object ceases to be a constant. The contour of this function is similar to that relating threshold contrasts and adaptation level. (Blackwell, 1946.)

FIG. 32. Curves indicating the relation between threshold contrast (between a disk and its background) and disk area, at various adaptation levels. Each curve represents a separate adaptation level is that produced by the intensity level of the field. Targets appear in any one of eight positions in an imaginary circle at the center of the field. There were five sizes of test object (disk). (Blackwell, 1946.)

FIG. 34. Each curve represents the relation between threshold contrast and area of test object for a given adaptation level. The curve for each different adaptation level is determined by the intensity level of the field. The ordinate indicates the size of the target. The abscissa indicates the threshold contrast. The target was always at the center of the field, whereas for Fig. 32 the target was in one of eight positions in an imaginary circle on the field. (Blackwell, 1946.)

FIG. 35. The relation between test-object area and adaptation level for test objects of threshold contrast with their background (field). Adaptation level is that produced by the stated intensity level of the field given on the abscissa. (Blackwell, 1946.)

stimulus, or test object, B_s . Contrast is designated as follows:

$$C = \frac{B_s - B_0}{B_0} \quad (\text{test objects brighter than surrounds})$$

$$C = \frac{B_0 - B_s}{B_0} \quad (\text{test objects less bright than surrounds})$$

Values ranging from $C = 0$ to $C = \infty$ were used for test objects brighter than the sur-

rounds, and $C = 0$ to $C = +1$ for test objects darker than the surrounds. Figure 32 shows the relation between the liminal contrast (in log units) and the logarithm of the visual angle in minutes of arc. Each curve represents the relation between threshold contrast and test object area for a given adaptation brightness. Some of the curves possess a linear portion indicating that the product of area and brightness ΔB is a constant. Test objects whose areas put them

on the linear parts of the curves are in effect "point sources." The critical visual angle is taken as the angle at which the product of area times brightness ceases to be constant. Critical visual angle is pictured in Fig. 33. The character of this function is similar to that relating liminal contrast and adaptation brightness. The curves for this latter relation are not given here, but they form the basis for the curves in Fig. 34. Figure 35 pictures the relation between test object area and the adaptation level for test objects of a number of contrasts.

When differential sensitivity is tested with isolated portions of the spectrum, the relation $\Delta I/I$ is shown to vary with intensity in the manner indicated in Fig. 36. The measurements with 670 m μ (red) exhibit a continuous function, whereas the measurements with 605 m μ (orange) begin to manifest a break because both rods and cones are involved.

Effect of anoxia on brightness discrimination. Anoxia produces a decreased differential sensitivity (see Fig. 37). The effect is marked at 15,000 feet and detectable considerably below that altitude. Impairment of brightness discrimination begins slowly and accelerates as higher altitudes are reached. It varies inversely with light intensity. Whereas the deterioration is most obvious with low intensities, it becomes negligible at full daylight levels. The oxygen lack affects vision in both the fovea and the periphery, and the general form of the relation between $\Delta I/I$ and I is the same for all oxygen concentrations. As shown in Fig. 37, anoxia merely shifts the curve along the intensity axis. This is taken to indicate that anoxia does not affect the photoreceptor system but affects rather the visual pathway beyond it.

Visual Acuity

The ability of the human visual mechanism to distinguish small spatial separations between portions of the visual field has been

FIG. 36. Human brightness discrimination for the red, orange, yellow, green, and blue parts of the spectrum. The labeling on the ordinate applies to the data for yellow (575 m μ). The orange and red curves have been raised 0.5 and 1.0 log unit, respectively, and those for green and blue have been lowered 0.5 and 1.0 log unit, respectively. (Hecht, Peskin, and Patt, 1938.)

rounds, and $C = 0$ to $C = +1$ for test objects darker than the surrounds. Figure 32 shows the relation between the liminal contrast (in log units) and the logarithm of the visual angle in minutes of arc. Each curve represents the relation between threshold contrast and test object area for a given adaptation brightness. Some of the curves possess a linear portion indicating that the product of area and brightness ΔB is a constant. Test objects whose areas put them

FIG. 37. The relation between just perceptible contrast $\Delta I/I$ and the prevailing I for each of three simulated altitudes. The curves are theoretical. (Hecht et al., 1946.)

studied in various ways. In most cases the test object has been characterized by abrupt transitions. That is to say, there are abrupt gradients (contours) between the intensity levels of the various parts of the visual field. Contours are usually seen as sharp, although the gradients in the retinal image are gradual and not infinitely steep. The kinds of test object commonly used include gratings, paired parallel bars or rectangles, single fine lines, illuminated single slits, and such figures as open circles or C's. In all cases spatial resolution is the central problem. The variation in fineness of resolution is studied in relation to intensity of illumination, state of adaptation, and duration of stimulation.

Visual acuity is defined as the reciprocal of the minimal effective visual angle in terms of minutes of arc. This notation is used in order to make high numerical values of acuity reflect high degrees of excellence in visual acuity, rather than the reverse.

A typical study is that of Shlaer (1937) whose results are pictured in Fig. 38. He used both a grating, whose overall visual angle was 4 degrees, and a C-shaped figure. He obtained somewhat different results in the two cases. Below about 30 trolands, the

grating yields better visual acuity. At higher levels, the C is better than the grating. Figure 39 is a plot of the visual acuities for the same two test objects, but here the

FIG. 38. The relation between visual acuity and retinal illumination for two kinds of test object—a grating, and a C, or broken circle. See Fig. 39 for theoretical curves on a log-log plot. (Shlaer, 1937.)

logarithm of visual acuity is plotted on the ordinate (hence a log-log plot). In this type of graph the cone and rod portions of the curves show up more distinctly than when visual acuity is plotted on a linear scale.

When parallel bars are used to test visual acuity, several factors are effective. They

FIG. 39. Curves showing visual acuity for two different test objects. On this log-log plot each curve appears to be composed of two segments. The lower segment represents rod function; the upper segment represents cone function. Below approximately 30 trolands the grating yields better visual acuity values, whereas the C is superior at higher intensities. At low intensities about ten times more light is necessary for the C than for the grating. (Shlaer, 1937.)

include the intensity relations between bars and surround (light bars on dark field or dark bars on light field) and the widths of the bars themselves. Wilcox found that visual acuity continued to increase with increases in the level of the ground when dark bars were seen against a light ground. As the intensity of the light bars was raised, however, visual acuity first improved, then reached a maximum, and finally declined (see Fig. 40). In order to explain this effect the ideas of *irradiation* and *negative irradiation* were used.

Fry and Cobb (1935) showed that the width of two bright bars on a dark field affects visual acuity. With both wide and narrow bars visual acuity initially improves as the intensity of the bars is increased. With the wide bars the initial rapid improvement changes to a slower improvement. With the narrow bars it changes to an actual decline in visual acuity.

Not only paired bars but also single fine lines have been used to determine visual acuity. Hecht and Mintz used a fine wire bisecting a homogeneous lighter visual field that subtended a large visual angle. They found that the finest resolvable line at the highest illuminations subtended a visual

angle of only 0.5 second. In terms of actual visual acuity this is 120 times greater than the "standard acuity" of 1 minute and about

FIG. 40. Curves showing visual acuity as measured by parallel bars. (Modified from Wilcox; Bartley, 1941.)

60 times greater than the acuity obtained with a C or a grating. It is shown in Fig. 41.

Niven and Brown used a bright slit on a dark ground to determine the relations

among three variables: the minimal visual angle, the duration of exposure, and the intensity of the slit illumination. The results

FIG. 41. The relation between intensity of background and the visual angle subtended by the thickness of wire when it is just resolved against its background. The upper section of the curve is for rod vision; the lower section is for cone vision. (Hecht and Mintz, 1939.)

are shown in Fig. 42. Each curve is for a single duration. Increasing the duration of the exposure simply displaces, to the left, the curves showing the relation between log visual angle and log intensity.

Figure 43 indicates the effect of selected portions of the spectrum, and pupils of con-

trolled size, on measurements of visual acuity. When red light (predominantly $670\text{ m}\mu$) is used, there is no break apparent between rod and cone levels of function. When blue light (predominantly $450\text{ m}\mu$) is used, the break shows up very plainly.

Flicker

Not only dark adaptation and various forms of stationary brightness discrimination, but also the discrimination of intermittent stimulation, has been studied for its possible contribution to photochemical theory. Figure 44 (left) indicates the findings when a 2-degree test object is studied. The critical flicker frequency (cff) is the flicker rate in flashes per second at which the field just becomes steady. It will be seen that the curve tends to reverse after reaching its maximum, especially with the 10-degree surround. This tendency is even greater with no illuminated surround whatsoever.

Figure 44 (right) shows the outcome when the area of the test object is varied.

Figure 45 (left) shows the results of shifting the original 2-degree test object to positions away from the fixation point. Figure 45 (right) represents the outcome of using a test object having a 19-degree diameter and different wavelengths. The intensity range covered by the red ($670\text{ m}\mu$) is the narrowest. Hecht and Shlaer (1936) state

FIG. 42. The relation between the logarithm of the visual angle subtended by the test object (illuminated slit) and the threshold intensity for exposures of various durations. The subject's task was to determine the direction of orientation of the slit. (Niven and Brown, 1944.)

FIG. 43. *Left.* A typical curve showing the relation between visual acuity and retinal illumination when red light and a grating test object are used. The filled circles are for a 2-millimeter pupil. The open circles are for a 3-millimeter pupil. *Right.* Same relation but for blue light and a 2-millimeter pupil. The open circles are for one subject, and the solid circles for another. All points below a log I value of -1.5 were made in a subjectively colorless field and represent pure rod function. (Shlaer, Smith, and Chase, 1942.)

FIG. 44. *Left.* Critical flicker frequency as a function of the illumination. The experiment employed central fixation of a 2-degree flickering field with a 10-degree surround and with a 35-degree surround. (Hecht, 1938.) *Right.* Influence of the area of the test field on the relation between critical flicker frequency and retinal illumination. (Hecht and Smith, 1936.)

FIG. 45. *Left.* The relation between cff and log I for white light with a 2-degree field in three different retinal locations: at the fovea, and at 5 and 20 degrees above the fovea. (Hecht, 1938.) *Right.* The relation between cff and log I for different parts of the spectrum. Eye of S. Hecht. (Hecht and Shlaer, 1936.)

that the measurements are faithfully described by two similar equations. One of these is for the rods; the other for the cones. Both equations are derived from the stationary state equation he uses for other visual functions.

NEURAL MECHANISMS

Even though the visual sense cell is a photoreceptor, its behavior is described here rather than in the previous section, which dealt with photochemical considerations. The sense cell also manifests electrical activity, and therefore its behavior is allied to that of the neural units succeeding it in the visual pathway.

Electrical Effects in Single Receptors

Hartline and co-workers (Hartline, 1940) have determined the temporal characteristics of the electrical discharge of single receptors under various conditions. They used the horseshoe crab, *Limulus*, which has compound eyes whose neural connections lie at some distance from the receptors. This permits recording from receptor units prior to the development of neurally produced complications.

In the undivided nerve of the horseshoe crab the response to light consists of slow potential changes upon which are superimposed rapid irregular fluctuations (impulses). When the nerve is divided into sufficiently small strands, a regular sequence of uniform nerve impulses appears. These are taken to be the successive discharges of a single fiber, the result of stimulating a single ommatidium. The discharge of a single fiber may reach a frequency as high as 130 impulses per second at the outset of stimulation.

Since the eye of this crab does not possess lateral connections analogous to the internuncial neurons of the vertebrate retina, it may be used for studying the "area effect." The ommatidia respond with the same latent period regardless of how many are stimulated. This is true over an intensity range

of from 1 to 10,000 (40 decibels). The magnitude of the retinal potential, however, is directly proportional to the number of elements illuminated, up to one-half the area of the eye. Beyond this the response increases less rapidly, owing to the angular displacement of the peripheral elements.

Each receptor of a compound eye exhibits a luminosity (visibility) curve just as does the human eye taken as a whole. Figure 46

FIG. 46. Luminosity curve for a single visual cell. Relative effectiveness of each spectral band is the reciprocal of the relative intensity necessary to produce a specified burst of impulses. Value at 530 $m\mu$ set equal to 100 per cent. (Data from Graham and Hartline, 1935; Hartline, 1940.)

shows a typical curve for a single receptor cell of the horseshoe crab. It is not greatly different from the curve for the human eye, except that the curve for the single receptor cuts off earlier toward the longer wavelengths.

The discharge rate in a single receptor following the onset of steady illumination is pictured in Fig. 47 (left). The rate is high at first, but it falls quickly to a much lower value. The very strongest illuminations result not only in the "initial burst" just described but also in a momentary pause in the discharge following the burst. This is called the "silent period." Low illuminations may yield records that show acceleration of the discharge rate from the very start, with no silent period.

Discharge rate is related positively to level of illumination, as indicated in the right-

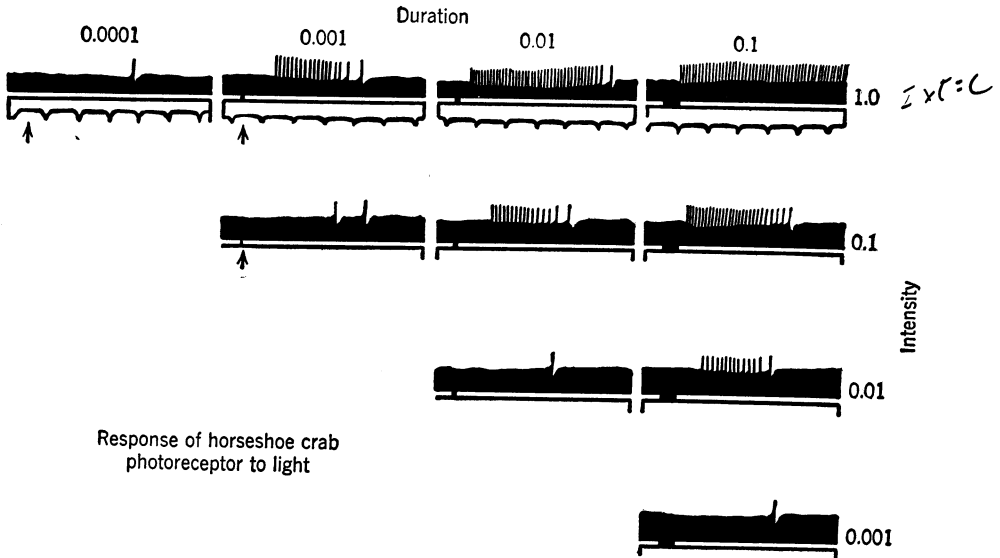

Fig. 47. *Left.* Frequency of impulses per second versus time after the onset of illumination. Curve A is for an intensity of 0.1. Curve B is for an intensity of 0.001. Curve C is for an intensity of 0.0001. Intensity is in arbitrary units (1 unit = 630,000 meter-candles on surface of eye). The points give the average frequency of four successive impulses. The time value is assigned to the second impulse. *Right.* The relation between frequency of impulse and intensity of stimulating light, in arbitrary units. Curve A, frequency of the initial maximum discharge. Curve B, frequency of discharge 3.5 seconds after onset of illumination. (Hartline and Graham, 1932.)

Response of horseshoe crab photoreceptor to light

Fig. 48. Oscillograms showing the bursts of impulses in a single optic nerve fiber in response to short pulses of light of various intensities and durations. Relative intensity for each horizontal row is given on the right (1.0 = 3×10^6 meter-candles). Duration of pulse for each vertical column is at the top, in seconds. Signal of light pulse blackens the white line above the time marker (arrows mark position of signal for very short pulses). Time marked in $\frac{1}{5}$ second. (Hartline, 1934.)

hand diagram of Fig. 47. Two curves are included: *A*, for the frequency of the initial maximum, and *B*, for the rate 3.5 seconds after onset of illumination.

For very short pulses of light it is the quantity of light that counts. The amount of light required to reach threshold or to elicit a given number of impulses is the product of the intensity and the duration of the pulse, $I \times t = c$. An actual demonstration of this reciprocity between intensity and duration is provided in Fig. 48.

Increasing the intensity of a pulse of constant duration reduces the time elapsing before the response occurs (latent period) and increases the frequency and the total number of impulses discharged. For various features of the response, such as the initial or the maximal frequency of discharge, only those pulse durations that are shorter than the time required for the appearance of the features themselves can be considered. When the pulses are shorter than the latent period, the lengthening of a pulse of fixed intensity acts as does an increase of intensity. For both initial and maximal impulse frequency the reciprocity relation ultimately fails and is replaced, at a critical duration, by the condition in which intensity alone determines the response. Since this critical duration is considerably shorter than the time that elapses before the appearance of the response impulses, it is inferred that the impulses are determined within the sense cell earlier than the time indicated by the appearance of the impulses at the recording site.

The process of adaptation in a single sense cell is shown in Fig. 49. In this figure, responses to a test pulse at each of four intervals during the sense cell's stay in the dark is pictured.

If pulses, ΔI , are added at random intervals to a steady illumination, I (which elicits a steady discharge of impulses), additional impulses will result. Significant information regarding receptor behavior can be obtained by varying the intensity of the pulses and by varying the level of the steady

illumination. Pulses of light added to a steady (adapting) light increase the impulse discharge frequency. This effect occurs throughout the interval from the twentieth to the eightieth second of light adap-

FIG. 49. Dark adaptation of a visual sense cell. Bursts of impulses in an optic nerve fiber in response to a test pulse of 0.01 second ("flash") thrown upon the eye at various times (given at left), following an adapting exposure. Signal of pulse appears on white line in the record. (Hartline, 1940.)

tation and declines slowly during the remainder of the adaptation period (see Fig. 50).

The value of ΔI that just elicits an additional single impulse with a given latency varies with the time elapsed since the appearance of the preceding impulse resulting from the steady "adapting" illumination (Riggs and Graham, 1945). This interval is called the "recovery time." As this in-

Retinal Ganglion Cell Discharge

In the vertebrate retina it is next to impossible to obtain records from single receptors. While this goal is being approached, the chief record now obtainable is from the ganglion cell axons. The ganglion cell discharge is not related so simply to intensity and timing of stimulation as is the discharge recorded from receptors of the horseshoe crab.

FIG. 50. *Left.* Increment Δf in impulse frequency as a function of time after the beginning of light adaptation. Each curve represents a designated value for ΔI , the increment in illumination responsible for Δf , the increment in impulse frequency. Adaptation intensity 49 foot-candles. *Right.* Logarithm of the sensitivity of the photoreceptor (defined as the reciprocal of the value of ΔI required to make the impulse frequency reach 30 per second) as a function of the time following the beginning of light adaptation. ΔI is the intensity of the flash above that of the steady illumination used to adapt the receptor. (Riggs and Graham, 1940.)

to elicit a response and changes the maximal interval within which recovery is measurable.

For constant added response (response to ΔI) the following relations hold: (1) At any level of adapting illumination, the latency diminishes as recovery time increases. (2) The value of ΔI needed to produce a constant response is small for low values of I and increases as I is raised. At low adapting illuminations the minimal latency of the constant added response (response to ΔI) tends to be long. (4) As I and the ΔI used with it rise, latencies tend toward smaller minimum values. (5) With increase in I and ΔI , the change of latency with recovery time increases. (6) As I and ΔI increase, maximum recovery time shortens.

In the frog, three kinds of discharge have been found. Some ganglion cell fibers exhibit trains of impulses only during the absorption of light by the receptors. Other cells discharge only at the beginning of illumination and just following its cessation. A third kind of discharge arises only after cessation of illumination and continues longer than the "off" discharge in the second group. The first kind of discharge has been called the maintained or X type; the second, the on-off or Y type; and the third, the off or Z type. About 20 per cent of the fibers belong to the X, 50 per cent to the Y, and 30 per cent of the Z type (see Fig. 51).

In the guinea pig retina, where there are only rods, the vast majority (90 per cent) of the elements begin their discharge at the onset of illumination. Whereas they all con-

tinue to discharge throughout receptor illumination, some possess a definite after-discharge. About 8 or 9 per cent of the elements are the on-off type, and 1 or 2 per cent are the pure off-type.

In the duplex (rods and cones) retina of the cat, the great majority of the elements

frequency is compressed. On this account, frequency-intensity curves for the light-adapted state rise more rapidly. In both the cat and the guinea pig spontaneous activity in isolated elements is demonstrable, and its suppression is taken to be an indication of inhibition.

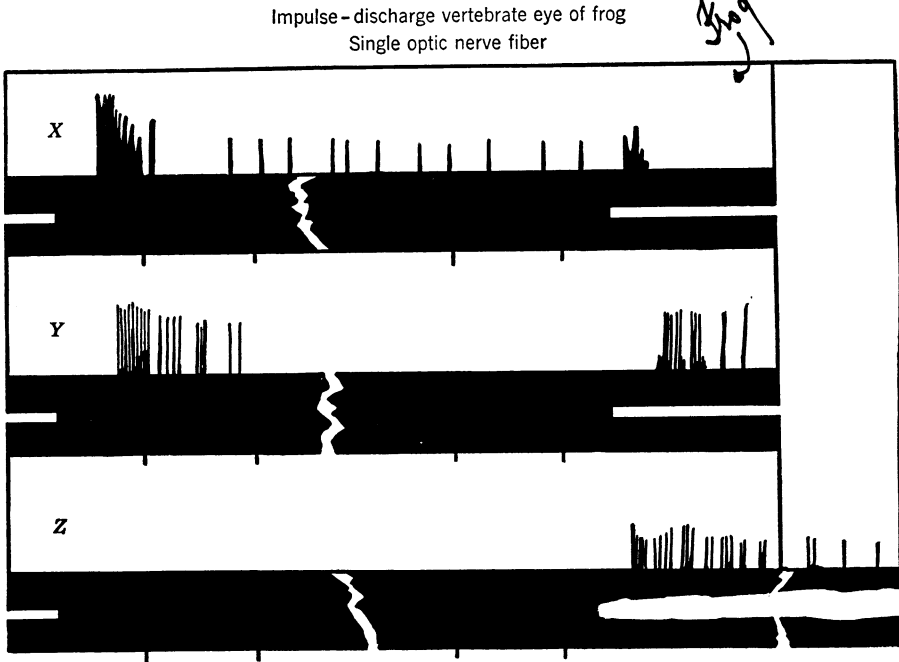

FIG. 51. Somewhat schematic oscillograms showing the discharge of impulses in single optic nerve fibers of the vertebrate eye (frog), illustrating the three most common types of response to illumination of the retina. Onset and termination of stimulation are indicated by the white line in the center of the black bands. Time marked in $\frac{1}{8}$ second. (Hartline, 1938.)

appear to be the on-off type. Pure off-elements are very rare.

It would appear that the proportion of the on-off discharges recorded in the cat varies greatly with stimulus conditions. Light adaptation tends to affect the activity in the following ways: (1) It raises the thresholds of the various elements. (2) It shortens the duration of the after-discharge, if any. (3) It decreases the number of impulses at the onset and termination of illumination. And (4) it does not alter the maximum rate of discharge. Since the threshold is raised, the intensity range effective in varying fre-

Each optic nerve fiber (ganglion cell axon) is fed from a *receptive field* of the retina. A single fiber responds to retinal stimulation anywhere within a limited area. The limits of such a field have been mapped by Hartline, by means of a very small spot of light whose location could be accurately manipulated. The receptive field is smallest under threshold illumination. It is then somewhere between 0.25 and 0.50 millimeter in diameter. When intensities are raised to 100 or to 1000 times the threshold, the area doubles. The effectiveness of a small spot is greatest when the spot is near the center

of the receptive field. Two spots of light placed within the receptive field summate in effect. Fibers carrying *Y* or *Z* responses respond to the movement of a bright spot or to a shadow produced within the receptive field.

The Electroretinogram

The electroretinogram is one of several types of record indicating features of the neural mechanism in the retina. The electroretinogram (ERG) is the overall pattern of potential elicited by momentary illumination of the retina and is recorded by placing one electrode on the cornea and one on the back of the eyeball. It does not exist as a recordable wave pattern during continuous illumination, nor when intermittent illumination reaches a high frequency. It is not a highly differentiated response, although it does vary with stimulus conditions and with internal conditions of the eye, such as degrees of asphyxia, drug application, etc. The ERG consists of a small, brief negative deflection (the *a* wave) a much larger positive wave (the *b* wave), and a second slow rise called the *c* wave. The *c* curve follows the decline of the *b* wave. The first two waves are the *on* response. At the cessation of illumination, if a *c* wave exists, an *off* response develops as a slight positive hump and a rapid decline to the base line.

From an analysis of these waves the existence of three components, *PI*, *PII*, and *PIII*, has been deduced. *PI* is a prolonged positive deflection, largely the *c* wave; *PII* is largely the *b* wave; and *PIII* is a negative component. Since *PIII* develops at the onset of stimulation, its initial negative swing is uncompensated and appears in the record as the *a* wave. From the way the components behave under various stimulus conditions, deductions concerning facilitative and inhibitive processes in the neuroretina have been made.

One significant result sometimes obtained with intermittent stimulation is that a *b* wave (the main feature of the response in

such cases) is not elicited by each pulse of light but only by alternate pulses. If the frequency of intermittent stimulation is reduced, a small *b* wave may appear as a response to each flash that formerly produced no wave. As the frequency is further reduced, the initially small wave increases in size. With low enough frequencies all pulses are followed by *b* waves of equal size. This phenomenon is taken by some (Bartley, 1939) to indicate that the recovery of elements responding to the first pulse is not accomplished by the time the second pulse is presented. If a little more time between pulses is allowed, a small response is possible; with still more time, a larger one. This "alternate-response" phenomenon does not always occur, nor would it be expected to. Under some conditions all pulses quite soon are responded to by equal numbers of elements, regardless of pulse rate, each pulse activating a fraction of the elements. Succeeding pulses would activate similar fractions, in keeping, of course, with the length of the actual activity-recovery cycle of the elements. That these elements are neural complexes, and not simply receptors themselves, is indicated by the length of the cycles involved.

In certain subfusional ("flicker") experiments it was found that the flashes or fluctuations seemed to have a rate one-half that of the stimuli. Hence there is a definite perceptual counterpart of the ERG phenomenon just described.

The ERG of the human eye elicited by a brief pulse of light can be divided into two parts, based on the dissimilar behavior of the scotopic and photopic mechanisms of the retina. The photopic part is a short diphasic potential, the cornea initially negative. This response is elicited by white light, or by any monochromatic light except blue. It is manifested in the light-adapted eye and is little augmented by dark adaptation. The scotopic part is a more prolonged monophasic potential (0.3 to 0.4 millivolts), and the cornea is positive. All parts of the spec-

trum except the deep red will elicit it. It is not elicited in the light-adapted eye, and it varies in size in keeping with the degree of dark adaptation, quite parallel to the increase in visual sensitivity.

The two response components, scotopic and photopic, can be elicited in pure form by deep blue and deep red illumination, respectively. The form of the responses does not change with intensity of illumination, whereas the size does. White light and wavelengths intermediate between red and blue give rise to a compound response containing the two response components. As might be expected, the photopic response is more dependent upon the intensity of illumination of the central part of the retina, and the scotopic upon that of the retinal periphery. Furthermore the scotopic response has not been detected when a brief light pulse is added to a field already steadily illuminated at a level of two apparent foot-candles, but is present when the level is reduced to 0.3 foot-candle. With repeated pulses the scotopic component diminishes quickly after the first few pulses.

The Optic Nerve Discharge

The optic nerve discharge provides another method for determining something about the behavior of the visual pathway. The optic nerve discharge is highly manipulable, and the responses to a series of light pulses disclose aspects of dark adaptation, as well as a number of other features related to brightness vision (see Bartley, 1942).

Pulses that are just suprathreshold elicit merely a single small wave in the optic nerve record. (Owing to the method of recording, all waves are monophasic.) Pulses that are either stronger or longer (greater quantity of light) elicit a larger wave that soon becomes somewhat bimodal and sharp-crested. The progress of these changes as the pulses are intensified or increased in length is shown in Fig. 52.

A perceptual counterpart of the secondary wave *S* in Fig. 52 has been demonstrated by

Bartley (1942). Within a certain range of stimulus intensities and durations, a second flash is seen, although only a single pulse of light is actually presented. Too little or too much light, in the form of either intensity or duration, elicits only the subjective end result of a single flash. The conditions that produce an *on* response with a secondary wave *S* are comparable to those that produce the impression of a pair of flashes. The *S* wave is presumably the basis for the second flash of the pair.

It is possible to arrange the stimulus conditions so as to bring out numerous other variations in the discharge record of the optic nerve. In the foregoing example, however, we have a demonstration of the possibility of correlating sensory outcome with neural events.

The Response of the Optic Cortex

It is possible to record electrical responses from the surface and from the underlying layers of the optic cortex in experimental animals and to correlate some characteristics of these responses with features of the sensory end result (in man) obtained with the same stimulus setup. The optic cortex, like other parts of the brain, is continuously active. One feature of the activity is the periodic fluctuation called the alpha rhythm. In the rabbit this rhythm is at a rate of about 5 per second; in the cat, 7 or 8 per second; and in man, about 10 per second.

The electrical response of the optic cortex to pulses of light indicates that it is made up of three components (Bishop and O'Leary, 1938): (1) a series of rapid small waves of the order of axon spikes; (2) a larger diphasic or triphasic wave (surface initially positive); and (3) a longer triphasic series of undulations of the temporal order of the alpha rhythm. The first of the small waves or spikes is interpreted as the activity of the axons in the afferent radiation. The second indicates the activity within the cortex analogous to the spread of activity in the inter-

calary neurons in the spinal cord. The third seems to signal the cortifugal discharge, perhaps in the pyramidal cells, to various regions including the superior colliculus; it can be recorded at depths below the cortex.

Experimental procedures may alter the waves of the second major component in

the elements responsible for the second component of the cortical response is enhanced.

The cortical response manifests both an *on* and *off* response to intermittent stimulation, and in this and other ways it forms a useful indicator for certain experimental purposes.

FIG. 52. A schematic diagram to show the components of the optic nerve discharge in response to pulses of light (black bars) varying in intensity (1st column) and in duration (2nd column). Record 1 is the response to a just suprathreshold stimulus. *O* is the *on* response. The succeeding records are the responses to light pulses of progressively greater intensity. *R* is the series of small irregular waves or ripples. *S* is a secondary wave that emerges to replace the ripples within a critical range of stimulus intensities. *S* reduces to a mere vestige, as shown in record 5. The second column shows that *S* also emerges as duration (quantity of light) of the pulse is increased. *S* is not to be mistaken for the off response *T* shown in records 9 and 10. *L*, in each record, represents latency or point of onset of response. *T* in record 9 indicates the first appearance of an off response, which in 10 has become longer and later. In 9 it precedes *S*, and in 10 it precedes the vestige of *S*. (Bartley, 1942.)

ways different from those in which the third or slow component is altered. Strychnine applied directly to the cortex obliterates the third and augments the second component. The spikes in the record, produced by application of strychnine to the cortex are quite like those seen in the human electroencephalogram (EEG) in epileptic seizures, and this has led to the conclusion that in such seizures it is *not* the alpha rhythm that is being augmented. Rather the alpha rhythm has disappeared, and the activity of

Intermittent Stimulation

The use of the factor of timing in stimulation, particularly as it is involved in the presentation of paired or serial light pulses, has yielded considerable information about the functioning of the visual pathways. It has led also to correlations between neural events and the sensory end result. A number of these findings have disclosed phenomena not explainable by photochemical theory. Major examples of such phenomena are brought together in what follows.

The studies of some workers have led them to reject the photochemical determination of the sensory outcome as affirmed by Hecht and others. Crozier and colleagues, Wolf and Zerrahn-Wolf, have studied the responses of a number of animal forms to in-

mal. The following are the animals used, according to the kinds of retinas possessed: (1) those having rods only (gecko, horned lizard); (2) those having cones only (turtle, bird); (3) those having both (duplex retinas) (frog, fish, man); (4) those pos-

FIG. 53. The cff curves for the horned lizard and the gecko. The horned lizard possesses a cone retina; the gecko a rod retina. The curves for both resemble probability integrals. With the gecko, certain techniques had to be employed to compensate for eyelid behavior that modified the cff. When the proper compensations were made, the cff at low intensity levels was taken to be that represented by the broken line. (Crozier and Wolf, 1939a; 1941.)

termittent stimulation and have outlined a neurostatistical rather than a photochemical picture of the underlying mechanisms at work. In their experiments the test animals are placed inside a rotating cylinder possessing alternate opaque and transparent vertical bands. Light of measured intensity shines through the transparent stripes, and the speed of the cylinder and the intensity of the light are so adjusted as just to produce the required reaction of the ani-

mal. The following are the animals used, according to the kinds of retinas possessed: (1) those having rods only (gecko, horned lizard); (2) those having cones only (turtle, bird); (3) those having both (duplex retinas) (frog, fish, man); (4) those pos-

sessing three groups of receptors (two kinds of cones plus the rods) (newt); and (5) those possessing compound eyes (crayfish, dragonfly, bee). The attempt throughout was to measure precisely the cff for the separate retinal receptor populations. When the activities of the rods and cones are separated, the curve representing the activity of each describes an integral of the normal probability curve. Accordingly, Crozier and his colleagues de-

veloped a *statistical* theory to account for the results obtained.

The following are some of the assumptions that underly their theory: (1) Visual brightness is a function of the total "neural effect"* reaching a certain crucial station in the nervous system. (2) A jnd, whether

that any increase in stimulus intensity can be expected to produce is, in part, determined by the difference between the effect then existing and the maximum possible effect. This is called the *availability principle*. Presumably the amount of effect representing a jnd is constant, whereas the amount of

FIG. 54. *Left.* Cff for the sunfish (*Lepomis*). The two curves are for two procedures: (1) in which the rotation of the stripes was held constant, and the illumination was varied to obtain the cff (open circles), and (2) in which illumination was held constant at each of the various levels, and the rotation speed was varied to obtain the cff. *Right.* Cff for man. Same type of apparatus used as with lower animals, i.e. a revolving drum with alternate black and white stripes. The data shown were taken on a series of successive days, after considerable practice. Each plotted point is the mean of ten readings. (Crozier, Wolf, and Zerrahn-Wolf, 1937b.)

absolute or differential, is the result of the addition or subtraction of a certain amount of neural effect to or from that already existing by virtue of the standard stimulus. (3) The threshold intensity (in logarithmic terms) for initiating nerve impulses varies from unit to unit and in the same unit from time to time in a random fashion. (4) There is a maximum neural effect that can be set up in any group of neural units under the most favorable conditions. (5) The effect

* This neural effect is not exclusively one of frequency of impulses, for it must also involve spatial distribution (ultimately, total number per unit time). Nevertheless the principles of Crozier's theory can be made clear by the expedient of description in terms of impulse frequency.

(stimulation required to set up this additional neural effect is a function of the additional impulse frequency or other neural effect left available before the maximum is reached.

The following curves illustrate the statistical nature of the visual responses in different types of retinas. Figure 53 presents the "flicker curve" for the rod retina of the gecko and for the cone retina of the horned lizard. Similar curves for duplex retinas (sunfish and man) are shown in Fig. 54. These are composite curves resolvable into two parts, one for the rods (at low intensities) and one for the cones (at high intensities). Each of these parts has the shape of a normal probability integral.

The cff curve for a retina having three types of functional units is shown in Fig. 55. Here we have a composite curve resolvable into three probability integrals.

ommatidia are not pointed toward the light coming from a single direction. Thus, especially when illumination is low, a sizable fraction of the ommatidia will not be act-

FIG. 55. Cff for the newt (*Triturus viridescens viridescens*). The dashed line is a probability integral. The left-hand dotted curve represents the rod contribution. The right-hand dotted curve corresponding to the bulge between $\log I = -2.0$ and $\log I = 0.5$ presumably represents the activity of a third group of receptor units. (Crozier and Wolf, 1940.)

FIG. 56. *Left.* Cff for the *Asellus*, an isopod with a rather flat compound eye. The data are fitted to a probability integral. *Right.* A comparison of the curves for the *Anax*, the bee (*Apis*), and the isopod *Asellus*. The departures from the probability expectations in the first two cases and the strict adherence in the third are made graphic by the plotting of the data on a probability grid, in which the numbers on the ordinate are so spaced that a probability integral plots as a straight line. F is critical flicker frequency. F_{\max} is maximal critical flicker frequency. (Crozier, Wolf, and Zerrahn-Wolf, 1939b.)

Figure 56 depicts the cff response for three animals having compound eyes. Some of these eyes are quite convex, and all their

activated, and a departure of the cff curve from the normal probability integral will ensue. This is especially true for *Anax* and *Apis*. In

contrast, a strict adherence to the probability function is shown in the isopod *Asellus*, whose eye is relatively flat.

Discrepancy between Flicker and Stimulus (Flash) Rate

When flash rate is low, the subjective alternation between light and dark follows the stimulus, but this principle does not hold when frequencies approach cff. Bartley (1938a) showed that even when (with feeble

(see Fig. 57). This phenomenon is not predicted by present-day photochemical theory. It would appear to be based upon the inherent discharge rate of the retinal ganglion cells. Hence it is an example of the participation of the neuroretina in visual brightness discrimination.

Spontaneous Activity in the Retina

Granit (1941) has recorded what he calls rotational activity and spontaneous rhythms

FIG. 57. Residual flicker is the last vestige of flicker just before a visually steady field is produced. The rate of this flicker is not related to the cff but remains nearly steady at a rate supposedly in the neighborhood of 20 per second. This result is attributed to the determination of residual flicker by the intrinsic discharge characteristic of the retinal ganglion cells, rather than by the flash rate. (Bartley, 1941.)

illumination) cff was as low as 4 per second, the subjective or perceived flicker manifested a relatively high rate. By a comparison method it was concluded that this rate lay in the neighborhood of 20 per second. When, at higher intensities, the cff was about 50 per second, the perceived flicker appeared to occur at the same frequency as in the former case, namely about 20 per second

from the retina. By means of a microelectrode technique, he has found that single activity units, as well as many individual active elements, exhibit definite rotation by pausing and again resuming activity at random intervals. He states that spontaneous activity in such elements is of two types: (1) discharges that can be temporarily or indefinitely inhibited by illumination or mo-

mentarily stopped by discontinuance of illumination, and (2) discharges that persist irrespective of the presence or absence of illumination. Spontaneous rhythms can be set up or enhanced by rhythmic stimulation. In these facts we see a possible basis for the discrepancy, found by Bartley, between the stimulus frequency and the sub-

hancement is at its maximum. This rate coincides with the alpha rhythm. That this is not a mere coincidence is suggested by the fact that optic nerve stimulation and light pulses to the retina are both maximally effective in producing responses at the optic cortex when supplied at the rate of the alpha rhythm. This and a number of other facts

FIG. 58. At some subfusional pulse frequencies the brightness of the pulses appears greater than the brightness of steady illumination of the same physical intensity. This enhancement is maximum in the neighborhood of 10 pulses per second. The three curves represent three different LDR's. $A = \frac{1}{4}$; $B = \frac{1}{2}$; $C = \frac{3}{4}$. D , E , and F are the Talbot brightnesses for these ratios. The Talbot brightness is the brightness predicted by Talbot's law: rapid intermittent stimuli produce a brightness equal to that produced by a steady stimulus having the same average intensity. (Bartley, 1939.)

jective frequency of intermittent stimulation described in the preceding section.

Brightness Enhancement

Another phenomenon that has not as yet been explicitly dealt with in photochemical theory is known as brightness enhancement (see Fig. 58). It is possible for an observer to match the brightness produced by a series of light pulses to the brightness produced by a steady light. This is done by adjusting the physical intensity of one or the other. For subfusional pulse rates it is found that the average physical intensity of intermittent light need not be so great as that of the continuous illumination in order to be equally effective. When the pulsation rate is in the neighborhood of 10 per second, en-

indicate that a major component of the optic-cortex response to light involves the same cortical elements as the alpha activity.

Relation between LDR and Cff

One of the most significant findings in this area is illustrated in Fig. 60, which shows a number of cases in which the light periods are long and the unstimulated (dark) periods are short, and vice versa. This information was taken from Fig. 59. The question is: why, with a fixed intensity of light pulse, may the LDR vary so greatly with only a small variation of cfi (critical flicker interval, or $1/\text{cfl}$)?

The problem is to explain why a slight shortening of the light fraction of the cycle, when the fraction is great, produces flicker;

FIG. 59. *Left.* The relation between *cff* and stimulus intensity for four different light-dark ratios (LDR). Each curve represents a different LDR. *A* = 0.97 of cycle in darkness, *B* = 0.90, *C* = 0.50, and *D* = 0.09. When the intensity is raised, the *cff* increases to a peak and then declines. The dashed lines numbered from 1 to 5 represent points at which values on the ordinate were taken to plot curves 1 to 5 in the figure at the right. *Right.* The abscissa represents critical flicker interval (*cfi*), or $1/cff$. The ordinate represents the percentage of the cycle occupied by the dark phase. Each curve is for a different pulse (flash) intensity. (Bartley, 1937.)

Light-dark ratios for various *cfi*'s

FIG. 60. The times occupied by the lighted and unlighted portions of the various *cfi*'s represented in Fig. 59. For example, the dashed line labeled 4 in Fig. 59 cuts curves *A*, *B*, *C*, and *D* at the same intensity level ($\log I = 2.5$). These curves represent closely similar *cfi*'s and *cfi*'s. This fact is represented in the present figure by the closely similar lengths of the bars in the group labeled $\log I = 2.5$. Each bar represents the actual *cfi* or the time occupied by a light-dark sequence (a "flicker cycle"). The white portion represents the light interval; the black portion represents the dark interval. Despite the closely similar values of *cfi* the fractions of the cycle occupied by the light and dark phases may be quite dissimilar. Thus for $\log I = 1.28$, the *cfi* may be shorter when the light pulse occupies most of the cycle than when it occupies a trivial fraction of it. (Bartley, 1937.)

because no flicker exists when the light fraction in a cfi of almost the same length is very short. Figure 60 pictures cases of this kind for pulses of several different intensities. Although the results are not quite the

nation of this curious fact is that shortening the long pulse allows enough time for an *off* response to occur at each repetition of the cycle. This off response would be expected to result in flicker. An off response does not

FIG. 61. The relation between the cfi of an area and the intensity of a surrounding annulus. The Talbot brightness of the disk is indicated by the vertical line at 0.5 candle per square foot. The curves indicate that a steady stimulus applied to one area of the retina affects the cfi of a stimulus in another region. As the intensity of the steady stimulus rises from zero the cfi also rises, but it falls again when a critical point is reached. Apparently the steadily stimulated area depresses activity in the intermittently stimulated area. Below a critical intensity it depresses the weak phases of activity and thus raises the cfi. Above this critical intensity it depresses the strong phases also and thus lowers the cfi. When the distance between the two stimuli is sufficient, the critical intensity lies beyond the range investigated and no reversal appears. (Fry and Bartley, 1936.)

same for all intensities, the general principle just implied is pretty well illustrated in all the examples.

If, for a given cfi, the very short pulse just succeeds in eliminating flicker, it might be expected that a long pulse would provide more light than needed for fusion. But shortening the long pulse may abolish fusion and give rise to flicker. A possible expla-

occur when the light portion of the cycle is very short. On the other hand, short light pulses are able to produce uniform firing of impulses throughout the cfi's represented. Long light pulses certainly are able to do the same. They even provide for more rapid firing of impulses and induce sensations of greater brightness. But when these long pulses are shortened just enough for off re-

sponses to develop, the result is an alternation of *on* and *off* responses. This produces flicker.

Interarea Effects

A steady illumination of one part of the retina influences the activity in an adjacent portion illuminated intermittently. The results pictured in Fig. 61 indicate that, as the

ferential between the weak and strong phases of the fluctuation cycle.

Another interarea effect of retinal stimulation shows up as contour formation. If the test object is a disk within an annulus, and if the disk is illuminated intermittently while the illumination of the annulus is kept constant, the following phenomena is observed. For flash frequencies below 10 per

FIG. 62. The intensity of an annulus surrounding a flashing disk has certain effects on the disk's contour. If the intensity of the surround is above the Talbot level, the disk's dark phase is predominant and contoured, and the light phase is uncontrored. If the intensity of the surround is below the Talbot level, the light phase is predominant and contoured, and the dark phase is uncontrored. Cff for the disk is designated by the perpendicular at the extreme right. The Talbot level is the level of the steady stimulus that is equivalent to the flashing stimulus in effective brightness. (Bartley, 1939.)

intensity of the steady illumination (annulus) is raised from zero, the cff of an enclosed disk undergoes significant changes. As the distance between the two retinal areas involved is increased from zero, the intensity of the annulus for which the cff of the disk is maximal becomes greater and finally lies above the range of intensities tested. This phenomenon is taken to mean that the steadily stimulated area depresses the activity in the fluctuating area. Below the critical intensity it depresses the weak phases of activity and thereby raises the cff. Above the critical intensity the strong phases of the fluctuation cycle are depressed also, and the cff is lowered by diminution of the dif-

ferential between the weak and strong phases of the fluctuation cycle. If, with the test object just described, the flash rate is varied from low to high, a point is reached at which *both* the light and the dark phases are seen *simultaneously*, the one behind the other. The light phase appears as a translucent surface through which the

second, a predominance of either the dark or the light phase can be produced by changing the luminance of the annulus. If the intensity of the annulus surround is raised, the dark phase becomes predominant and contoured. If the intensity of the surround is dropped, the light phase is contoured. The results are pictured in Fig. 62. Beyond a frequency of 10 per second, both phases become partially fused.

dark phase is seen lying behind it. This is an example of how temporal factors in stimulation affect spatial factors in sensation.

OCULOMOTOR MECHANISMS

Oculomotor responses may be divided into three categories: (1) movements of the extrinsic eye muscles for convergence and for cyclofusional adjustments of the eyeballs; (2) accommodative processes in adjusting the lens for best focus; and (3) pupillary adjustments. The neural pathways involved in some of these processes were sketched in a previous section.

Convergence

Convergence, or the pointing of the two eyes at an object of regard occurs in conjunction with accommodation, or the focusing of the dioptric systems of the eyes. Normally there is some kind of "coupling" between the convergence and the accommodation mechanisms. Not all convergence is, however, induced by accommodation; part of it is supposedly brought about by a fusion center in the brain and is called fusional convergence. Some convergence is also supposed to be controlled by still other factors, but the isolation of these is not satisfactory at present.

Cyclofusional Movements

Cyclofusional movements of the two eyes to maintain single binocular vision can occur, particularly in forced optical conditions like those involved in vision through a stereoscope.

Suppose the eyes are fixating a line perpendicular to the line of regard and that the line appears vertical to the observer. The retinal images in the two eyes fall on corresponding points. If the top of the line is then tilted toward the observer, the retinal images are no longer vertical. Each has been displaced in an opposite direction around the axis of fixation, and the line

should appear to be inclined (cf. Chapter 23). But this predicted appearance does not always occur. There is said to be a "compulsion" toward fusion of the two disparate retinal images, and this induces a cyclotorsional eye movement that compensates for the declination. The eyes rotate about their axes until the two images lie on corresponding points in the two retinas. This may obliterate the initial declination of the images and obliterate the *seen* inclination of the line. Such tendencies for the eyes to take compensatory positions must be recognized when we attempt to explain certain visual effects.

Accommodation

Theories of accommodation have, from time to time, proposed changes in the axial length of the eyeball, in the corneal curvature, or in the position of the crystalline lens to account for the changes in degree of blurredness of vision. Some writers have insisted that nothing but changes in axial length could account for certain phenomena in aphakic vision (vision without the lens, as in eyes that have undergone cataract removal). The more general tendency has been, however, to rely upon changes in the *curvature* of the lens to account for changes in the dioptric power of the eye. The three most prevalent theories of accommodation have been spoken of as the "hydraulic theory," the "theory of increased tension," and the "theory of decreased tension."

The hydraulic theory asserts that accommodation is accomplished by a properly balanced transfer of fluid from the front to the peripheral regions of the lens, brought about by the ciliary muscle. This causes the lens to become more convex.

× According to the theory of increased tension, in distant vision the ciliary muscle is relaxed and the lens is free from stress. For the eye to focus on a near object, the ciliary muscle contracts and exerts pressure on the vitreous humor, thereby causing the lens to bulge.

The theory of decreased tension states that the capsule of the lens is elastic and under perpetual tension by the suspensory ligaments, even when the eye is focused on a distant object. Accommodation for a nearby object involves the contraction of the ciliary muscle. This counteracts the pull exerted by the suspensory ligaments upon the elastic lens, which is thereby permitted to assume a more highly curved form. This is Helmholtz's theory and is the one most prevalently held.

Each theory has its difficulties. The objections to them have led more recent investigators to look for reciprocal innervation in the ciliary muscle system. It now seems that this has been proved, although no sympathetic innervation of the ciliary muscle fibers has been disclosed. The latest theory postulates that the sympathetic system supplies a tonal background via vascular innervation and that it is upon this that increased or decreased innervation via the oculomotor nerve supplies the variations spoken of as positive and negative accommodation. The tonal background sets the "level" of accommodation, and the oculomotor nerve innervation provides the specific adjustments.

Pupillary Behavior

There are several considerations regarding pupillary light response that are pertinent here: (1) At what rate does the pupil contract, when subjected to an increase in light intensity? (2) At what rate does the pupil dilate in the dark after exposure to various light intensities? (3) What are the expected pupillary apertures during protracted exposure to various levels? (4) What are some of the important factors evidencing relations between pupillary and sensory behavior? (5) What are the facts regarding pupillomotor areas in the retina? The following information from Talbot answers some of these questions.

Contraction of the pupil to pulses of light shows the following typical characteristics. Contraction begins at a latency of about 0.25

second. The contraction is at first very rapid, but at about 0.60 second a jog occurs. From there on the contraction slows up until at about 0.93 second a rebound or reversal carries the contraction to a value that is roughly maintained, except for irregular variations or oscillations. This picture may be described as one of overshooting. A second jog or irregularity in the curve of contraction at about 1 second is quite usual. With intermediate stimuli the response fails to develop a reversal, and after the first second the curve depicting pupillary behavior becomes quite flat. In general the reversal is over within 12 seconds. Some say that, for all durations of light pulse, equilibrium is arrived at within 6 seconds. Questions of this sort pertain only to long stimuli, however, whereas we are here concerned with the results of pulses of not more than 2.5 seconds.

Contraction latency is related to strength of stimulus, but only in a "statistical" manner. The course of the contraction varies systematically with the initial diameter of the pupil, independently of the strength of the stimulus or of the retinal adaptive state. Contraction always displays the same general form, regardless of the shortness of the stimulating pulse. There is a minimum duration of the contraction beyond which it does not diminish, regardless of the shortness of the pulse. This seems to be of the order of 1.1 seconds for a pulse producing a contraction of 1.5 millimeters. Speed of contraction is apparently not a reliable feature of the pupillary response. Naturally the response to intense light diminishes when the initial pupillary aperture is smaller, for the pupil is already nearer its minimum aperture value.

The pupillary response depends upon the size and location of the retinal area stimulated. The macula seems to have ten times the pupillomotor sensitivity possessed by areas 10 degrees from the fovea. The area of the retina stimulated must be increased faster than the intensity is decreased in order

for the amplitude of the pupillary response to remain constant.

The first jog in the course of the pupillary contraction occurs earlier as the initial size of the pupil diminishes. The latency of the first jog does not vary systematically with stimulus strength as do the second jog and the latency of the initial contraction. This points to an independent mechanism for the

Then the stimulus patch was illuminated for 1 second, at the end of which a picture was taken. Four pictures were taken at the end of successive 7-second intervals. For these the same test-object area was used, but different intensities of illumination were employed. The adapting conditions were then repeated, and three additional pictures were taken at the same time intervals. Thus,

FIG. 63. Pupil area as a function of intensity for foveal stimulation by test objects of different sizes. The radii of the test objects in minutes of angle subtended are as follows: 1 = 30.6, 2 = 17.9, 3 = 12.7, 4 = 8.21, 5 = 4.86, 6 = 3.0, 7 = 2.03, 8 = 1.28, and 9 = 0.97. The values obtained are those produced by flashes 1 second in duration and represent maximum constrictions for the stimuli used. (Page, 1941.)

first jog. The second jog also arises earlier as the initial size of the pupil increases.

Dilation latency appears generally to be shorter with small initial pupil sizes, and to be more or less independent of the intensity change producing it. Light adaptation also reduces pupillary sensitivity, and much greater intensity is necessary for a given amplitude of response.

As an answer to question 3 concerning the relation of light intensity to pupil size, we have the work of Page, which is illustrated in Fig. 63. The subjects were light adapted for 15 seconds. This was followed by 105 seconds of dark adaptation prior to the taking of the first photograph of the pupil.

seven pictures, each at a different stimulus intensity, were taken for each of the nine different test objects whose radii subtended visual angles ranging from 0.97 second of arc to 30.6 seconds of arc. The right eye alone was measured, and the left eye was left uncovered. The order of taking pictures was always from the smallest area and the lowest intensity upward. The whole procedure was repeated twenty times for each of the subjects.

Figure 64 shows the earlier results of Reeves in which he plotted the relation between pupil size and level of illumination. Although Reeves' data did not cover the same intensity range, the shape of the curve

in Fig. 64 is somewhat similar to that of curves obtained by Page. Reeves used full-field illumination, rather than small test objects, and he preadapted his subjects to 15

A Pupillary Parallel to Brightness Sensation

An investigation that has disclosed a fundamental property of pupillary behavior made use of the fact that a pupil exposed

FIG. 64. Relation between pupil size (area) and level of general illumination. (From the data of Reeves, 1920.)

minutes of darkness before subjecting them to the test levels.

Figure 65 shows how the area of the pupil changes with the duration of the illumination.

FIG. 65. Relation between pupil area and duration of exposure to light of 100 millilamberts. (From Reeves, 1920.)

Exposure of one eye alone to light induces constriction of both pupils. The constriction in the unexposed eye is called the *consensual reflex*.

to a sequence of increasing light intensities can be photographed in infrared illumination and the course of its constriction can be plotted. When a high intensity had been reached in one eye, it was maintained in that eye and the corresponding area of the other retina was exposed to the same sequence of intensities. These increments of light, added via the second eye, did not at first induce further constriction. Instead they resulted in dilatation. But as more and more light was added, the dilatation reached a peak and then subsided. The ultimate result was a constriction beyond the amount existing at the moment of initial stimulation of the second retina. For a picture of this, see Fig. 66. This is an oculomotor parallel of Fechner's paradox.

Fechner's paradox is the sensory result when two eyes are independently exposed to unequal amounts of light. When the light falls on corresponding areas of the two retinas, it is seen as a single light or object. But instead of the stimulation of the two eyes combining to yield a brighter object, it results in an object (or surface) whose brightness level lies somewhere between the

FIG. 66. The relation between pupil diameter and intensity of a disk test object. Curve A indicates the behavior when part of the light is presented to one eye and the remainder is then presented to the other eye. The broken perpendicular line indicates the level reached by the stimulus to the first eye before the presentation of light to the second eye. In each eye the illumination was at first feeble and was increased step by step. The light presented to the second eye evoked dilatation at first. Curve B indicates pupil behavior when all the light was given to one eye. (Bartley, 1943.)

brightnesses of the two lights seen separately. On the other hand, when the intensities of the stimuli to both eyes are equal, the combined subjective effect is greater than from one stimulus alone.

Actually the sequence of events in the pupillary response described above results not only from stimulating *corresponding* areas of the two retinas but also from stimulating *noncorresponding* areas. In fact, essentially the same pattern of behavior accrues from the stimulation of two areas on the same retina.

Basic Correlates of the Auditory Stimulus

J. C. R. LICKLIDER

Massachusetts Institute of Technology

In hearing, as in other fields of psychology, the problem has been to understand the stimulus. Our aims in the first part of this chapter will therefore be to consider a few of the fundamental characteristics of sound vibrations and to develop a language that will allow us to describe them effectively.

Waveform

When the diaphragm of a loudspeaker vibrates to and fro, it alternately compresses the air and allows it to expand. The pressure built up, during compression, in the layer of air next to the diaphragm is passed on to more distant layers, and waves travel out from the loudspeaker. In this process the air particles themselves do not move far from their original positions, but the sound wave—the compression and the rarefaction—travels far and fast. In air at ordinary temperatures the speed of sound is a little over 1100 feet per second (330 to 340 meters per second). These sound waves strike our eardrums and become the stimulus to hearing. They can be recorded with the aid of a microphone fitted with a narrow probe tube, the end of which we can place within a millimeter of the eardrum. By plotting the alternating sound pressure as a function of

time, we obtain a representation of the acoustic stimulus that we shall call the *pressure waveform at the eardrum*.

Recording the pressure variations near the eardrum has the advantage of getting us near the auditory receptors, but we purchase this advantage at a price. First, the measurement is difficult to make. Second, we do not yet have probe microphones that give us faithful reproductions of complex sound waves. And third, what we measure in this way depends to some extent upon the characteristics of the eardrum.

An alternative method of specifying the sound pressure as a function of time achieves independence of the listener's characteristics by getting him out of the way so that the measurements can be made in a free sound field, i.e. in an anechoic (echo-free) space like that shown in Fig. 1. The sound pressure is measured at the point at which the center of the listener's head was, or where it will be when he returns to serve as a subject. The resulting graph of pressure against time is the *free-field pressure waveform*.

Although the sound pressure is what we usually measure, it is by no means the only aspect of the sound vibration. We might equally well plot, as a function of time, the displacement of the air particles from their normal positions (*displacement waveform*) or the velocity of their vibratory motion

This chapter was prepared at the Psycho-Acoustic Laboratory, Harvard University, under contract with the U. S. Navy, Office of Naval Research (Contract N5ori-76, Project NR142-201, Report PNR-78).

FIG. 1. An anechoic chamber for research in acoustics and hearing. The wedge-shaped fingers protruding from the floor, ceiling, and walls are of Fiberglas, covered with muslin. As sound waves approach the boundaries of the room, they are trapped, as it were, in the fibrous, weblike structure of the wedges. Since very little sound is reflected, echoes and standing waves are negligible. The chamber provides the 'free-field' conditions that are required for many of the fundamental measurements in psychoacoustics. (From Beranek, Sleeper, and Moots, 1945.)

(*velocity waveform*). But — and herein lies the beauty of the situation — if we know the properties of the medium, all three waveforms give us the same information. In a free field the pressure waveform and the velocity waveform of a plane wave are identical in shape, and the displacement waveform is the time integral of either of the other two.

The waveform represents a *time analysis* of the acoustic signal. It has two dimensions, *amplitude* (which we shall use as a general term for pressure, velocity, or displacement) and *time*. The information it contains is all we need in order to specify the stimulus to (monaural) hearing. It is not, however, the only form in which this information can be presented.

Spectrum

An alternative method, based on *frequency analysis*, stems from the discovery by Fourier (1822) that any waveform of the type with which we shall be concerned can be analyzed into, or synthesized from, a series of sinusoidal waveforms. We must,

angle. The frequency is the number of to-and-fro oscillations per unit time: it is specified in cycles per second (cps). The Amplitude is the maximum displacement from the zero position. And the phase angle, which has meaning only in relation to an arbitrarily selected reference instant, des-

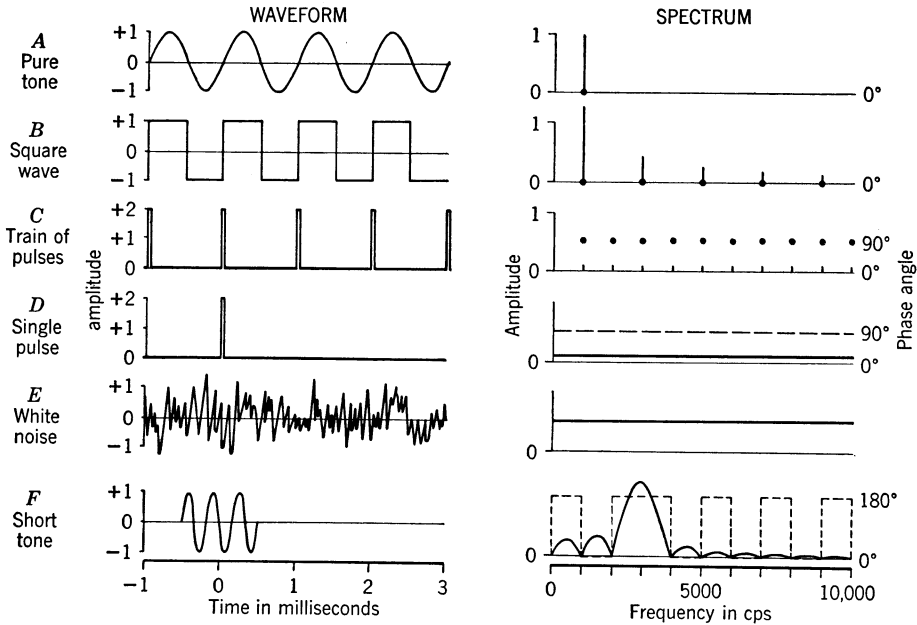

FIG. 2. Waveforms and spectra. In each of the six pairs of diagrams the waveform at the left showing amplitude as a function of time provides exactly the same information as the spectrum at the right showing both Amplitude and phase angle as functions of frequency. The waveform graphs are to be thought of as extending indefinitely in both directions. The spectrum graphs are to be thought of as extending indefinitely to the right. Amplitude (solid lines) is specified in arbitrary units, and phase angle (dashed lines or heavy dots) in degrees.

therefore, examine the properties of sinusoidal waves with some care.

The word *sinusoidal* refers to the class of simple harmonic motions—the most elementary vibratory motions—of which the sine wave (A in Fig. 2) is the most familiar member.

Any sinusoidal wave may be described in terms of three characteristics: its frequency, its maximum Amplitude,* and its phase

ignates the part of its cycle in which, at the reference instant, a point on the wave finds itself.† In order to have a convenient method of specifying the phase, we divide the full cycle into 360 degrees or 2π radians, beginning with the upward crossing of the zero line. If the reference time ($t = 0$) falls at the beginning of a cycle (0 degrees) as it does in Fig. 2A, we refer to the sinusoid as a *sine wave*. If $t = 0$ corresponds to the

* The maximum amplitude (Amplitude) will be distinguished from the varying instantaneous amplitude (amplitude), the capital letter 'A' being used for the former, the lower case 'a' for the latter.

† In the expression $a = A \sin (2\pi ft + \phi)$, the whole quantity $2\pi ft + \phi$ is the instantaneous phase angle. It is the constant part ϕ to which we refer here as the third parameter of the sinusoid.

maximum of the waveform (phase angle of 90 degrees), we refer to the wave as a *cosine wave*. If neither of these coincidences occurs, we state the phase angle at $t = 0$ in degrees or in radians.

The task of frequency analysis is to break up a complex wave into sinusoidal components of various frequencies, then to represent the complex wave in terms of the Amplitudes and the phases of the components. This process is illustrated in Fig. 3. The complex waveform that oscillates

are sine waves (zero phase angle at time $t = 0$).

Relation between Waveform and Spectrum

The spectrum, with its three dimensions (frequency, Amplitude, and phase), describes the wave completely and uniquely, just as does the waveform with its two dimensions (amplitude and time). Almost always, however, one or the other of the two representations is the more convenient for a given purpose. Consequently the conversions from

FIG. 3. An example of the transformation from waveform to spectrum.

between the dashed *envelope* lines was constructed by adding the ordinates of the two sinusoids above it. In order to perform a frequency analysis, therefore, we break the complex wave down into its components (photoelectric and mechanical analyzers and purely mathematical methods have been developed for this purpose). For each component we describe the frequency, the Amplitude, and the phase angle at time $t = 0$. The representation of the complex wave in terms of its spectrum is then obtained by placing the component spectra side by side, as in the lower right-hand corner of the figure. The vertical lines are located at 12 and 15 cps on the frequency scale because there are 12 full cycles of one wave and 15 of the other in each second. The heights of the lines indicate the Amplitudes of the sinusoidal components, and the fact that the heavy dots are side by side on the zero line indicates that the two components

waveform to spectrum and from spectrum to waveform, called the Fourier transformations, are important tools in the study of hearing. We cannot, here, go into the mathematical details of the process, but we can extend our intuitive grasp of the problem by examining the paired diagrams of Fig. 2.

We have already considered the sine wave A with its periodic oscillations and its single-component spectrum. We note now that the square wave has as one of its components a sinusoid of the same frequency and phase as that of A , but of slightly greater Amplitude. Added to this fundamental component (first harmonic) are a series of higher harmonics, sinusoids with frequencies equal to integral multiples of the fundamental frequency. Note that, in this particular instance, the multipliers are all odd integers: the frequencies are 1000, 3 times 1000, 5 times 1000, etc. Note also that the

harmonics are all sine waves (0-degree phase angle), and that their Amplitudes are inversely proportional to their frequencies. In order to give an accurate graphical representation of the spectrum of the square wave, we would have to extend the figure indefinitely to the right because, although the high-frequency components are very weak, all the odd harmonics would be present in an ideal square wave. Ideal square waves never occur in nature, because air particles have finite mass and hence cannot be given the infinite acceleration that the square corners on the wave imply.

It is of interest to compare the train of pulses (C in Fig. 2) with the square wave on the one hand and with the single pulse on the other. The train of pulses has even harmonics as well as odd, the components are cosine waves (90-degree phase angle) instead of sine waves, and, to a first approximation, all the harmonics shown in the figure are equally strong — or, more aptly, equally weak. The presence of even harmonics in the pulse spectrum is related to the fact that the pulse waveform does not oscillate about the center axis in a self-balancing way as the square wave does, and the presence of cosine components instead of sine components is due to the fact that the waveform is symmetrical about a vertical line through time $t = 0$. The uniformity of the pulse spectrum is related to the brevity of the pulses. By making the pulses short enough, we can make the spectrum as nearly uniform as we please up to any desired frequency.

Even if we have only one pulse (Fig. 2D), the spectrum is still uniform. Now, however, it consists not of concentrations of energy at particular frequencies, but of a continuous distribution of energy along the frequency scale. This is called a *continuous spectrum*, whereas the spectra of the sine wave, the square wave, and the train of pulses are called *line spectra*. The Amplitude scale of the single-pulse spectrum is not calibrated because apportioning the energy of the single pulse among an infinitude of

frequency components leaves only an infinitesimal Amplitude for each component. The phase-angle scale, however, can be labeled as before; all the components are cosine waves.

White noise (Fig. 2E), or random fluctuation noise as it is often called, is of peculiar significance because it is always present. The thermal movements of the molecules of the air produce a noise that is only a little too weak to be audible. The fluctuations of electrons in conductors and in vacuum tubes give rise to the familiar 'hiss' of radio sets and public address systems. The distribution of instantaneous amplitudes in the waveform follows the normal distribution curve. The spectrum is uniform in Amplitude and random in phase. One way to picture the relation between the waveform and the spectrum is to think of superimposing an infinitude of waves, each of a different frequency. Because there is no orderly phase relation among the sinusoids, they reinforce one another or cancel one another in an entirely haphazard way.

Finally, the short tone (Fig. 2F). One of the reasons why short tones are of practical importance in research on hearing is that, in an actual experiment, we cannot present a stimulus for the eternity that would be required to make a pure tone ideally a *pure tone*. Whenever we turn it on or off, we sully its purity. Whenever we change its frequency or its Amplitude or its phase, we spread energy along the frequency scale. The spectrum of Fig. 2F is an example. Instead of finding the energy concentrated at 3000 cps, as we might expect since there are 3 cycles in 1 millisecond, we find an almost continuous distribution of energy from 0 to 10,000 cps. This is, admittedly, an extreme case; for longer tones the spectral energy is concentrated more closely around a center frequency. But the essential fact remains: whenever we change anything about a pure tone, we cease to have an ideally pure tone.

Power Spectrum and the Autocorrelation Function

The spectrum of white noise, we have seen, contains the same (infinitesimal) amount of energy at each frequency within the frequency interval under consideration, but the phase angles of the component sinusoids are distributed at random. In dealing with signals like white noise, therefore, we can adopt a representation that omits information concerning phase. Such a representation is achieved by giving the mean-square amplitude instead of the Amplitude and the phase of each of the components. Since, in resistive media, power is proportional to the square of amplitude, the plot of mean-square amplitude against frequency is called the *power spectrum*. Note that, because the spectrum of white noise is uniform within the interval represented in Fig. 2E, the substitution of the mean-square amplitude for the maximum amplitude of the components changes the picture only to the extent that the ordinate scale must be relabeled.

An alternative way of expressing the information contained in the power spectrum is to give the *autocorrelation function* of the waveform. The autocorrelation function is obtained by drawing the waveform twice, the second time below the first, and determining the correlation between corresponding ordinates of the two curves. If the second waveform is directly below the first, the correlation is, of course, unity. If, however, the second waveform is shifted in time relative to the first by an amount τ , the correlation in general becomes less than unity. The correlation between the original wave and the shifted wave, plotted against the amount of the shift, τ , gives us a useful picture of the signal. This plot relating r (the coefficient of correlation) to τ (the shift) is the normalized autocorrelation function. It is called normalized to distinguish it from the closely related function that relates the mean square product of the original and the shifted waveforms to the amount of the shift. The latter, called the

unnormalized autocorrelation function, is equal to the former multiplied by the mean square ordinate of the original wave and is the Fourier transform of the power spectrum. It thus bears to the power spectrum the same relation that the waveform bears to the spectrum that specifies Amplitude and phase.

In Fig. 2E, for example, we see that the waveform zigzags up and down so rapidly that the correlation between the original wave and the same wave shifted by even a small amount will almost certainly approach zero in the long run: there is practically no relation between the amplitude at one instant and the amplitude a short time later. In an ideal random noise, with its power spectrum uniform to indefinitely high frequency, there would be *no* relation. This means that the autocorrelation function derived from the waveform to Fig. 2E will drop from unity, for zero shift, to zero for any appreciable shift. The autocorrelation function for white noise will therefore have approximately the same shape as the waveform shown in Fig. 2D. To check the rule that the power spectrum is the Fourier transform of the autocorrelation function, we can compare the spectrum of 2D, which is the Fourier transform of the waveform of 2D and thus the Fourier transform of the autocorrelation function of the waveform of 2E, with the spectrum of 2E. We find that they are both horizontal lines. Since the ordinate scales of both graphs are arbitrary, the two horizontal lines are functionally identical, and the rule is checked. Autocorrelational methods are being used more and more widely in communication and related fields. A comprehensive discussion of them is given by Wiener (1949b).

Steps and Pulses as Elemental Waveforms

In addition to the method of representing a complex waveform as the sum of a number of elementary sinusoidal components, there are other methods in which the elements are nonsinusoidal. In the 1880's,

Oliver Heaviside worked out a method of analyzing the characteristics of communication lines and cables with transient instead of steady test signals. His elemental waveform was a single, abrupt step of amplitude, like the rise or fall of a square wave. Any complex wave can be regarded as the result of superimposing a sufficient number of such step-waves, for any curve can be approximated as closely as desired by a staircase pattern. Studying the mathematical foundation of Heaviside's method, J. R. Carson (1920) showed that it was closely related to a way of representing mathematical functions that had been developed by Laplace. In Laplace's calculus, the elemental waveform is an impulse (cf. Fig. 2D) of negligible duration but with sufficient amplitude to make the area under the curve equal to unity. Because of their roles in the operational calculus, which has been developed around the methods of Heaviside and Laplace, acoustic stimuli consisting of steps and impulses are of interest in experiments on hearing.

Intensity-Frequency-Time Patterns

As we have seen, the waveform deals with instants in time and says not a word about frequency; the spectrum deals with points along a frequency scale and fails to distinguish between events that happen at different instants in time. Although time analysis and frequency analysis have provided the foundation upon which the science of communication has grown, neither method bears a one-to-one correspondence with the actual behavior of any physical analyzing system. No physical system can single out and record the event of a mathematical instant, and no physical system can wait the eternity required for the isolation of a mathematical sinusoid.* What we should like to have in the study of hearing

*The cathode-ray oscillograph provides what is for our purposes an excellent approximation to time analysis, and the harmonic wave analyzer or narrow-band filter performs a reasonably good frequency analysis. Neither is perfect.

is a compromise method of analysis, a method that would represent sounds the way we hear them. Such a method must distinguish to some extent between events occurring successively in time (sounds follow one another in auditory experience) and must distinguish also between signals that differ in frequency (a 1000-cycle tone sounds quite different from a 2000-cycle tone).

The musical notation is, of course, just such a method of describing patterns of sound in frequency and in time. It is better for art than for science, however, for it leaves a great deal to the imagination of the interpreter. For the purpose of describing auditory stimuli, we need a notation that allows us to set down in unambiguous form all the relevant information. We can get an idea of how we might achieve this goal by considering a simple model.

The standard at the left-hand side of Fig. 4 carries a series of weighted springs. All the springs are equally stiff, and all the damping constants are equal. Because the weights are heavy at the bottom of the series and light at the top, the bottom springs vibrate slowly when struck while the top springs vibrate rapidly. The natural frequency of each tuned vibrator is indicated in the figure. Now let us suppose that all the springs are hit in exactly the same manner at $t = 0$ on the time scale at the bottom of the figure. The small diagram *A* at the right-hand side of the figure shows what we can call the pressure waveform of the blow; it is simply a brief pulse. Diagram *B* shows its spectrum (cf. Fig. 2E). The question is, how do the weighted springs respond? This question is of interest because we have here a physical model that can perform neither perfect time analysis nor perfect frequency analysis. Its behavior should give us insight into the compromise method of representing the pulse.

The vibrations of the eleven springs are traced out in terms of their waveforms in the plots in the center of the figure. Each spring goes through a damped oscillation that

dies down to $1/2.718$ ($= 1/e$) of its maximum amplitude in about 1 millisecond and eventually becomes negligible. The dashed curves show the *envelopes* of the oscillations. If we deal only with the envelopes, we lose some detail, but we retain a good indication

gram *C* at the right-hand side of Fig. 4. Now we apply the pulse to the infinite set of resonators and represent the amplitudes of the envelopes of their oscillations by stippling more or less densely in the frequency-time plot. This gives us a pattern with the three

FIG. 4. An intensity-frequency-time pattern. The standard at the left supports a number of resonators, equally damped and tuned to the frequencies indicated. Simultaneously, the resonators are struck an impulsive blow, the force-versus-time pattern of which is shown at *A*, the spectrum at *B*. The oscillatory responses of the resonators to the blow are shown in the velocity-versus-time plots (*a* versus *t*) in the center of the figure. The envelopes of these responses can be used to provide a picture of the original signal itself, i.e. of the impulsive blow. This picture, schematized at *C*, is a compromise between *A* and *B*. It indicates at least approximately the time of occurrence of the blow, and it shows that energy is distributed uniformly along the frequency scale.

of the magnitude of the disturbance, and we greatly simplify the picture. The picture now says simply that the same thing happens at each frequency (i.e. to each weighted (spring)).

Now let us imagine, instead of eleven springs, an infinite set of springs so constructed that, after equal excitations, their oscillations decay at equal rates, and so ordered that their natural frequencies form a frequency scale. At right angles to the frequency scale we set a time scale, as in dia-

dimensions, *intensity* (the amplitude of the envelope), *frequency*, and *time*. This pattern represents the pulse almost as exactly as does the waveform or the spectrum. We lost some detail by neglecting the phases of the oscillations when we turned our attention to the envelopes.

The same method of analysis can, of course, be applied to any input wave, and the resulting pattern provides a convenient representation of the signal. It is the basis of the Sound Spectrograph, the development

of the Bell Telephone Laboratories (Koenig, Dunn, and Lacy, 1946) that produces "visible speech" (cf. Chapter 26). The Sound Spectrograph uses electrical resonators, of course, instead of weighted springs, but the important thing is that the method of analysis gives us pictures of sounds that show what goes on both in time and in frequency.

If we could find a convenient way of showing not merely the amplitudes of the envelopes but the actual oscillations of the array of resonators, we would have a notation (cf. Gabor, 1946) of even greater generality and flexibility, one that would reduce under certain idealizing assumptions to the spectrum and under others to the waveform. For example, let us imagine the resonators of Fig. 4 to be entirely frictionless, so that the oscillations, once started, will never stop. Here we would have perfect frequency analysis; the idealized arrangement records the spectrum of the applied signal. Or we can assume that the viscous friction of the fluid in which the resonators are immersed is so great that their tendency toward oscillation is negligible. All the elements would then behave in exactly the same way; each would vibrate only while the input signal is acting, and each would yield with a velocity proportional to the applied force. As a result, the arrangement would provide perfect time analysis—it would trace out the input waveform.

It should now be clear that to any given wave there corresponds not just one pattern in intensity, frequency, and time, but an infinite number of patterns. Between pure time analysis and pure frequency analysis we can strike any compromise we choose. Although the human auditory system is by no means so simple as the series of tuned circuits we have been considering, it too must strike a compromise. The nature of its solution to the time-frequency problem is, in fact, one of the central problems in the psychology of hearing.*

* The problem can be formulated alternatively by contrasting the waveform and its autocorrela-

Although in the foregoing analysis we get both time and frequency into the picture we do so at a cost. In a sense, we lose precision in specifying one as we gain precision in specifying the other. The analogy has often been drawn between the time-frequency problem, which we have been examining, and the position-momentum and energy-time problems that led Heisenberg in 1927 to state his uncertainty principle. The formal analogy is very close:

$$\Delta p \cdot \Delta q \geq h \text{ (Heisenberg);}$$

$$\Delta t \cdot \Delta E \geq h \text{ (Heisenberg);}$$

$$\Delta t \cdot \Delta f \sim 1 \text{ (Hartley, 1928); or}$$

$$\Delta t \cdot \Delta f \geq \frac{1}{2} \text{ (Gabor, 1946).}$$

Here Δ is the interval of uncertainty, p is momentum, q is position, E is energy, t is time, and f is frequency. This analogy has led Gabor to suggest that we may find the solution to the time-frequency problem in quantum mechanics, and it has led Joos (1948) to speak of the "smear" (region of uncertainty) in intensity-frequency-time plots of acoustical waves. It should be noted, however, that there is no uncertainty about the spectrum that corresponds to a given waveform, no matter how brief the waveform. The only sense in which there is uncertainty about the frequency of a short wave is that a short wave has many frequency components. Conversely, narrow-band spectra imply stretched-out waveforms, but the waveform corresponding to a given narrow-band spectrum is quite precisely determined.

Sound Intensity and Decibels

The intensity of a sound wave, as we have seen, is usually measured with a pressure-

tion function instead of the waveform and its spectrum. The compromise representation is then a 'running' autocorrelation function. R. Fano and W. H. Huggins have suggested (personal communications) that it may turn out that the auditory mechanism can be understood better as an autocorrelator than as a frequency analyzer.

indicating instrument and specified in pressure units, i.e. in dynes per square centimeter. It is sometimes advantageous, however, to specify sound intensity in units of power or of energy.* The relation between the pressure of a plane sound wave in a free field and acoustic power is a simple one because open air is an almost purely resistive medium. In resistive media, the so-called volume velocity v is always proportional to the pressure a . Since power P is equal to pressure times volume velocity, we have the relations

$$v = ca \quad P = va \quad P = ca^2$$

where c is the reciprocal of the acoustic resistance of the air. From the third equation, we see that the power is proportional to the square of the pressure.

The *decibel* scale is essentially a logarithmic form of the power or energy scale. In order to obtain units of convenient size, the *bel* (the logarithmic unit) is divided into 10 decibels. Hence the number of decibels corresponding to a given ratio of acoustic power or energies is

$$N_{(db)} = 10 \log_{10} \frac{P_1}{P_0}$$

Thus if one sound intensity P_1 , measured in power or energy units, is ten times as great as another sound intensity P_0 , also measured in power or energy units, P_1 is said to be 10 db greater than P_0 . Note that the expression *10 db* represents an intensity ratio, not an absolute intensity. In order to specify the absolute intensity of a sound in terms of the decibel notation, it is necessary to state that the intensity P_1 of the sound is N decibels above or below a given *reference intensity* P_0 .

The reference intensities most commonly used are 1 dyne per square centimeter and

* In physical acoustics the word *intensity* almost always means power or energy — or, more precisely, energy flux density. In this chapter, however, we shall find it convenient to use intensity as a generic term for amplitude, pressure, voltage, power, energy, etc.

0.0002 dyne per square centimeter. These values, however, are given in *pressure* units, and we have seen that the decibel scale is essentially a logarithmic form of the *power* scale. We can, of course, circumvent the difficulty by converting the reference intensity from pressure units into power units; we can note, for example, that 0.0002 dyne per square centimeter is equivalent in open air to 10^{-16} watt per square centimeter. It is often more convenient, however, to adapt the decibel notation so that it expresses ratios of pressure as well as ratios of power. This is done by recalling that, in resistive media, $P = ca^2$, where P is power, a is amplitude (pressure), and c is a constant. It then follows that

$$N_{(db)} = 10 \log_{10} \frac{P_1}{P_0} = 10 \log_{10} \frac{ca_1^2}{ca_0^2} = 20 \log_{10} \frac{a_1}{a_0}$$

Thus we see that, since a tenfold increase in pressure (amplitude) corresponds to a hundredfold increase in power, it is represented by +20 db. Other decibel equivalents for power and amplitude ratios are given in Table 1. (For a discussion of the decibel notation see Rao, 1944.)

TABLE 1
RELATIONS BETWEEN POWER RATIOS, AMPLITUDE RATIOS, AND DECIBELS

Amplitude Ratio	Power Ratio	Decibels	Decibels	Amplitude Ratio	Power Ratio
1.00	1.00	0	0	1.00	1.00
0.89	0.79	-1	+1	1.12	1.26
0.79	0.63	-2	+2	1.26	1.59
0.71	0.50	-3	+3	1.41	2.00
0.50	0.25	-6	+6	2.00	3.98
0.32	0.10	-10	+10	3.16	10.00
0.10	0.01	-20	+20	10.00	100.00

AUDITORY THRESHOLDS

The intensity at which a sound is just discriminable from silence is called the *absolute threshold* for that sound. To simplify matters, experimenters have worked chiefly with

pure tones, and they have tried to minimize differences among observers by using as listeners young adults without obvious defects of hearing. But their methods of measurement and their ideas of what to measure have varied. Some experimenters have presented

in Fig. 5. This graph contains twelve curves, of which six show the absolute threshold of hearing as a function of the stimulus frequency. The vertical scales indicate the root-mean-square* sound pressure relative to the two widely used reference intensities.

FIG. 5. Determinations of the threshold of audibility and the threshold of feeling. Curves 1 to 6 represent attempts to determine the absolute threshold of hearing at various frequencies. MAP = minimum audible pressure at the eardrum; MAF = minimum audible pressure in a free sound field, measured at the place where the listener's head had been. Curves 7 to 12 represent attempts to determine the upper boundary of the auditory realm, beyond which sounds are too intense for comfort, and give rise to nonauditory sensations of tickle and pain, etc.

the tone monaurally; others have presented it binaurally. Some have delivered the tone via an earphone and have measured the sound pressure at the listener's eardrum (*minimum audible pressure*); others have delivered the tone via a loudspeaker and have measured the sound pressure, after removing the listener from the sound field, at the center of the region that had been occupied by his head (*minimum audible field*).

Absolute threshold curves. Some of the discrepancies among the determinations of the absolute intensive threshold are shown

Curve 1 is a summary curve prepared by Sivian and White (1933) to represent the weighted mean of a number of determina-

* 'Root-mean-square sound pressure' is a short form of 'the square root of the mean of the squares of the instantaneous sound pressures.' To make it still shorter, 'root-mean-square' will be abbreviated to 'rms.' The reasons for using the rms pressure instead of simply the mean pressure or the mean absolute pressure (mean without regard for sign) are (1) that the mean pressure over an integral number of cycles of a sinusoidal sound wave is, of course, zero, and (2) that the rms is more tractable than the mean absolute pressure in computations involving complex waves.

tions of the minimum audible pressure (MAP). Curve 2 represents, in a similar way, the minimum audible field (MAF). Curve 1 is for monaural listening, curve 2 for either monaural or binaural listening. The fact that the two curves do not coincide is due in part to the fact that the sound pressure measured in a free field at the place to be occupied by the listener's head is not the same as the pressure developed at his eardrum when he is listening (see Chapter 27, p. 1079). This effect would not be expected to account for the discrepancy at frequencies below 1000 cps, however.

More recent laboratory determinations of the monaural MAP have yielded values somewhat lower than those of Sivian and White's summary curve. Curves 3 and 4 show the threshold pressure at the eardrum as determined by Békésy (1936*a, b*) in Budapest, and by Waetzmann and Keibs (1936*a, b*) in Breslau. Békésy generated intense sinusoidal pressure variations at very low frequency and found that the lower frequency limit of hearing is far below 20 cps, the value usually given in textbooks. The irregular line, for one of Békésy's listeners, shows that, as frequency is varied, the absolute threshold changes in jumps. This effect suggests that auditory sensitivity may actually be "quantal" in nature. Additional evidence on this point will be described later.

The curves marked 5 in Fig. 5 show the results of audiometric surveys made under less ideal conditions than are usually provided for laboratory measurements. The solid line represents the median values for listeners 20 to 29 years of age who took the hearing tests at the Bell Telephone Company's exhibits at the New York and San Francisco World's Fairs in 1938 and 1939 (Steinberg, Montgomery, and Gardner, 1940). They agree reasonably well with the neighboring dashed and dotted curves obtained, respectively, by the Bell Telephone Laboratories (Montgomery, 1932), and by the United States Public Health Service (Beasley, 1938); and they are consistent

with criteria for "normal hearing" adopted in clinical work with audiometers. It is possible that some part of the discrepancy between the curves marked 5 and the other absolute threshold curves of Fig. 5 is due to the fact that, in the audiometric surveys, the listener held the earphone to his ear as though he were using a telephone. Brogden and Miller (1947) found that the act of holding the receiver produces a measurable amount of low-frequency noise in the ear canal—the 'noise of the sea' that one hears in a sea shell.

Since the parametric value of the threshold has not been pinned down very closely, the American Standards Association has decided somewhat arbitrarily that the MAF at 1000 cps shall be taken (until further measurement indicates otherwise) as 0.0002 dyne per square centimeter. The ASA has, in fact, adopted a "standard" MAF curve (curve 6 in Fig. 5). Note that this curve crosses the 1000-cycle ordinate at 0 db on the right-hand scale.

Variations in absolute sensitivity. In asking about differences among listeners, we risk the semantic hazard of trying to distinguish between normal variations in the absolute threshold and partial deafness. It is clear from the United States Public Health Surveys that the thresholds even of young listeners without known otological pathology cover a considerable range. But it is by no means certain where to draw a line of division between normal and abnormal. In Fig. 6, for example, we see that there is no discontinuity in the distribution of thresholds. The median of this distribution is represented in Fig. 5, curve 5, by the filled circle at 880 cps.

Although for most listeners the absolute thresholds for low-frequency tones remain essentially constant throughout the span of life, the thresholds for high-frequency tones increase markedly with advancing age. This fact is illustrated in Fig. 7, which shows typical *audiograms* for various ages. Note that the ordinate scale in this figure is the

number of decibels by which it differs from the average for listeners 20 years of age. This method of representation is widely used in audiometry.

We have as yet no detailed analysis of the day-to-day variations in the absolute thresh-

FIG. 6. Distribution of auditory sensitivity among individuals 20 to 29 years of age. The data are measurements of the absolute thresholds of 35,589 subjects for an 880-cycle tone. (After Steinberg, Montgomery, and Gardner, 1940.)

old, but we know that the variations are significant. When we compare the overall variance (variability) of a set of threshold measurements taken over a period of days with the average of the variances of the daily

FIG. 7. Progressive loss of sensitivity at high frequencies with increasing age. The audiogram at 20 years of age is taken as a basis of comparison. (From Morgan, 1943, after Bunch, 1929.)

subsets, we find that the overall variance is three or four times as large as the average (Pollack, unpublished data; Goodfellow, 1938). During a test session of an hour's duration, the threshold of a well-motivated

listener may show no consistent trend either upward or downward, but there are variations of as much as 5 db from one half-minute to the next (Békésy, 1947b).

Even within an interval as short as 5 seconds the threshold appears to fluctuate. If the stimulus consists of five 0.4-second bursts of tone separated by intervals of 0.6 second, the listener may hear all five bursts, or four, or three, . . . , or none. The lowest intensity at which all five are heard is about 6 db higher than the highest intensity at which none are heard (Lifshitz, 1939).

Finally, the absolute threshold depends to a considerable extent upon how long the observer has been listening. Tones of very high frequency tend to disappear, as Lord Rayleigh several times observed, even if they are, at the onset, well above what is then the threshold. Rosenblith and Miller (1949) find, in fact, that the threshold of a 4000-cycle tone may change with continued listening by as much as 20 db.

The thresholds of discomfort, tickle, feeling, etc. We can map the upper boundary of the auditory realm by determining how intense the tones of various frequency can be made before they give rise to reactions that indicate that the auditory mechanism is being overloaded. Because there are several alternative criteria of overload, several end points can be distinguished.

These upper boundaries are represented in Fig. 5 by curves 7 to 12. Curves 7 and 8 were obtained by Silverman, Harrison, and Lane (1946) at the Central Institute for the Deaf (CID), in St. Louis. Curve 7 shows the intensity level at which, after an extended period of getting used to intense acoustic stimulation, the listeners reported "discomfort," and curve 8 marks the onset of "a tickling sensation." The earphones broke before some of the experienced listeners complained of "pain." Before the listeners had become hardened to the rigors of the experiment, however, they complained of discomfort and tickle at levels 5 to 10 db lower than those shown in the curves, and

they reported "pain" at about 140 db above 0.0002 dyne per square centimeter. It appears, therefore, that listeners develop a certain amount of tolerance for intense sounds. This may explain the fact that Wegel's (1932) curve for feeling (curve 9) lies below the CID curve (8) and the curve (10) obtained by Békésy (1936*b*). Békésy was able to explore the boundaries of the "auditory area" in the very-low-frequency range. He found that at frequencies below 15 cps his listeners could report consistently in terms of two criteria. Curves 11 and 12, labeled "touch" and "pricking in middle ear," show the central tendencies of the judgments.

The listener's subjective impression is that the criteria for the 'upper boundary' thresholds are chiefly nonauditory. As the names imply, feeling, tickle, touch, and pricking seem to be tactile. This impression is supported by the observation that the tickle, etc., remains localized in the ears when the sound itself is shifted from one position to another in phenomenal space. The sensations are probably to be accounted for in such terms as the stretching of the drum skin and contact between the ossicles and the wall of the middle ear. Discomfort is the exception; it appears to be a characteristic of the auditory sensation.

Other nonauditory effects of intense acoustic stimulation have been noted in connection with work with ultrasonic sirens (e.g. Allen and Rudnick, 1947). Exposure to a siren-generated sound of 20 kilocycles at 1 watt per square centimeter kills cockroaches in 3 to 4 minutes, mice in 1 minute, and mosquitoes in 10 seconds. They are literally cooked to death. The operators of the siren have to be careful, when they place objects in the sound field, to hold their fingers wide apart lest heating between the fingers, where they almost touch, cause burns. Even when they are wearing earplugs, the operators experience a slight dizziness when they get near the siren, and they report a "cool sizzling sensation" in the mouth and an un-

pleasant tingling in the nasal passages. Similar effects have been observed at lower frequencies (Parrack, Eldredge, and Koster, 1948).

DIFFERENTIAL THRESHOLDS

The *differential threshold*, or difference limen (DL), is an inverse measure of discriminatory capacity. It answers the question: how small a change in the stimulus can an average observer detect? This question is important because we can communicate with one another only by means of *changing* signals.

Differential threshold for intensity. Let us consider, first, changes in sound intensity. On first thought, it would appear that the following procedure, used by Knudsen (1923) to determine the differential intensity threshold, is unequivocal: A tone is switched abruptly from one intensity level to another, and listeners report whether or not they can detect the change. The intensity difference is varied until, for the average listener, the change is just detectable. This intensity difference is taken as the differential threshold. We have already seen, however, that it is impossible to change the intensity of the tone without spreading energy along the frequency scale, and we might ask whether it is the intensity change or the spread of energy along the frequency scale that is detected by the listener.

We cannot avoid the problem posed by this question, but we can try to minimize the difficulty by changing the intensity in such a way as to cause as little spread of energy as possible along the frequency scale. Riesz (1928) introduced the change in intensity by adding to a steady tone a second tone differing in frequency from the first by 3 cps. The second tone sometimes augmented the first and at other times partially canceled it, thereby introducing recurrent variations of amplitude at a rate of three per second. These variations at supra-

threshold levels give rise to the sensation of beats (cf. Fig. 3). Riesz' results are shown in Fig. 8. The upper surface of the solid figure defines the just noticeable increment in intensity as a function of the frequency and of the intensity* of the standard to which the increment was added. It is

switch the oscillator abruptly from 1000 cps to 1003 cps, we produce not two frequencies, but an infinitude of frequencies. The trouble is that we try to use time language and frequency language both in the same sentence, and that is very difficult to do correctly.

FIG. 8. Three-dimensional surface showing the differential intensity threshold as a function of the frequency and the intensity of the standard tone. The threshold is represented as the difference in decibels between the standard intensity and the standard plus the increment. Following the contour lines from 1000 cps and 30 db, we see, by way of illustration, that the intensity of a 1000-cycle tone must be raised 1.0 db from a level 30 db above threshold before the average observer can detect the change. If we start with levels 60 or 70 db above threshold, we find that an increment of less than 0.5 is detectable. (Based on the data of Riesz, 1928.)

important to note that the differential threshold is given in decibels. The difference limen (DL) in decibels = $10 \log (1 + \Delta I/I)$, where I is measured in terms of energy flow.

Differential threshold for frequency. The concept of a threshold change in frequency brings us up against the same difficulty that we faced in the case of the differential threshold for intensity. Again, it is impossible to change any of the parameters of a pure tone and leave the tone pure. If we

* The *sensation level* of a sound is the intensity of the sound in decibels above its absolute threshold level.

Despite its inherent difficulties, the question of frequency discrimination has been studied for many years and by many methods (see Boring, 1940). Probably the best procedure would be to vary the dial of an oscillator smoothly (sinusoidally) back and forth between two frequency settings and determine how far apart the settings have to be to make the average listener report 'change' in half the trials. This would be sinusoidal frequency modulation, and it would have the advantage that both the waveform and the spectrum of the frequency-modulated tone are easy to describe.

Shower and Biddulph (1931) used almost, but not exactly, the procedure just outlined. They modulated the frequency of the test tone in the way that would be achieved if the oscillator dial were moved sinusoidally from one frequency to the other and were then allowed to rest a moment before being moved back.

cps from 60 to 1000 cps, beyond which point it increases rapidly. Above 1000 cps, the *relative DL* ($\Delta F/F$) is approximately constant.

Factors influencing the DL's for intensity and for frequency. As we shall see when we examine temporal and binaural effects in hearing, the size of the DL depends to some

FIG. 9. Three-dimensional surface showing the differential frequency threshold as a function of the frequency and the intensity of the standard tone. Frequency discrimination is poor at intensity levels near the absolute threshold (rear part of figure) and at high frequencies (right-hand part of figure). At sensation levels above 30 db and at frequencies below 1000 cps, however, a change of about 3 cps can be detected. (Based on the data of Shower and Biddulph, 1931.)

They tried various rates of modulation and found that the sharpest discriminations were made when the frequency was varied back and forth about twice a second. They then determined DL's at various frequencies and intensities, for subjects listening monaurally, binaurally, and via bone conduction. The monaural results are shown in Fig. 9.

It is important to note that in Fig. 9 it is the absolute frequency change ΔF that is represented on the vertical scale. This method of representation emphasizes the fact that, at sensation levels above 30 db, the *absolute DL* is roughly constant at 2 or 3

extent upon the duration of the stimulus and upon whether it is presented to one ear (Figs. 8 and 9) or to both ears. The DL is influenced also by the mode of transition between the standard and comparison tones. Rawdon-Smith and Grindley (1935) have dramatized the latter fact by presenting to the listener a tone that periodically jumps upward in intensity, then falls slowly to the initial level. Subjectively, the sound seems to grow ever louder: the DL's are lower for abrupt than for gradual transition. Intervals of silence between the standard and comparison tones make the DL's larger, but

Harris (1948) has found that listeners can make surprisingly accurate discriminations of frequency with intervals as long as 25 seconds. Finally, as we should expect, the listener can make more accurate discriminations if he controls the switch that introduces the increment to be detected than if he has no way of concentrating his attention at the critical moment.

Quantization in the Auditory Process

In the simplest conceptual neurology, the stimulus threshold owes its existence to the effect of a small barrier, a threshold in the root sense of the word, between successive stages in the sequence of neural processes that underlie hearing. Actually it is difficult to determine whether or not the differential threshold is, in this sense, a true threshold, because the measured threshold is influenced by small but unavoidable fluctuations in the stimulating apparatus and in the listener himself. Nevertheless the overcoming of a barrier (or barriers) is fundamental to the concept of threshold. If the DL is more than a statistical artifact, the neural mechanism must function in a stepwise or quantal manner.

The best evidence of the existence of true barrier-determined thresholds in audition comes from experiments in which the transition from the standard to the comparison stimulus is abrupt. (In a short interval of time there is little opportunity for the occurrence of extensive fluctuations of sensitivity that might obscure the true threshold.) The curves of Fig. 10 show Békésy's (1930*b*) results on differential sensitivity to intensity. Plot *B* was obtained with highly sensitive, well-trained listeners, plot *A* with less sensitive or less well-trained listeners. The discontinuous and rectilinear nature of the curves suggests strongly that differential sensitivity to intensity is quantal (cf. Chapter 1). Experiments by Stevens, Morgan, and Volkman (1941), by Flynn (1943),

and by Miller and Garner (1944) have confirmed Békésy's observations and have further defined the conditions under which the quantal effect appears. The discovery of quantization in the psychometric function leads us to ask whether or not quanta can actually be heard. Some of Békésy's

FIG. 10. Evidence of quantization in intensity discrimination. The data (especially in curve *B*) are fitted better by straight lines than by ogive curves. The V-shaped and trapezoidal graphs are just what we should expect on the assumption of (1) fluctuating transmission efficiency and (2) a quantal discriminatory process. (From Stevens and Davis, 1938, after Békésy, 1930*b*.)

(personal communication) observations are of interest in this connection. A tone of very slowly declining intensity sounds as though it jumps down every so often. Very slow but continuous changes in frequency also produce subjective jumps. In the vicinity of the absolute threshold the almost discontinuous nature of sensation is, in Békésy's experience, especially marked (cf. Fig. 5, curve 4). The physiological basis of the quantization, however, is not clear. Stevens, Morgan, and Volkman (1941) attribute it to a central rather than to a peripheral process.

DIMENSIONS OF TONAL EXPERIENCE

The intensity and the frequency of a tone can be measured, if need be, by entirely automatic apparatus, far removed from the nearest listener. The loudness and the pitch of a tone, on the other hand, are attributes of the tone as heard and reacted to by a listener. Loudness and pitch are thus dimensions of auditory experience, whereas in-

concept of independent variability if the number of subjective attributes is greater than the number of stimulus dimensions. He suggests instead that the test for an attribute is its independent constancy or its invariance in the face of changes in the other attributes.

The Loudness of Pure Tones

In order to handle loudness quantitatively, we should like to have a ratio scale of loud-

FIG. 11. Three-dimensional surface showing loudness as a function of intensity and frequency. Subjective loudness in sones is represented vertically above the intensity-frequency plane. The heavy curves coursing from front to rear in the diagram are equal-loudness contours for pure tones. (After Stevens and Davis, 1938.)

tensity and frequency are dimensions of the acoustic stimulus. These distinctions between loudness and intensity and between pitch and frequency have not always been observed.

The term *subjective* attributes as used by Külpe and by Titchener referred to a rather limited set of the characteristics of subjective experience, characteristics that were regarded as inseparable (e.g. if there is no pitch, there is no sensation of tone) and independently variable (e.g. pitch can vary while loudness remains constant and vice versa). Stevens (1934*a, b, c*) has pointed out, however, that there is a difficulty in the

ness such that a sound of 1 loudness unit is twice as loud as a sound of $\frac{1}{2}$ loudness unit, half as loud as a sound of 2 loudness units, etc. (cf. Chapter 1). Whether or not such a scale can be constructed is, of course, an empirical question best answered by trying.

Several experimenters (Ham and Parkinson, 1932; Geiger and Firestone, 1933; Churcher, King, and Davies, 1934) measured the intensities at which one tone sounds twice as loud, half as loud, etc., as another tone; and Békésy (1929) and Fletcher and Munson (1933) performed experiments from which the intensities required for half-loud-

ness can be inferred. Putting these data together with other data obtained by measuring the intensity levels at which tones of different frequencies are equally loud, Fletcher and Munson (1933) constructed a ratio scale of loudness. As a name for the unit of loudness of this scale, Stevens' (1936) term *sones* has been widely adopted, one sone being the loudness of a 1000-cycle tone, 40 db above threshold. Other tones can be compared in loudness with a 1000-cycle tone by referring to the three-dimensional surface shown in Fig. 11.

The solid curves running from front to back in Fig. 11 are *equal-loudness contours*. We note, for example, that a tone of 10 cps, 120 db above 0.0002 dyne per square centimeter, has for the average listener the same loudness (80 sones) as a tone of 1000 cps at 100 db. It is thus evident that loudness is a function of frequency as well as of intensity. Following the dashed lines, we see that, for a given intensity, the loudness is greater in the middle range of the frequency scale than it is at either extreme. And, following the solid curves that sweep upward from left to right, we see that, as the intensity is increased uniformly along the logarithmic scale, loudness increases slowly at first, then more and more rapidly. The loudness is in fact over three times as great at 100 db as it is at 80 db. This is, however, by no means a violation of the law of diminishing returns: the stimulus power is 100 times as great at 100 db as it is at 80 db.

The Pitch of Pure Tones

The pitch analogue of the loudness scale shown in Fig. 11 would be a surface representing the pitch of each audible tone as a function of its intensity and of its frequency. The variation of pitch with intensity, however, is small (Zurmühl, 1930; Stevens, 1935; Snow, 1936; and Morgan and Garner, 1947), and a single function relating pitch to frequency will suffice, as a first approximation, as a pitch scale for all inten-

sities. Such a scale was determined by Stevens, Volkman, and Newman (1937) and later modified by Stevens and Volkman (1940) with the aid of the fractionation and the bisection procedures. The 1940 scale is shown in Fig. 12. The function is plotted twice, once against a linear frequency scale

FIG. 12. Pitch as a function of frequency. The upper curve shows that subjective pitch (in mels) increases less and less rapidly as the stimulus frequency is increased linearly. The lower curve shows that subjective pitch increases more and more rapidly as stimulus frequency is increased logarithmically. (The musical scale is a logarithmic scale.) The pitch of a 1000-cycle tone, 40 db above threshold, is defined as 1000 mels. (After Stevens and Volkman, 1940.)

(top of graph) and once against a logarithmic frequency scale (bottom of graph).

There are many claims and some evidence that, in addition to the ordinary type of pitch perception to which the pitch scale just described refers, there is another type of pitch perception that endows the musical note C with a certain 'C-ness,' that makes middle C more like the C an octave higher than like the D that is only an interval removed along the musical scale. This quality, which characterizes tones of frequencies below 5000 cps, we may call *tone chroma*, or *tonality*, to distinguish it from ordinary pitch—realizing, however, that there is probably no field of psychology in which the

terminology has been more confused (cf. Boring's summary, 1942). Bachem (1948) has restated the view, held earlier by Révész (1913) and by Max Meyer (1914), that individuals with "genuine absolute pitch" are able to identify tonal frequencies with great accuracy because the "tone height" (ordinary pitch) points out the proper octave and the "tone chroma" locates the note within

Volume, Brightness, and Density of Pure Tones

In addition to loudness and pitch, tones differ from one another in such dimensions as *volume* (size, extensity), *brightness*, and *density* (compactness). The tones of a tuba sound bigger than those of a piccolo, and a bugle blast appears to be hard and compact and to have a luster that is lacking in the

FIG. 13. Equal-volume contours for pure tones. Those tones are judged equal in volume whose frequency and intensity coordinates fall along one of the curves. The upper left-hand curve represents the largest volume, the lower right-hand curve represents the smallest, but the subjective volume ratios have not been determined. The parameter is the sensation level (number of decibels above threshold) of the 1000-cycle tone in each contour. (After Thomas, 1949.)

the octave. "Genuine absolute pitch" is quite different, according to Bachem, from the "quasi-absolute pitch" developed by musicians who learn to estimate the frequencies of tones in relation, for example, to the lowest notes they can sing. The recent discussion of absolute pitch by Neu (1947, 1948) and Bachem (1948) serves to emphasize, however, that we must have (1) agreement on a definition of absolute pitch and (2) careful measurements with controlled stimuli on (3) an adequate sample of listeners before we can be sure that there is reason to postulate a special mechanism for absolute pitch. We do not, for example, postulate a special kind of vision to account for unusual accuracy in color naming.

more diffuse sound of an organ. It is true, of course, that we visualize the sound source as larger in the case of the tuba and as shinier and more compact in the case of the bugle, but the subjective dimensions are held to refer to the sounds themselves and not to their sources. The question is, do listeners react confidently and consistently when they compare sounds in respect of the dimensions, volume, brightness, and density?

In early experiments on the question of tonal volume, Rich (1919) and Halverson (1924) determined the DL's for volume as functions of frequency and intensity, respectively, and concluded that volume is, as an attribute of tonal experience, separate and distinct from pitch and from intensity.

The inconsistent results later obtained by Gundlach (1929), Gundlach and Bentley (1930), and Zoll (1934), however, made it appear for a time that volume is not a characteristic upon which different listeners can agree. Nevertheless, by giving the listeners control over the variable stimulus, and by determining equality rather than differential sensitivity, Stevens (1934*a*, *b*) was able to obtain consistent determinations of equal-volume contours, and Thomas (1949) has extended these contours over a wide range of frequencies and intensities.

Figure 13 shows smoothed equal-volume curves based on Thomas' data. Knowing that the volume of a sound increases as we raise its intensity, we can tell from Fig. 13 that the increase is very rapid as soon as we elevate low-frequency tones above their absolute thresholds. High-frequency tones, on the other hand, must be raised to intensities far above their absolute thresholds before they attain any appreciable volume. We should like to be able to label each of the equal-volume contours of Fig. 13 with the appropriate parameter in volume units, but we do not yet have the data needed to construct a subjective ratio scale of volume. Hence we designate each contour with the sensation level of the 1000-cycle tone to which the other tones are equal in volume.

Stevens (1934*b*, *c*) employed the equating procedure to determine not only equal-volume contours but equal-density and equal-brightness contours. His results indicate that volume and density are separate attributes, different from each other and from pitch and loudness. Boring and Stevens (1936) later suggested that brightness and density might well be different words for the same attribute.

MASKING AND FATIGUE

When we say we hear two tones at once, we give evidence of having made an analysis of the acoustic stimulation, for, even though the air vibrations at the eardrums

represent the superposition of waves from two separate sources, they constitute one physical sound, not two. It is a remarkable fact that our auditory mechanisms can analyze compound acoustic stimuli into components, that we can describe the loudness or the pitch or the location of one component while effectively ignoring another.

However, analysis is not perfect. A weak tone is audible in a quiet room, but not in a noisy one, where the tone is *masked* by the noise. Masking is thus the opposite of analysis; it represents the inability of the auditory mechanisms to separate the tonal stimulation into components and to discriminate between the presence and the absence of one of them.

The degree to which one component of a sound is masked by the remainder of the sound is usually determined by measuring two thresholds. Let us call the part that does the masking the primary component, and the part that is masked the secondary component. First we find the intensity at which the secondary component is just audible in the presence of the primary; this is its masked threshold. Then we find the intensity at which the secondary component is just audible when sounded alone; this is its absolute threshold. The ratio of these two intensities, expressed in decibels and referred to as the threshold shift, we take as a measure of the masking.

Masking of pure tones by pure tones. Wegel and Lane (1924) made a study of the masking of one pure tone by another. They worked chiefly with a single listener but covered a wide range of frequencies and intensities. Their results are shown in Figs. 14 and 15. Figure 14 describes what is heard when a primary tone of 1200 cycles, 80 db above its threshold, is used to mask a secondary tone of variable frequency and intensity. When the secondary tone is above its masked threshold, the sensation cannot be described simply as a pair of tones; it is complicated by the presence of beats, subjective harmonics, and combination tones.

Figure 15 presents the results in greater detail, showing how much the threshold for the secondary tone is shifted when the primary tone is turned on.

The main facts about masking, evident in Figs. 14 and 15, are these: (1) Masking tends to be greater for tones of neighboring frequencies than for tones widely separated

Masking of pure tones by white noise. As we have already seen (Fig. 2E), white noise contains components of all the audible frequencies, sounding simultaneously. When a pure tone is presented against a background of white noise, therefore, it is masked, as it were, by all of Wegel and Lane's masking tones at once. We should,

FIG. 14. The various sensations produced by a two-component tone. The primary component is a sinusoid of 1200 cps, 80 db above threshold. The secondary component is a sinusoid of the frequency and sensation level indicated by the frequency and sensation level indicated by the coordinates. When the secondary component falls below the solid curve it is masked. When the secondary component is above its masked threshold, however, the auditory sensation may be quite complex, as indicated by the descriptions in the several regions of the graph. (From Fletcher, 1929, after Wegel and Lane, 1924.)

along the frequency scale. (2) Low-frequency tones effectively mask high-frequency tones, whereas high-frequency tones are much less effective in masking low-frequency tones. (3) The rate at which masking increases as the masking tone is raised in intensity depends upon the frequencies of the tones. When the masked tone is applied to one ear and the masking tone to the other ear, very little masking occurs (Wegel and Lane, 1924). What little masking is observed can be attributed largely to leakage of the masking vibration around the head (Békésy, 1948).

of course, expect the resultant masking to be much less critically a function of the frequency of the masked tone than was the masking produced by a single pure tone.

This expectation is confirmed by the results of Hawkins and Stevens (1950), shown in Fig. 16. The lowest contour is the absolute-threshold curve, and the other contours mark the monaural thresholds for pure tones heard against a background of white noise. The parameter is the intensity of the noise, expressed in terms of level per cycle. The level per cycle, or spectrum level, as it is often called, is the amount of

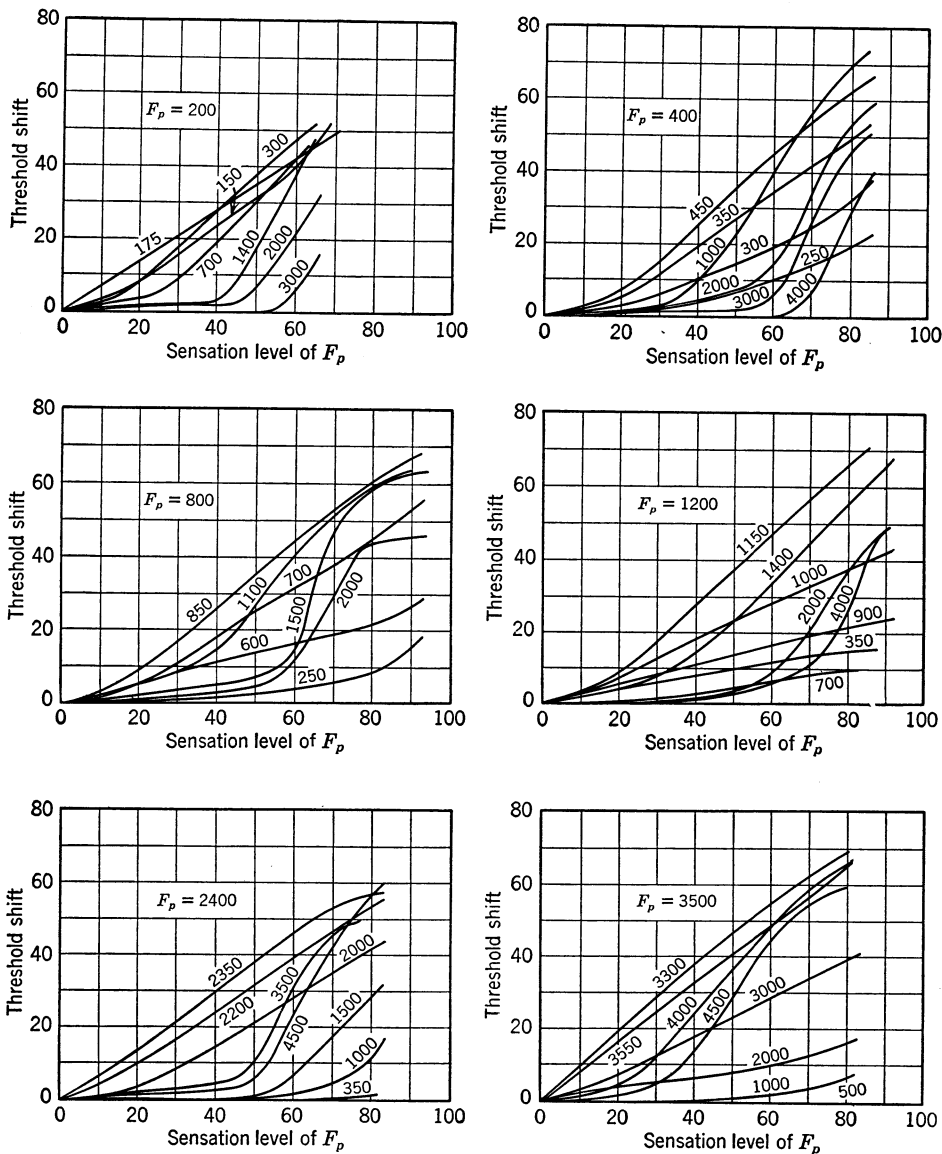

FIG. 15. The masking of secondary by primary components. The frequency of the primary component F_p is given in each plot, and the frequency of the secondary component is attached to the curve. Note that the growth of masking with increasing intensity of F_p is approximately linear only when the two components are nearly equal in frequency. (From Fletcher, 1929, after Wegel and Lane, 1924.)

FIG. 16. The masked threshold for pure tones presented against a background of white noise. The ordinate gives the sound pressure that the sinusoid must reach to be audible against random fluctuation noise of the spectrum level shown as the parameter. (From Hawkins and Stevens, 1950.)

FIG. 17. The relation between the masking produced by a white noise and the effective level of the noise. The effective level is the amount of noise power in a narrow frequency band, the "critical band" (see text), centered about the frequency of the masked sinusoid. It is expressed in decibels relative to the absolute threshold (in power units) at that frequency. When the intensity is given in terms of effective level, the function shown in the graph is essentially independent of the frequency of the masked sinusoid. (From Hawkins and Stevens, 1950.)

sound energy in the small fraction of the noise spectrum that lies between two frequency limits 1 cycle apart. Since the spectrum of the noise was uniform within the frequency limits set by the earphones, the total noise energy is equal to the level per cycle multiplied by the total bandwidth.

Since masking is the shift in threshold produced by the masking sound, we can find

by Fletcher and Munson (1937). Instead of a white noise, however, they used a random noise with a nonuniform spectrum. The spectrum was so adjusted that it produced approximately the same amount of masking at each frequency. This adjustment had, of course, to be determined empirically.

Having established the shape of the spectrum that produces uniform masking,

FIG. 18. Four functions relating Δf to f . The critical band function (circles and solid curve) shows the width of the band of noise that contributes to the masking of a sinusoid at the center of the band. In the frequency-discrimination curve (squares and solid curve), Δf is 20 times the jnd (cf. Fig. 9, approximately 70-db sensation level). The curve based on the pitch scale gives the width in frequency of intervals that are 50 mels wide in pitch. The curve based on intelligibility data shows the widths of frequency bands that contribute equally—2 per cent of the total—to the intelligibility of speech (cf. Chapter 26). The similarity of the curves suggests that they have a common basis in the auditory mechanism. (Based on the data of Fletcher, 1940; Shower and Biddulph, 1931; Stevens and Volkman, 1940; and French and Steinberg, 1947.)

from Fig. 16 how much a white noise of given intensity masks a pure tone of given frequency by noting the separation of the masked-threshold and the absolute-threshold contours. This separation increases as we go from the left-hand side of the graph to the center. No matter what the frequency of the masked tone, however, the amount of masking increases at an almost constant rate as we make the noise more and more intense. The relation between masking and noise intensity is shown in Fig. 17.

The Concept of Critical Bands

An experiment quite similar to that of Hawkins and Stevens was performed earlier

Fletcher (1940) was able to derive, with the aid of an important assumption, the relation that tells us the width of the critical band mentioned in the legend of Fig. 17. Fletcher's assumption can be stated in two parts: (1) that we can neglect the masking produced by all the components of the noise except those whose frequencies lie within a narrow band around the frequency of the masked tone; and (2) that, when the tone is just audible against the background of noise, the acoustic power of the tone is the same as the acoustic power of the noise components within the narrow band. We cannot go into the details of Fletcher's reasoning, but we can get an idea of the fundamental

nature of his critical band function by comparing it (Fig. 18) with three other basic psychophysical functions that relate a frequency bandwidth to a center frequency. In Fig. 18 the critical band function is marked by the circles and approximated by the solid curve. The other three functions are based on (1) Shower and Biddulph's data on frequency discrimination (squares

19 gives, for comparison, what might be called the critical band function for the basilar membrane. It is derived by measuring the frequency intervals (Δf) between the half-amplitude points of the frequency-selectivity curves in Fig. 31 of Chapter 27, which describe the vibration of the cochlear partition as seen through a microscope by Békésy.

FIG. 19. The heavy solid curve shows the widths (between half-amplitude points) of the selectivity or resonance curves at various points along the basilar membrane, as observed by Békésy. The difference between this curve and those of Fig. 18 argues against the interpretation of the psychophysical data (of Fig. 18) as reflecting directly the mechanical frequency-resolving of the cochlea. The functions for beats and trills, however, are roughly parallel to the heavy solid curve. These are referred to later in the text. (Based on the data of Mayer, 1894; Békésy, 1943; and Miller and Heise, 1949.)

and solid curve), (2) Stevens and Volkman's pitch scale (dashed line), and (3) French and Steinberg's curve showing the importance of various frequencies for the intelligibility of speech (dotted lines; cf. Chapter 26).

The fact that the four curves of Fig. 18 follow such parallel courses suggests that they stem from a common source, the frequency-resolving characteristic of the auditory system. They are no doubt related to the function that describes the sharpness of tuning of the cochlear mechanism, but probably not in the very direct way suggested by Fletcher (1940). The solid curve of Fig.

Masking and differential sensitivity. If we compare the operations that we perform when we measure the masked threshold with those we perform when we measure the differential threshold for intensity, we find that we do essentially the same things in the two experiments. The principal differences lie in our selection of signals and in our interpretation of the measurements. If we recall, for example, Riesz's procedure for determining the just noticeable increment in intensity, we note that he actually measured the masking of one tone by another 3 cycles removed along the frequency scale. In fact, his data were used in preparing that part

of Fig. 14 that shows how much tones near 1200 cycles are masked by a 1200-cycle tone.

G. A. Miller has recently pointed out that this equivalence of operation holds also for (1) the masking of white noise by white noise and (2) the differential threshold for noise intensity. Miller's results are presented in Fig. 20. The figure shows how large the increment in the intensity of a

FIG. 20. The differential intensity threshold for white noise. The open circles are for the type of noise illustrated in Fig. 2E. The closed circles are for noise consisting of rectangular waves of irregular lengths. The square-wave noise sounds like white noise and has essentially the same jud's. (After G. A. Miller, 1947.)

white noise, heard binaurally, must be before a listener can detect a change. Regarded from the point of view of intensity discrimination, his data indicate that an increment of about 0.4 db can be heard to produce a change when it is added to a fairly intense white noise. Regarded from the point of view of masking, Miller's data indicate that one fairly intense white noise is entirely masked by another white noise 12 db more intense.

Auditory Fatigue

Masking refers, as we have seen, to the elevation of the threshold for one tone by a second tone sounding simultaneously. The threshold for a tone may be elevated also by prior stimulation. The post-stimulation depression of sensitivity is called auditory fatigue or adaptation, temporary hearing loss, or permanent hearing loss, depending

upon its persistence. Here we shall consider only the effects of relatively short duration. Previous work has been summarized by Banister (1934) and by Stevens and Davis (1938).

Measurements of short-duration auditory fatigue following tonal stimulation have been made by de Maré (1939), by Gardner (1947), by Caussé and Chavasse (1947), and by Lüscher and Zwislocki (1947). These experimenters used variations of the same basic procedure, which runs as follows: A fatiguing tone of fixed duration is presented to the listener. After the fatiguing tone has been turned off and an interval of silence has elapsed, a short burst of tone is applied to test the momentary sensitivity of the

FIG. 21. The momentary threshold at various intervals after a burst (0.4 second) of fatiguing or preconditioning tone. The parameter is the intensity of the preconditioning tone in decibels re 0.0002 dyne per square centimeter. (After Lüscher and Zwislocki, 1947.)

auditory system. The test is repeated with fatiguing tones and with test tones of various frequencies and intensities. The curves of Figs. 21 to 23 illustrate the results, showing the degree to which the threshold for the test tone was shifted by the previous stimulation. We see (Fig. 21) that, when the fatiguing tone and the test tone are applied to the same ear, the after-

effects of even moderate stimulation persist for over a tenth of a second. There is little or no depression of sensitivity when one ear is fatigued and the other tested.

The results shown in Figs. 21 to 23 are for listeners with normal hearing. Listeners with so-called nerve deafness yield curves of a characteristically different shape. Listeners with conductive deafness yield curves

given in terms of phase difference), the amount by which the masking wave shifted the threshold for the masked wave. Typical results are shown in Fig. 25. For masked frequencies higher than the masking frequency, we see that masking is greatest when the masked tone *precedes* the masking tone by about $\pi/4$ radians, i.e. about 2 milliseconds. This result appears reasonable

FIG. 22. Frequency characteristic of the momentary threshold 20 milliseconds after a 0.4-second preconditioning tone. The parameter is the intensity of the preconditioning tone in decibels re 0.0002 dyne per square centimeter. (After Lüscher and Zwislocki, 1947.)

similar to those of normal subjects except that their thresholds are shifted upward by a number of decibels equal to the conductive hearing loss.

Retroactive masking. Since one tone can raise the threshold for a second presented either at the same time or after a short delay, it is natural to ask what happens when the masked tone is presented before the masking tone. R. L. Miller (1947) has obtained data on this question in an experiment with pulsed tones. Both the masked tone and the masking tone were turned on and off periodically as shown in Fig. 24. With the Amplitude of the masking wave fixed, Miller found, for each of a number of time intervals (in the figure, the time is

when we consider the fact that the synaptic facilitation lets intense neural activity proceed up the auditory pathways at a faster pace than weak neural activity. Apparently the activity set off by the intense masking pulse catches up with that set off by the weak masked pulse by the time the latter activity reaches the auditory cortex.

Sensitization. Following a procedure very much like that used in the experiments on auditory fatigue except for the use of sharp clicks instead of short tones, Buytendijk and Meesters (1942) obtained results that point to the existence of what might be called negative masking (cf. Bronstein, 1936). A moderately intense click makes another click, presented either a little earlier or a little

later, sound *louder* than it would have sounded had it been presented alone. If the facilitative effect depends upon central rather than cochlear processes, we might expect the augmentation to be greater when

An Auditory After-Image?

The problem of an analogue in hearing for the visual after-image has interested many investigators. The most nearly comparable phenomenon is the tinnitus, the an-

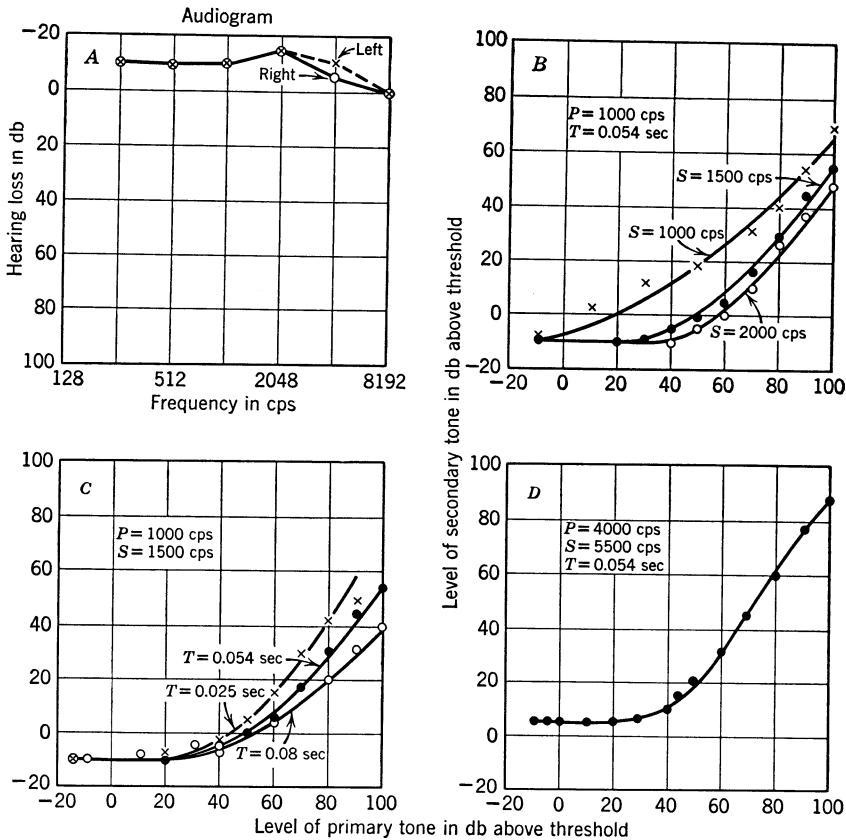

FIG. 23. Auditory fatigue at one frequency S produced by stimulation at another frequency P . Diagram A is a conventional audiogram; it shows that the ears of the listener are more sensitive than average. The other three diagrams show the elevations of the threshold for the secondary burst of tone S (second in time) that are produced by primary (preconditioning) bursts of tone P . The frequencies of the two tones and the duration of the interval between them are indicated in the diagrams. (From Gardner, 1947.)

the clicks are led to opposite ears than when they are applied to the same ear — this because there is very little ‘cross masking,’ and the binaurally separated clicks would not tend to mask each other. Buytendijk and Meesters found, indeed, that the facilitative effect was especially marked when one click is led to one ear, the other to the other.

noying ringing in the ear that often follows exposure to deafening sounds; but tinnitus may persist for hours, is often pathological in origin, and resembles spots before the eyes more than a true after-image.

Although perhaps not technically an after-image, an after-effect of acoustic stimulation observed by Rosenblith et al. (1947) is of considerable interest. After listening for

FIG. 24. The stimuli used to study the temporal spread of masking are repeated spindles of tone. The masked spindles can be made to come a little early (as shown in the figure) or a little late. With a given time (or phase) interval, the Amplitude of the masked spindle is adjusted until the listener can just notice its presence. For comparison the threshold of the masked wave is also determined in quiet. (From R. L. Miller, 1947.)

FIG. 25. Masking as a function of the temporal separation of the masked and masking waves illustrated in Fig. 24. Note that for masked frequencies greater than the masking frequency (1000 cps) masking is greatest when the masked wave arrives slightly earlier than the masking wave. (From R. L. Miller, 1947.)

some seconds to a train of sharp pulses (cf. Fig. 2C), the listener finds that familiar noises do not have their expected quality. Instead, they sound "jangly" or "twangy" as though they were being modulated in an unusual manner. This effect is noted after the pulses are turned off, and it continues for some seconds (Fig. 26A), depending upon the intensity and duration of the pulses. The after-effect does not manifest itself in the absence of acoustic stimulation, but it impresses itself upon almost any familiar sound. The characteristics a sound must have in order to set up the after-effect are not yet thoroughly understood, but it appears that the sound must contain relatively strong high-frequency components and that the overall sound pressure must undergo sudden jumps about 100 times a second.

BEATS, AURAL HARMONICS, AND COMBINATION TONES

If we stimulate the ear with two equally intense sinusoids and gradually increase their separation along the frequency scale, we find that the sound passes through four stages (Wever, 1929). First, a single subjective tone is heard; its loudness waxes and wanes. When the difference between the frequencies reaches 6 or 7 cps, we cease to hear the waxing and waning: the tone takes on an intermittent, throbbing quality like a violinist's vibrato. At about 25 cps we can no longer make out the individual throbs, and the sound has the rough quality of a Scotsman's burr. This third stage lasts until the two sinusoids are separated by a frequency interval, Δf , shown in Fig. 19 by the curve marked "beats," which is based on the data of Mayer (1894). In the fourth and final stage, the listener hears two smooth tones and, if the sinusoids are intense, a mixture of harmonics and combination tones.

According to Helmholtz' widely accepted theory, we hear beats only because the cochlear mechanism provides imperfect fre-

quency analysis. The essential condition for beats is that the two frequency components of the stimulus affect overlapping segments of the basilar membrane. In the region of overlap, two oscillations are superimposed, and the pattern of vibration is similar to that shown in Fig. 3. Outside the region of overlap, on the other hand, the oscillation is

FIG. 26. Characteristics of the auditory after-effect. A. The duration of the after-effect depends upon the duration and upon the intensity of the preconditioning stimulation. B. To produce a constant duration (2 seconds) of after-effect, the intensity and duration of the preconditioning stimulation (140 pulses per second) must be related in the way shown by the curve. (From Rosenblith et al., 1947.)

principally attributable to a single frequency component.

Historically, beats and difference tones have been regarded as closely related phenomena because they are always characterized by the same frequency of recurrence (cf. Boring, 1942). It would appear, however, that their underlying processes are quite different. Beats occur whenever two tones are superposed. Combination tones (of which difference tones form a subgroup) occur only when two tones are superposed in a nonlinear system.

With difference tones, therefore, we come to the general question of nonlinear effects

in hearing (see also Chapter 26). The output of a nonlinear circuit characteristically contains frequency components not present in the input. This effect is illustrated in Fig. 27 in which the input is a single-frequency tone: the output contains frequencies that are integral multiples of the input frequency. These are called har-

ing to multiples and to combinations of the stimulus frequencies.

SUBJECTIVE ATTRIBUTES OF COMPLEX SOUNDS

A sound that is acoustically complex, i.e. one that has more than one frequency component, may or may not give rise to a complex sensation. Complexity also has interesting effects on the attributes, loudness, pitch, and volume, and may even give rise to new attributes.

The loudness of complex sounds. Experiments with acoustically complex tones (Fletcher and Munson, 1933; Fletcher, 1935; Howes, 1949) have shown that, if the components are sufficiently separated from one another along the frequency scale, the total loudness is equal to the sum of the loudnesses of the individual components presented separately. If the frequency components of the complex tones are not widely separated, however, the total loudness is somewhat less than the sum of the individual loudnesses. The failure of simple additivity is due to the fact that the cochlear or neural activities set up by the several components overlap. Following this reasoning to the extreme case, we should expect the growth of loudness (with increasing intensity) to be slowest for a single-component tone, because all the activity would be concentrated in one region of the basilar membrane and one channel of the auditory system. As is shown in Fig. 28, noises grow in loudness more rapidly than does a tone.

The pitch of complex sounds. We have already seen that there is not a direct, one-to-one relation between pitch and frequency, because pitch depends also upon intensity. But the variation of pitch with intensity is less marked for complex tones than for pure tones (Fletcher, 1935). The main problem to consider, therefore, is: to what aspect of the spectrum of a sound is pitch so closely (though not uniquely) related? Is it, indeed, the fundamental frequency?

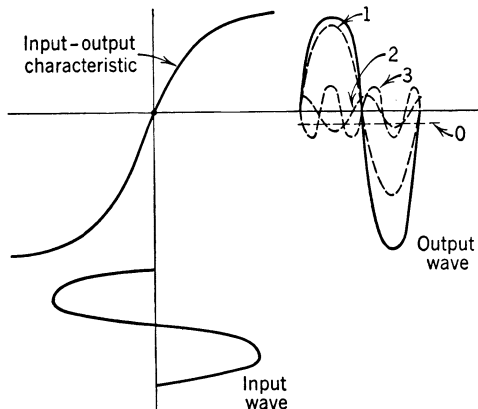

FIG. 27. Nonlinear distortion in the sound-transmission apparatus of the ear. By projecting points from the input waveform up to the characteristic curve, then over to the proper time position in the output plot, we see that the sinusoidal input is transformed into a complex output. The latter can be analyzed into a steady component (dotted line 0) and harmonics (dotted lines 1, 2, 3, ...) of the input frequency.

monics or overtones. When the input consists of two beating tones, the output contains not only the two input frequencies and their harmonics, but components whose frequencies are sums and differences of the input frequencies and their integral multiples.

The peripheral auditory mechanism is nonlinear when driven to high amplitudes of oscillation. The nonlinearity appears to be of the type represented in Fig. 27. It is only to be expected, therefore, that, when the intensity of an acoustic stimulus is sufficient to drive the system into the curved part of its characteristic, the resonant mechanism should analyze the complex into components, and that we should hear pitches correspond-

Fletcher (1935) has pointed out that almost everyone hears the complex tone consisting of components 700, 800, 900, and 1000 cps as having approximately the same pitch as a 100-cycle pure tone. Although it has no energy at 100 cps, the 700-800-900-1000-cycle tone has by definition a fundamental frequency of 100 cps: the highest frequency of recurrence of the waveform is 100 cps.

FIG. 28. The growth of loudness with increasing intensity. Loudness increases most rapidly for the uniform masking noise, which distributes excitation as widely as possible. The increase is least rapid for the pure tone, which produces a maximal concentration of excitation. The uniform spectrum noise (white noise) is intermediate. (Based on the data of Fletcher and Munson, 1937, and Pollack, 1948c.)

However, since the common difference frequency is also 100 cps, the observation that the pitch is approximately that of a 100-cycle tone does not decide between the two possible determiners of pitch, fundamental frequency and common difference frequency. Schouten (1940) resolves this question by asking listeners the pitch of a tone consisting of components at 300, 500, 700, 900, ..., cps. This tone has a fundamental of 100 cps and a common difference frequency of 200 cps. The listeners say that the pitch is approximately that of a 100-cycle pure tone, thus deciding in favor of the former alternative, that the fundamental frequency (or, as Schouten puts it, the periodicity of the waveform) is the important thing,

whether there is energy at the fundamental or not.

If we accept this conclusion, that pitch depends upon the fundamental frequency whether there is energy at the fundamental or not, we find ourselves on the verge of rejecting the place theory of pitch perception. We can reconcile the two theories only by arguing that, although in the acoustic stimulus there is no energy at the fundamental frequency, energy is shifted to the fundamental by nonlinear processes that intervene between the vibration of the eardrum and the excitation of the neurons of the auditory nerve. However, Schouten does not think the place theory can be rescued so easily. He points out that pitch is determined by the "missing fundamental" even at intensity levels so low that little or no nonlinear distortion should occur.

It might be possible, of course, for the central nervous system to determine the fundamental frequency from the neural correlates of the higher harmonics. Schouten thinks, however, that the clue for pitch is transmitted to the central nervous system as an actual periodicity. How the periodicity of the waveform can be preserved despite the analytical action of the cochlear mechanism is illustrated in Fig. 29. This figure is similar to Fig. 4 except that a train of input pulses has replaced the single pulse, and that here each low-frequency resonator responds only to a narrow band of the pulse-train spectrum, whereas each high-frequency resonator responds to a band wide enough to include several harmonics. The periodicity of the waveform is retained, therefore, in the responses of the high-frequency resonators. Schouten reports that a complex wave consisting entirely of frequency components above 3000 cps is heard as having a pitch of 200 cps if its components are spaced along the frequency scale at multiples of 200 cycles.

Schouten's theory applies, however, only within limits. If the period between recurrences of the complex wave is too long — a

second, for example — we should not expect the pitch to be determined in any simple way by the periodicity. Ekdahl and Boring (1934) have shown, in fact, that the pitch of a tonal mass (e.g. 236, 244, 252, 260, 268,

276, 284, and 292 cps) is, as we should expect on the basis of the resonance-place theory, equal to the pitch of a pure tone lying near the midfrequency of the mass. The same result appears to hold for bands

FIG. 29. The preservation of a periodicity corresponding to the fundamental frequency of a complex input wave of 200 pulses per second. The pulses are applied to each of the frequency-selective (resonant) circuits for which selectivity curves are shown. These resonant circuits differ from those of Fig. 4 in that they have equal Q 's rather than equal damping constants. (The selectivity of the auditory system is intermediate between these two.) Only a single component of the input wave gets through the low-frequency resonators, but several pass through the higher resonators. These several components beat together and produce a periodic, complex output. If the auditory nerve fibers respond to this output, they may preserve the periodicity of the original pulse train. Eliminating the low-frequency components of the pulse train would have no effect upon this periodicity. (After Schouten, 1940.)

of random noise, for which the fundamental frequency is zero, i.e. the waveform never recurs.

A question arises as to how rigorously we should interpret Schouten's term, periodicity. If the component frequencies are incommensurable, the signal is not rigorously periodic, yet its *envelope* may be recurrent. We have evidence from experiments by Mathes and R. L. Miller (1947) that periodic recurrence of the envelope is sufficient, that rigorous periodicity of waveform is by no means an essential, to give the sound a pitch or at least a subjective attribute very much like pitch.

An instance in which a totally aperiodic sound appears to have a definite pitch has been described by G. A. Miller and Taylor (1948). They used a white noise turned on and off at various rates. When the rate of interruption was very low, the noise appeared to come, of course, in successive bursts. But when the rate was increased to about 40 per second, the noise took on a fairly definite pitch — this despite the fact that the intensity of the 40-cycle component of the interrupted noise was no stronger, and no less strong, than any other component. Listeners were able to match the interrupted noise in pitch to a pure tone with reasonable accuracy until the interruption rate exceeded 200 per second. Thus we have an instance in which pitch appears to depend solely upon fluctuations in the rms pressure of the sound wave.

On the basis of the foregoing evidence, we are justified in looking for two different bases for subjective pitch. The pitch of a pure tone — of a high-frequency tone, at any rate — appears to be related to the place within the higher nervous centers at which it excites activity, whereas the pitch of a complex tone of fundamental frequency between approximately 25 and 300 cps may depend principally upon the rate at which the fluctuations of this activity occur. (Note that the frequency region between 25 and 300 cps is a region of poor mechanical

frequency analysis, described in Chapter 27, Fig. 44.)

The volume of complex sounds. In the same experiment in which he determined equal-loudness contours for various bandwidths of white noise, Thomas (1949) had his listeners make equal-volume judgments. From the equal-volume contours, we can infer that as we increase the bandwidth of a uniform, continuous-spectrum noise, holding the total noise power constant, the volume of the noise grows even faster than the loudness does. This is especially true at high intensity levels. On the basis of Thomas' results we might hypothesize that volume is more dependent upon the spread of neural activity and less dependent upon the intensity of that activity than loudness is.

The timbre of complex sounds. The timbre of a complex sound has usually been defined as the subjective quality that depends upon the complexity or overtone structure of the physical sound. We have seen, however, that both the loudness and the pitch of a complex tone are influenced to some extent by its overtone structure. We must, therefore, fall back upon the ill-defined notion that timbre has to do with the distribution or pattern of pitch and loudness in the total sensation. Until careful scientific work has been done on the subject, it can hardly be possible to say more about timbre than that it is a "multidimensional" dimension.

The annoyance value of complex sounds. Noises are often annoying. Upon what factors does their annoyance value depend? Everyday observation tells us that annoyingness is usually bound up with meaning (the knock or sputter of an automobile engine, the honk of the car behind), with the state of the listener (the robin stomping on the lawn in the early morning), with repetitiveness (the incessant tick of the clock, the footsteps on the bare floor of the apartment upstairs), with intensity (the subway, the elevated), and with frequency (the squeak

of the chalk on the blackboard, of the finger-nail on the window pane).

Despite the obvious practical importance of accurate knowledge on these points, only the last two factors have been studied in the laboratory. Laird and Coye (1929) studied the annoyance value of tones as related to pitch and loudness, and Reese and Kryter (1944) (also Kryter, 1948b) determined

duce effects. We should anticipate, therefore, that the process of stimulation must involve some sort of accumulation of excitation. The question is, what are the rules that govern this accumulation?

One of the principal methods employed in attempts to answer this question has been to determine the relation between the duration of a sound and the intensity it must

FIG. 30. Temporal integration at the absolute threshold. The curves show how the threshold power decreases as the duration of the acoustic stimulus increases. (After Garner, 1947a.)

equal-annoyance and equal-loudness contours for narrow frequency bands of random noise. The two experiments agree in indicating that annoyance goes up with loudness and that high-frequency sounds are more annoying for a given loudness than are low-frequency sounds.

TEMPORAL EFFECTS IN HEARING

Up to this point we have been concerned principally with sustained sounds, sounds of sufficiently long duration that the question of changes in their duration is of little concern. Now, however, we must examine more closely the temporal dimension of hearing.

Temporal integration. Acoustic power alone does not activate the auditory mechanism. The power must be expended for some length of time: it takes energy to pro-

duce effects. This method has been used by Hughes (1946), Garner (1947b), G. A. Miller (1948), and de Vries (1948). From their results, shown in part in Fig. 30, we see that, within the range of durations studied, the threshold decreases as the duration increases.

If we had only the 4000-cycle curve of Fig. 30 to consider, we might set up the hypothesis that the auditory mechanism simply integrates the stimulus power, that the threshold expressed in terms of the time integral of power, i.e. in terms of *energy*, is constant. In simplest form,

$$It = \text{Constant}$$

where I is intensity and t is duration. According to this hypothesis, however, all the curves should fall 1 log unit (10 db) in intensity for each log unit increase in duration, and we see that the slope of the noise

curve is only about -8 db per log unit of duration. A second difficulty is that the 250-cycle curve levels off instead of continuing upward to the left as the duration is decreased. And, finally, common sense tells us that all the curves must level off instead of continuing downward to the right if only we make the stimulus durations long enough.

Therefore we must modify the hypothesis of simple integration. There is, of course, an infinitude of possible variations, two of which have been considered for the masked threshold by Garner and Miller (1947). The first, we can call the diverted input hypothesis. Briefly, it says that a constant portion of the stimulus power I_0 is diverted from the excitation process and is not integrated. The threshold function is therefore given by

$$(I - I_0)t = \text{Constant}$$

The second variation is the auditory analogue of Crozier's (1940) statistical theory of visual sensitivity. This formulation leads, however, to a prediction so similar to the one just mentioned that the data are not capable of discriminating between the two. As is so often the case, both hypotheses are tenable, and neither is proved to be correct.

We have as yet no real understanding of the difference between the curve for noise and the curve for the 4000-cycle tone. We can say only that the accumulation process is influenced by the frequency bandwidth of the acoustic signal. The peculiar behavior of the 250-cycle curve, on the other hand, is explicable. As the tone is made shorter, energy is spread along the frequency scale. Some of this energy falls within a frequency range in which auditory sensitivity is considerably higher than it is at 250 cycles. This increases the audibility of the tone and makes the curve less steep at short durations.

Not only the absolute threshold but also the masked threshold (Garner, 1947a) and the differential thresholds (Miller and Gar-

ner, 1944; Turnbull, 1944) of tones are dependent upon duration. The relation between the differential threshold for intensity and the duration of the increment added to an otherwise steady tone is shown in Fig. 31. The differential threshold for frequency also grows larger as the duration of the increment decreases.

FIG. 31. The differential threshold for intensity as a function of the duration of the added increment. $\Delta I/I$ is the ratio of the sound-pressure increment to the standard sound pressure. Increments that last 0.5 second are as readily detectable as longer ones, but shorter durations require greater intensity. The open and the closed circles distinguish two listeners. (From Miller and Garner, 1944.)

The rise and fall of loudness. When we listen to a short sound, we hear its loudness build up rapidly, reach a maximum, and then decline. The problem of determining the temporal course of the sensation has interested several investigators (Metzger, 1932; Roelofs, 1939; Buytendijk and Meesters, 1942), but the measurement of loudness at instants closely spaced in time has proved very difficult. It has been possible, however, to answer questions phrased more directly in terms of the stimulus. How must we vary the intensity of a tone to compensate for changes in its duration? How long must a sound last before it gets to be as loud as it will ever become? How slowly can we turn a sound off and still have it appear to terminate abruptly? (Békésy (1933), Lifshitz (1933), and Munson (1947)

have studied these questions with tonal stimuli, and G. A. Miller (1948), taking advantage of the uniform spectrum of white noise in order to avoid the problem of the 'impurity' of short tones, has studied them with bursts of noise.

Békésy found that, in order to hold the loudness of short tones constant, he had to

or noise with varying degrees of abruptness, and to find the highest rate of decay that could be distinguished from instantaneous cessation. Békésy's and Miller's results agree in indicating that, regardless of the intensity of the sound, the length of time required for the sensation to disappear is approximately constant. However, the noise

FIG. 32. Equal-loudness contours for white noise as a function of stimulus duration. The sound pressure of a short burst of noise that sounded equal in loudness to a standard 1.0-second burst is plotted as a function of the duration of the short burst. The dashed curve indicates the shortest duration for which loudness is independent of duration. (After G. A. Miller, 1948.)

trade intensity (I) for duration (t) according to the rule, $\log I = -k \log t + c$. Loudness did not increase further, however, after the duration of an 800-cycle tone reached 180 milliseconds. Munson, using tones of 125, 1000, and 5650 cps, arrived at a slightly larger value, 250 milliseconds, for the critical duration. Miller's results (Fig. 32) indicate that the critical duration for white noise depends to a considerable extent upon the intensity, but it is shorter than Békésy's and Munson's values for tones. By studying the responses of two subjects lacking both the muscles and the ossicles to which they are normally attached, Miller was able to show that the dependence upon intensity is not due to contraction of the middle ear muscles.

The method used in studying the decay of auditory sensation was to turn off the tone

takes only about half as long to disappear as the tone. One way to explain how an intense sensation can disappear as fast as a weak one is to suppose that the individual elements of the auditory system operate in parallel, not in series. Except for differences in latency and rate of conduction, therefore, it should take no longer to set up activity in all the elements, or to stop that activity once it has been set up, than to start or to stop a single element. The reason why a noise disappears faster than a tone is not entirely clear, but it may be related to the fact that noise activates substantially the entire auditory system whereas a tone activates only a part of it. When a tone is turned off, activity declines in the part of the system that had been activated, but a trace of the activity may remain for

some time. This trace stands out, it is reasonable to suppose, against the background of quiescence (or of neutral activity) of the unstimulated tissue. When noise is turned off, however, there is no background with which the trace can contrast.

Closely related to the questions of the rise and the decay of auditory sensation is the question of the loudness of short impulses. This question has been studied by Steudel

with clicks of other shapes (see Fig. 34), by taking into account the distribution of the stimulus energy in frequency rather than in time. Garner (1947a) later used this approach to account for the audibility and loudness of interrupted tones. Thus far, however, there have been no successful efforts to handle loudness as a function both of frequency and of time.

The pitch of short tones. As the duration of a sinusoidal tone is increased from 2 or 3 milliseconds to 0.5 second or more, three stages can be distinguished in its subjective quality. These have been described by Büreke, Kotowski, and Lichte (1935) and by Doughty and Garner (1947) as (1) the stage

FIG. 33. The relation between the loudness level of a declining exponential impulse and its time constant. The loudness level is defined as the sensation level (decibels above threshold) of the 1000-cycle tone judged to have the same loudness. (From Stevens and Davis, 1938, after Steudel, 1933.)

(1933), who had his subjects judge the loudness of the clicks that resulted when he applied electrical impulses of various shapes and magnitudes to a loudspeaker. Steudel's results are illustrated in Fig. 33. The time constant T of the impulse is the length of time the impulse takes, in its exponential decay, to reach an amplitude equal to $1/e$ (about 37 per cent) of its initial amplitude.

Steudel interpreted his results as indicating that the important part of the click is the first 0.3 millisecond and that the loudness of the click is proportional to the integral of the pressure over that time interval. Büreke, Kotowski, and Lichte (1935), however, determined the spectra of Steudel's clicks and found that they could account for Steudel's results, as well as results obtained

FIG. 34. The relation between the loudness level of a rising exponential impulse and its time constant (the length of time required for the impulse to reach approximately 63 per cent of its final amplitude). The impulse grows fainter as the time constant is increased beyond about 0.3 millisecond, because a slowly rising impulse (large time constant) has most of its energy concentrated at very low frequencies, for which the auditory mechanism is insensitive. (From Stevens and Davis, 1938, after Büreke, Kotowski, and Lichte, 1935.)

in which the subject hears only a click, (2) a stage in which the sound is a click with discernible tonal quality, and (3) the stage in which there is an on-click and an off-click with a tonal part of easily identifiable pitch in between.

In order to understand the stimulus basis of these three stages, it is helpful to think of the short tone in terms of its intensity-

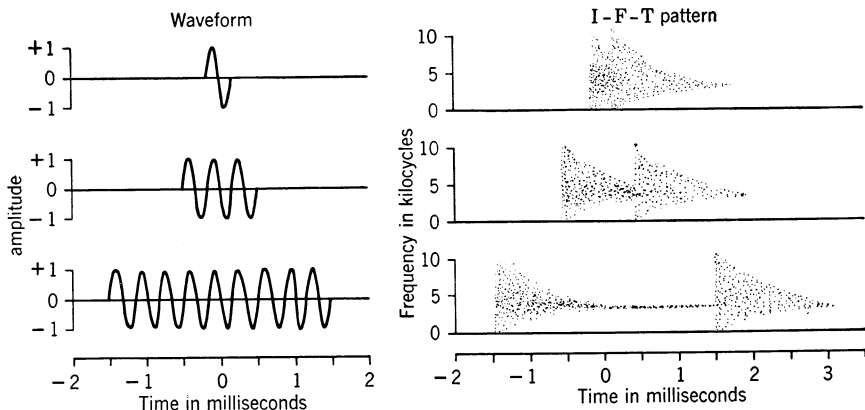

FIG. 35. Intensity-frequency-time patterns of short segments of a sinusoidal pressure wave. These patterns are of the type illustrated in Fig. 4. The visual appearances of the patterns are closely analogous to the auditory impressions obtained by listening to the three stimuli.

frequency-time pattern. This pattern, shown schematically in Fig. 35, makes it clear that the concentration of energy in the frequency dimension depends markedly upon the duration of the sinusoidal segment. In the upper pair of diagrams the energy is spread so diffusely along the frequency scale that there is no basis on which the auditory system can arrive at a judgment of pitch. In the middle pair, however, there is a discernible concentration of energy at 3000 cps. And in the lower pair the concentration is almost as clear-cut as it is in a pure tone. When we look at the stimulus from this point of view, what we see corresponds closely to what the listener hears.

Doughty and Garner have determined the shortest duration at which the listener can just discern "click pitch" and the shortest duration at which the listener can hear "tone pitch." Threshold durations determined at moderately high intensity are shown in Fig. 36. At lower intensities the threshold durations are somewhat greater.

Monaural detection of differences in phase. The responsibility for the statement that a listener "cannot perceive phase" is often attributed to Helmholtz. In fact Helmholtz did write, in his *Sensations of Tone*, that

... the quality of the musical portion of a compound tone depends solely on the num-

ber and relative strength of its partial simple tones, and in no respect on their differences of phase. [P. 126.]

FIG. 36. The duration thresholds for two degrees of 'pitchedness' as functions of frequency. Below 1000 cps, two or three cycles of the wave must be heard for the sound to have any predominant pitch at all, whereas above 1000 cps the threshold is not a fixed number of cycles but a fixed length of time. (From Doughty and Garner, 1947.)

But Helmholtz also said:

We were not able to embrace these [non-musical tones with upper partial tones close together along the frequency scale] in our experiments, and hence we must leave it for the present doubtful whether in such dissonating tones difference of phase is an element of importance. Subsequent theoretic

FIG. 37. Stimuli used to study monaural discrimination of phase differences. Both members of each pair of waveforms have the same Amplitude-vs-frequency characteristic. Each wave consists of three components, $1000 - f$, 1000 , and $1000 + f$, where f is designated as the "signal frequency." The only difference between members of a pair is that in one the 1000-cycle component has one phase angle, in the other it is retarded 90 degrees. This phase shift makes a clear and obvious difference in the subjective sound. The upper wave sounds rougher and lower in pitch than the lower wave. (From Mathes and Miller, 1947.)

considerations will lead us to suppose that it . . . [probably] is. [P. 127.]

Little note of this latter statement appears to have been taken by the pioneers in auditory research (Koenig excepted). With Helmholtz' prestige misplaced behind it, the theory that we are 'phase deaf' was generally accepted (for references, see Boring, 1942).

We see how unfounded the theory was when we recall that phase differences are simply time differences. When we shift the phases of components of a complex wave, we advance them or retard them in time. Now everyday experience tells us that the auditory system is capable of distinguishing temporal differences. Therefore it cannot be entirely phase deaf. To prove the point conclusively, we need only consider again the white noise and the single pulse of Fig. 1. Both sounds have 'flat' spectra. The only difference is one of phase: the various frequency components of the white noise are assigned their phase angles at random; the frequency components of the single pulse all reach their maximum amplitudes at the time $t = 0$, and they cancel one another at all other times. As a result, we hear the white noise as *sshhhh* and the single pulse as *pt*.

Mathes and R. L. Miller (1947) studied a wide variety of stimuli devised to show up phase effects in monaural perception. In one of their experiments, they used stimuli of the type shown in Fig. 37. In each pair of tracings the pronounced difference in waveform is due solely to difference in phase; the Amplitude-versus-frequency patterns are identical. Nevertheless there were decided differences in the sensations evoked by the stimuli. The waveform characterized by the wider fluctuations of the envelope sounded rough. When the second waveform was substituted, the listeners noticed a marked diminution in the roughness. They also reported that the "apparent pitch sensation" increased markedly.

Mathes and Miller found several other pairs of stimulus patterns that differed only

in phase, yet were readily distinguishable by ear. Three conditions appear to be prerequisite to the monaural phase effects. First, the important components of the stimulus must be close together in frequency (as Helmholtz thought). Second, there must not be too many frequency components. And third, the phase changes must make clear-cut differences in the envelope of the waveform.

SOUND LOCALIZATION

Thus far we have restricted our attention to what has been called *monotic* and *diotic* hearing.* Now, however, we must take into account the fact that the auditory system has two input channels. *Dichotic* stimulation is especially involved in the spatial localization of sounds.

The localization of actual sources. Stevens and Newman (1934, 1936a) noted that much of the earlier work on sound localization (see Boring, 1942) suffered from the defect that the listener was in a reverberant room and therefore received sounds from all sides, no matter where the source might be located. They tried, therefore, to get away from sound reflections by seating the observer in a chair at the top of a post rising above the roof of a building. The sound came from a loudspeaker located at the end of a rotatable boom and at the same level as the listener's ears. The loudspeaker was always set at the listener's right, and at an integral multiple of 15 degrees azimuth. The average errors of two observers are shown in Fig. 38A. This figure, which does not take into account confusion between symmetrical locations in the front and rear quadrants, shows that the errors of localization increased with the frequency of the stimulus

* *Monotic*: stimulus applied only to one ear; *diotic*: same stimulus to both ears; *dichotic*: different stimuli to the two ears. Binaural stimulation may be dichotic in respect of several dimensions or in respect of one dimension, e.g. dichotic in phase but diotic in Amplitude and frequency.

tone up to about 3000 cps, then decreased until they were again quite small for tones of 10,000 cps. The front-rear confusions are shown in Fig. 38B. The two curves, taken together, support the observations of Rayleigh (1907) and of von Hornbostel and Wertheimer (1920) that there are two bases for localization, one for high-frequency tones

only at low frequencies. It is an easy inference, therefore, that one mechanism of (pure-tone) sound localization operates on the basis of intensive clues, the other on the basis of temporal clues.

When the physical sound is complex, each frequency component has *both* a characteristic interaural phase difference and a characteristic interaural Amplitude ratio. Furthermore it is not certain that the phase effect is restricted to low frequencies when the stimulus is complex. It is not surprising, therefore, that complex sounds are more readily localized than pure tones.

Intensive clues. In order to investigate the mechanism of sound localization, it is of interest to separate the intensive from the temporal variables and to study them individually.

One thing that we should like to know is how much more intense a tone must be made in one ear than in the other before the listener notices a shift in the apparent source of the tone. Upton (1936) and Ford (1942) determined this differential threshold for an 800-cycle tone and found that it varied as a function of the intensity of the tone. The differential dichotic sensitivity was greatest when the tone was between 70 and 100 db above threshold; at these levels the jnd was approximately 1 db, which is about twice as large as the monaural jnd for intensity determined by Riesz. When the difference between the intensities at the two ears is increased beyond threshold, the apparent source of sound waves moves farther toward the side with the greater intensity. The rule, followed approximately, is that the angle measured from the midline is proportional to the logarithm of the Amplitude ratio (Stewart, 1920a, 1922, 1930, 1932).

Temporal clues (phase and time of arrival). Many experiments have been conducted to determine the relation between the interaural phase difference and the phenomenal location of tones, but the results have been equivocal. The more recent results agree, however, in restricting the im-

FIG. 38. Errors made in judging the direction of a sound source in the horizontal plane. Plot A shows the average of the errors, in degrees, for various tonal frequencies. The circles and the crosses are for two different series of observations with pure tones. The triangles are for impure tones. Plot B shows the percentage of confusions between front and rear quadrants. (After Stevens and Newman, 1936b.)

and the other for low-frequency tones. At frequencies near 3000 cps, evidently neither mechanism is effective, and the errors of localization are greatest.

A pure tone, emanating from a source to the right of the listener, travels a somewhat shorter and more direct path to the listener's right ear than to his left. Consequently the pressure waves in the two ear canals differ both in phase (or in time of arrival of a given phase) and in Amplitude. The Amplitude differences are considerable only at high frequencies because the head and the auricles act more efficiently as barriers against high frequencies than against low. The phase differences are, as we shall see, detectable

portance of the interaural phase of pure tones to frequencies below 1500, or in any event below 2000, cps (Langmuir et al., 1944; Hirsh, 1948*a*, *c*). The tone tends to be localized toward the side to which the wave leading in phase is delivered. The degree of lateralization increases with increasing interaural phase difference until the sound appears to be localized in one ear. Stewart (1920*b*, 1922) reported that the angle of deviation from the midline is proportional to the interaural phase difference.

Using a 100-cycle tone as a stimulus, Monnier and Viaud (1946) found that the threshold for interaural phase difference was less than 3 degrees (time difference: 100 microseconds) for subjects practiced in locating aircraft by aural means. When pulses or clicks are used as stimuli, the just detectable interaural time difference is even smaller than it is with low-frequency tones (von Hornbostel and Wertheimer, 1920; Bennett, 1927; Wallach, Newman, and Rosenzweig, 1949). Results obtained by the latter experiments are illustrated in Fig. 39A. The graph indicates that a listener may tend to report localizations to one side when the interaural time difference is zero, but that a time difference of 30 or 40 microseconds clearly predominates, in a statistical sense, over his bias. If the time difference is increased to 2 or 3 milliseconds, the listener hears a double click, and longer time differences give rise to reports of two clicks with different localizations.

A listener in a reverberant room is stimulated not only by the sound wave transmitted directly to him from the source but also by echoes from the walls. A single pulse at the source becomes a series of pairs of pulses at the listener's ears. And each pair has its own interaural time difference. What happens in a situation of this kind has been investigated by Békésy (1930), by Langmuir et al. (1944), and by Wallach, Newman, and Rosenzweig (1949). The results can be summarized by describing two effects. First, similar impulsive sounds fuse into a

single auditory sensation if they are closely spaced in time. Second, the first wave to arrive at the listener's ears tends to preempt the mechanism of localization. For example, consider the stimulus situation schematized in Fig. 39B. The two pairs of 1-millisecond pulses are described by giving the interaural time difference of the first pair, the interaural time difference of the second pair, and the interval between the two pairs. If the interval is more than 2 or 3 milliseconds (and if the time differences are considerably shorter than the interval), the listener reports that he hears two clicks. As the interval is made shorter, the two clicks fuse into a double click, then a single click, the subjective location of which is approximately that occupied by the first click when, with the longer interval, two clicks had been heard. The predominance, in determining localization, of the first pair of pulses over the second is illustrated in Fig. 39C, which shows how great the first interaural time difference must be to neutralize a second interaural time difference of given magnitude and opposite sign. The fusion and precedence effects offer an explanation of the fact that sound sources are localized reasonably well, even in highly reverberant rooms.

Externalization. In experiments in which the intensive and the temporal clues are separated, it is necessary to lead the two tones individually to the two ears. Earphones are usually employed for this purpose. It is interesting to note, therefore, that the tones are characteristically localized within or very near the head, which is quite different from the localization that is made when the tone is transmitted to the ears through the air from an actual source. Wallach (1938, 1939, 1940) proposed the theory that the externalization of the sound in the latter case is related to the fact that the listener can change the interaural phase and intensity relations by moving his head, whereas in the laboratory situation the earphones follow the head movement, and there

is therefore no concomitant variation in the acoustic stimulation.

Clues to elevation. If sounds were localizable only in terms of right and left, only in the horizontal plane, we should have to

stationary, judgments of elevation are very poor. The listener must move his head in order to determine the angle of elevation.

Wallach (1939) has shown that (when vision is ruled out) head movements give us

FIG. 39. The influence of interaural time differences upon the localization of impulsive sounds. If a single pulse is presented to one ear slightly before the other, it is localized to the side of prior stimulation as shown in A. If the stimulus is complicated by adding a second time-dichotic pulse after an interval of 1 millisecond (B), it is heard as a single click, and the localization of the sound image is determined to some extent by the second time difference but mainly by the first (C). (After Wallach, Newman, and Rosenzweig, 1949.)

look no further for sensory data than the intensive and temporal relations just mentioned. However, sounds can be localized also in respect of elevation. The key to the problem of elevation is that, when both the sound source and the listener's head are held

the sensory data on the basis of which we make the judgments of elevation, quite as they give us the data on the basis of which we project the sound into the external world. Wallach found that, if he made the source of sound rotate with the listener's head in the

horizontal plane, the listener reported that the sound appeared to come from above. Directly above and perhaps directly below, Wallach points out, are the only source locations for which horizontal rotation of the head normally produces no change in interaural phase and intensitive relations. Thus it appears that the mechanism of sound localization takes into account not only auditory data but also data from other sense systems as well.

Stereophonic sound localization. The effort to increase the realism of sound reproduction has led to experiments in two-channel sound transmission and in stereophonic sound reproduction. The idea of the simplest two-channel scheme is to record the sounds with two microphones, placed in the positions of the two ears of a dummy listener. When these sounds are led to a remote listener and applied to his ears via earphones, he gets almost exactly the same auditory picture that he would get if he were in the dummy's position. The effect is very compelling. When someone with hobnailed boots walks past the dummy, the listener pulls in his feet to keep them from getting stepped on. If loudspeakers are used to transduce the sound, the problem is considerably more complicated. It has been found, however, that a reasonably realistic reproduction can be achieved by recording the sound through two or more microphones and reproducing it with two or more loudspeakers (Steinberg and Snow, 1934; de Boer, 1940).

OTHER BINAURAL EFFECTS

Binaural summation at the absolute threshold. The question of binaural summation—whether or not the binaural threshold is lower than the monaural threshold—has been asked, and answered equivocally, for many years. Tarchenow, Preyer, and Körtling (see Hirsh's review, 1948a), reported individually that, with both ears, they could hear sounds inaudible to either ear alone.

But the weight of authority—Fechner, Stumpf, and von Hornbostel—was behind a negative answer to the question, and we find Sivian and White (1933) deciding on the basis of what we should probably call inadequate evidence (comparable measurements on only two listeners) that their curve for the monaural MAF (Fig. 5) was equally representative of the binaural MAF.

When we turn to more recent experiments (Gage, 1932; Hughes, 1938; Caussé and Chavasse, 1942a; Shaw, Newman, and Hirsh, 1947; Keys, 1947; and Pollack, 1948b), we find emphasized the principal reason (originally mentioned by Urbantschitch in 1893) for the earlier divergence of opinion. These experiments show definitely that the binaural threshold for pure tones, expressed in terms of sound pressure developed at the eardrum, is lower than the monaural threshold. They show also, however, that, unless the two monaural thresholds are nearly equal, the difference between the binaural threshold and the threshold of the more sensitive ear is very small. Since the two ears of the average listener differ in sensitivity by almost 6 db, the amount of binaural summation actually found (about 1 db) is approximately what we should expect on the basis of perfect power summation. If we happen to find a listener whose ears are equally sensitive (or if, in applying the sound stimuli, we handicap the more sensitive ear, making the two ears artificially equal in sensitivity), we find that the binaural threshold is about 3 db lower than the monaural threshold. This again is perfect power summation: the listener is just able to detect the sound, no matter whether we offer all the acoustic power to one ear or divide it equally between the two. Hughes finds, in fact, that the rule holds for other than equal divisions of the total acoustic power, but Pollack's (1948b) data indicate that, both for a 1000-cycle tone and for white noise, binaural summation runs a little short of what would be expected on the power-summation hypothesis.

Binaural versus monaural DL's. Binaural DL's are somewhat smaller than monaural DL's. One explanation attributes this superiority of binaural hearing to what might be called binaural supplementation: (1) both ears are continually varying in sensitivity; (2) sometimes the right ear is the more acute, sometimes the left; (3) the central nervous system takes advantage of the better of the two incoming signals.

A more quantitative explanation has been formulated by Crozier, who views the sensory systems as statistical problem solvers for which the determination of the DL is the problem of finding a difference that just reaches a predetermined level of statistical significance. Two ears are better than one, according to this notion, because the sample (of neural elements) is twice as large. Since doubling the sample divides the standard error by $\sqrt{2}$, differences that would fall short of statistical significance for the monaural system are significant for the binaural system. Actually the binaural DL for intensity has been reported to be about 3 db lower than the monaural DL (Upton and Holway, 1937). Since 3 db corresponds to a voltage ratio of $\sqrt{2}$, the result is just what the statistical theory would predict.

Binaural summation of loudness. Early observations by Seebeck, by Mach, by Fechner, and by Docq (see Hirsh's review, 1948a) indicated that tones sound louder to both ears than they do to one, and that the binaural summation of loudness is more evident than binaural summation at the absolute threshold. But these observations did not carry as much weight as did Stumpf's dictum to the effect that the greater clarity, fullness, and volume of binaural sounds lead to an *illusion* of greater loudness. Stumpf's conclusion was not challenged successfully until 1929, when Békésy took the sound step of thinking that, if loudness is the listener's subjective reaction, it must *include* the illusion. Békésy made monaural-binaural loudness matches, obtaining the quantitative

evidence of summation shown in Fig. 40. We see that, for maximal summation, the tones delivered to the two ears must be of the same frequency. This is quite the opposite of what we noted in the case of monaural summation of loudness: when two tones are led to the same ear, they must be widely separated in frequency if their loudnesses are to add up.

FIG. 40. Binaural summation of loudness. Two tones of equal sound pressures, one presented to one ear, the other to the other ear, sound as loud as a single monaural tone of the relative sound pressure shown by the ordinate. The abscissa gives the relation between the frequencies of the two tones. Their sensation levels were 40 db. (From Stevens and Davis, 1938, after Békésy, 1929.)

In more recent experiments, Fletcher and Munson (1933) and Caussé and Chavasse (1942b) determined, for various monaural intensities, how much weaker than the monaural tone a binaural tone can be and still give rise to the same loudness. The results are not in complete agreement, but it is clear that binaural summation increases with intensity level, at least up to 60 db. Regardless of the intensity level, Fletcher and Munson found that a tone heard binaurally seems just twice as loud as the same tone heard monaurally.

Interaural phase and masking. We have seen that two ears are better than one when it comes to distinguishing between sound and silence. Are two ears better than one when the signal must be heard against a background of noise? In exploring this question, Hirsh (1948b) presented the tone first to one ear, then to both, *but he left the mask-*

ing noise in both ears all the time. To his surprise, he found that, in the tests with intense low-frequency tones, two ears were worse than one—worse by as much as 7 db. This effect he called “interaural inhibition” because it appeared that applying the tone to the second ear set up a process that, in some way, interfered with the process already going on. As indicated in Fig. 41, interaural inhibition is found only when the

to one side of the ball. When, on the other hand, the noise delivered to one of the ears was reversed in polarity so that both eardrums moved together toward the right, then back toward the left, the noise sounded spread out, and the tone was most audible when it was diotic in phase and had, therefore, a central localization.

Hirsh (1948c) worked out the functions relating audibility to interaural phase and

FIG. 41. Binaural summation and inhibition. Binaural inhibition occurs only with the 250- and 1000-cycle tones and in the presence of fairly strong masking noise. The masking noise was always presented binaurally. (From Hirsh, 1948a.)

stimulus tone is low in frequency and when the masking noise is high in intensity. Under other conditions some degree of binaural summation is found.

A related observation that throws light on Hirsh's interaural inhibition was described, more or less incidentally, in a report by Langmuir et al. (1944) on binaural effects in sound localization. They found that the audibility of a tone heard against a background of random noise was dependent upon the interaural phase relations of the tone and of the noise. When the noise was presented in such a way that it made the two eardrums move inward together toward the center of the head, then outward together, the noise sounded as though it were a compact ball in the center of the head, and the tone was most audible when it was sufficiently dichotic in phase to be localized, subjectively,

found that, under certain conditions, changing the interaural phase relations can shift the masked threshold by as much as 14 db. His results are illustrated in Fig. 42. This demonstration that interaural relations are so important in determining masking upsets the notion that masking is exclusively peripheral in origin. Evidently, masking is by no means determined entirely by cochlear processes: events taking place in the central nervous system, at or beyond the point at which the two afferent channels come together, have a considerable influence upon the degree to which the total excitation can be analyzed into parts.

Loudness, too, is influenced by interaural phase relations. Hirsh and Pollack (1948) found that the loudness of a tone, heard against a background of intense noise, is considerably greater if the tone and noise have

FIG. 42. The influence of interaural phase relations upon binaural summation and inhibition. The ordinate shows the relation between the monaural and binaural masked thresholds for pure tones of the frequencies indicated along the abscissa. The masking was by white noise at a sound pressure level of 59 db re 0.0002 dyne per square centimeter. The tones in the two ears were sometimes in phase ($\phi_T = 0$ degrees), sometimes 180 degrees out of phase ($\phi_T = 180$ degrees). The noise waveforms were sometimes the same in both ears ($\phi_N = 0$ degrees), sometimes right-side up in one ear and upside down in the other ($\phi_N = 180$ degrees). Thus there were four different interaural phase relations and, corresponding to them, four different curves of binaural summation and/or inhibition. (From Hirsh, 1948c.)

opposite interaural phase relations than if they have similar interaural phase relations. In the quiet, however, interaural phase has no effect upon loudness, nor upon the absolute threshold (Hirsh, 1948b).

Binaural pitch disparity — diplacusis. Otologists have long been familiar with a condition, known as *diplacusis binauralis*, in which the patient hears one pitch when his right ear is stimulated with a pure tone, another pitch when his left ear is stimulated with the same tone. But little note was taken of the early observations of von Liebermann and Révész (1914), and for many years it was not generally realized that a moderate degree of binaural pitch disparity is the rule rather than the exception. Diplacusis is measured by finding how much the stimulus frequency has to be changed, as the tone is switched from one ear to the other, to hold the pitch constant. Typical data (Stevens and Egan, 1941) are shown in Fig. 43. The amount of diplacusis depends upon the intensity of the stimulus: it decreases as the intensity is raised.

Diplacusis is most apparent after one ear has been subjected to intense stimulation. Pitch disparities amounting to as much as an

FIG. 43. The diplacusis of a 'normal' listener. The frequency of the tone delivered to the left ear had to be changed to make the left-ear pitch match the right-ear pitch. The ordinate shows the percentage of change in frequency required. (From Morgan, 1943, based on the data of Stevens and Egan, 1941.)

octave were found by Davis et al. (1944) in listeners who had been exposed for several minutes to tones 130 to 150 db above 0.0002

dyne per square centimeter. Sometimes, in fact, the sound heard with the affected ear had not one pitch but two pitches: one higher, the other lower, than the pitch heard with the previously unstimulated ear. Rüedi and Furrer (1945, 1946, 1947) found that the pitch tends to be shifted upward if the preconditioning tone is below 4000 cps in frequency, downward if the preconditioning tone is above 4000 cps.

Diplacusis provides the place theorist with excellent ammunition to use against frequency theories of hearing. If one is to maintain that pitch depends upon neural frequency, he must explain how neural frequency gets out of step with stimulus frequency; he must reject the notion of synchrony between the acoustic stimulus and the neural response. In terms of the place theory, on the other hand, the facts of diplacusis almost explain themselves. We need assume only that a small segment of the basilar mechanism is relatively insensitive — for example, as a result of previous stimulation. When we apply a weak tonal stimulus that would normally excite the nerve fibers that innervate this segment, nothing happens. As we raise the intensity, nerve fibers innervating an adjacent region are activated before the elevated thresholds of the local fibers are reached. The neighboring fibers give rise to a pitch that is characteristic of their 'place,' hence slightly different from the pitch normally associated with the stimulus frequency.

AUDITORY THEORY

The principal tasks of auditory theory are (1) to explain the psychophysics of hearing in terms of aural mechanics and neurophysiology, (2) to give audition its proper setting in a general theory of communication, and (3) to provide a calculus of response to auditory stimulation. In this chapter we have been concerned principally with the third of the three objectives. The first and second considerations set the pattern for the

chapters that follow. Now is the time, therefore, to see how near we are to having an auditory calculus. Can we start with data about the listener and the acoustic stimulus, and from these data calculate the listener's auditory experience or response? Can we parallel the auditory process by manipulating symbols?

In some situations, we can — with fair approximation. If the stimulus is simple enough or nearly enough like stimuli with which we have had experience, we can take advantage of empirically determined relations and predict, for example, the loudness in sones and the pitch in mels. The calculation involved in making the prediction (usually little more than graphical interpolation) is admittedly primitive, but it is a start.

The next question is, how do we proceed when we encounter acoustic stimuli that are complex and unfamiliar? Must we make empirical tests with these new sounds or others nearly like them, or may we reason from our knowledge based on simpler stimuli? This question brings us up against one of the greatest obstacles to the study of psychology: it is difficult to calculate from components to the whole when the system under consideration is nonlinear.

We should like to break the complex stimulus down into familiar components, to look up the expected responses to these components, and then to arrive at a prediction for the complex stimulus by adding up the component responses. The trouble is that, knowing we are dealing with a nonlinear mechanism, we cannot count on linear additivity. We must take into account the possibility of interactions among components, and there is no way to learn about the interactions except through experiment. Except in the few instances (e.g. loudness of complex tones, masking) in which interactions have been rather thoroughly studied, we must admit that we have not yet reduced psychoacoustics to symbols.

This admission need not discourage us; it is evidence of approaching maturity that the question of a calculus should even arise. What we should see, actually, is this: it is patently not feasible to explore experimentally the infinitude of acoustic stimuli that may some day prove to be of interest. We must learn to predict the complex from knowledge of the simple; we must learn to combine components. The first step, logically, is to choose the right basic components. The next is to study their interactions.

Actually, it will probably take considerable study of interactions to determine what are the right basic components. Sinusoids, for all their mathematical beauty, are probably not the right ones because transient changes are so important in hearing. It may turn out that exponentially declining spindles of the type illustrated in Fig. 4, or perhaps pulses with envelopes the shape of the normal distribution curve, may turn out to be the proper building blocks. At any rate, as the later parts of the chapter have indicated, we have already put behind us the preoccupation with pure tones that characterized the early period of research in hearing. Perhaps in reaction we have adopted as a favorite stimulus that most complex of all sounds, white noise. In order to achieve a calculus of psychoacoustics, however, we must do extensive work in the intermediate region—work with simple combinations of simple components—so that we can learn the rules of interaction.

The Perception of Speech

J. C. R. LICKLIDER

Massachusetts Institute of Technology

and

GEORGE A. MILLER

Harvard University

Although the perception of speech is a psychological problem, it remained for telephone engineers interested in the adequacy of their equipment to develop procedures for the quantitative investigation of speech perception. These procedures were evolved, principally by the Bell Telephone Laboratories, without reference to the traditional problems and methods of experimental psychology. The concern was with intelligibility rather than perception, and the results were used to evaluate equipment rather than listeners. Although the question "What must the equipment do?" can be rephrased to "What can the listener do?" the marks of the engineers' original interests will be unmistakable in the following summary.

ACOUSTIC CHARACTERISTICS OF SPEECH

We can begin with a brief summary of the physical dimensions of vocal stimuli. A large and respectable body of experimental literature exists in this area, and we shall have space to consider only a few of the more important studies.

Speech Power

The *average power* radiated by a talker during conversational speech, when this

average is taken over a long period of talking and includes pauses between phrases, is about 10 to 20 microwatts. If the pauses are omitted in averaging, the figure increases about 50 per cent (Sacia, 1925; Dunn and Farnsworth, 1939). When one talks as loudly as possible, the average speech power increases to about 1000 microwatts. The faintest voice possible without whispering is 0.1 microwatt, and a whisper may radiate as little as 0.001 microwatt. Thus from the faintest whisper to the loudest shout there is a range of about 60 db.

When the power is averaged over short periods of time—0.01 second, for example—the rise and fall of the average power during the course of a syllable can be determined. Sacia and Beck (1926) have made such measurements during conversational speech with a variety of speakers. The maximum value of the average power reached during the course of a given sound was taken to represent the power in that sound, and values for different talkers were averaged to give the results summarized in Table 1.* Since the measurements were made for conversational speech, these averages include values for both accented and unaccented occurrences of the sounds. Several consonants were omitted from the analysis because their power was insufficient for measurement.

This chapter was prepared at the Psycho-Acoustic Laboratory, Harvard University, under contract with the U. S. Navy, Office of Naval Research (Contract N5ori-76, Project NR142-201, Report PNR-79).

* The phonetic symbols in this chapter are the same as those in Chapter 21.

TABLE 1

CONVERSATIONAL VALUES OF AVERAGE POWER OF SPEECH SOUNDS IN MICROWATTS (SACIA AND BECK, 1926)

Vowels	Diphthongs	Semi-vowels	Consonants
u 13	ou 22	l 0.33	d 0.08
o 47	ai 20	ŋ 0.35	t 0.14
ɑ 34		n 2.11	k 0.34
æ 9		m 1.85	v 0.03
ε 17			f 0.08
ɪ 9			dʒ 0.47
i 12			tʃ 1.44
ʃ 10			ʃ 1.83
Δ 15			z 0.72
			s 0.94

Instantaneous power has been measured at random instants during conversational speech. From a large number of such meas-

FIG. 1. Statistical distribution of instantaneous speech power. (After Sivian, 1929.)

urements a statistical distribution can be drawn showing the percentage of the time the instantaneous power equals or exceeds a given value. The results of Sivian's (1929) measurements for men's voices are so plotted in Fig. 1. The instantaneous power has a relatively low value most of the time, but occasionally it rises to very high peak values. According to Dunn and White (1940), the distribution of instantaneous pressures is very nearly a normal distribution similar to that obtained from similar measurements with random noise.

Dunn and Farnsworth (1939) have shown that the sound is radiated best in front of and slightly below the talker's lips. Especially for the high-frequency components of speech, radiation is poorest in back of the head.

The Speech Spectrum

The various methods for analyzing speech into its component frequencies can be classified under two headings, the graphic and the electric. The graphic procedures, which employ Fourier analysis of the waveform, are summarized in convenient form by Budde (1930). Electric methods have been discussed by Trendelenburg (1930), Dunn and Farnsworth (1939), and Stevens, Egan, and Miller (1947). In its usual form the electric analysis employs 10 or 15 band-pass filters which divide the range from about 30 to 12,000 cps into contiguous bands of frequencies. The talker is located in an anechoic (echo-free) room. The microphone is placed at a known distance directly in front of the talker's lips, and the inverse square law is applied to relate intensity (power) and distance. The output voltage of the microphone is passed through the filters, and the output of each filter is measured and averaged. The measured voltages are then converted to the sound pressure levels that would have been obtained if each of the filters had had a pass band 1 cycle wide.

Figure 2 shows the average spectra measured by Dunn and White (1940) for six men and five women, and by Rudmose et al. (1944) for seven men. (See also Clark et al., 1948). Over a long period of time most of the speech energy is found in frequencies below 1000 cps. For brief periods of time, however, the energy distribution may be quite different, and it is these changes in the distribution of speech energy that carry the perceptual clues to which we react.

Graphic analysis provides a more detailed picture of the changes in the distribution of speech energy as a function of time. Figure

3, for example, shows a series of harmonic analyses made by Steinberg (1934) of the successive periods of the vowel in the word *out*. The heights of the darker lines represent the amplitudes of component vibrations at those frequencies. The dotted lines mark the regions of resonance, or formants, which change continuously throughout the produc-

ordinate, time on the abscissa, and intensity as the brightness of the record. Figure 4 illustrates the basic principle of this device (cf. also Fig. 4 in Chapter 25). The technical aspects of the Sound Spectrograph have been discussed in a series of papers from the Bell Telephone Laboratories (Steinberg and French, 1946; Koenig, Dunn, and

FIG. 2. Average speech spectra. The overall levels, not indicated in the graph, were as follows: 18 inches in front of the seven male talkers, 74 db; 30 centimeters in front of the six male talkers, 76 db; and 30 centimeters in front of the five female talkers, 73 db. (After Dunn and White, 1940, and Rudmose et al., 1944.)

tion of the sound. Similar analyses have been reported by Gemelli and Pastori (1933), Lewis (1936), Black (1937, 1939), Laase (1937), Kaiser (1943) and others. The generation of such a series of graphs for a whole sentence requires a formidable amount of labor.

An electric device that indicates the changes in the intensity-frequency pattern as a function of time is called a Sound Spectrograph (Potter, 1945). The speech is passed through a set of filters, and the output voltages from each pass band are used to control the brightness of small lamps that leave traces on a moving belt of phosphor. A record is obtained with frequency on the

Lacy, 1946; Riesz and Schott, 1946; Dudley and Gruenz, 1946; Kopp and Green, 1946; Koenig and Ruppel, 1948; Kersta, 1948), and in a book by Potter, Kopp, and Green (1947).

Figure 5 illustrates the kind of spectrogram that is obtained for speech. The dark bars indicate the major vocal resonances, and these bars shift from sound to sound, vanish, and reappear as the sentence progresses. The different sounds have different spectrograms, but the formants in the same sounds, as pronounced by different people, are quite similar. The pitch of the voice, whether soprano or bass, has little effect upon the relative positions of the vocal reso-

nances, and upon the durations of the phonemes. Adjacent sounds interact, and the spectrograms of some consonants are considerably modified by the vowels that precede or follow them. The most susceptible are the consonants k, g, h, η , l, and r. These

FIG. 3. The results of graphical analysis of the diphthong in the word "out." The numbers 1 to 12 indicate successive periods of the fundamental. Note changes in vocal resonance with time. (From Steinberg, 1934.)

consonants are produced in the back of the mouth and thus are more affected by the positions of the vocal cavities than are consonants produced in the front of the mouth.

In Fig. 6 the spectrograms are shown for six different vowels. The greatest differences appear in the relative positions of the two lowest resonant areas. Potter and Peterson (1948) suggest that these differences among the vowels can be represented conveniently by plotting the center frequency of the first

resonance against the center frequency of the second resonance (Fig. 7). The sustained vowels appear as points on this plot, and the diphthongs are represented as movements from one sustained vowel to another. The dotted line indicates the boundaries of the vowel region—normal speech traces paths through this region but seldom passes outside it. These plots suggest a new method for vowel designation that is particularly adaptable to quantitative analysis.

QUANTITATIVE EVALUATION OF INTELLIGIBILITY

There are several possible ways to measure the efficiency of speech communication. If standard messages are adopted, the time required for their transmission provides an index of efficiency. Or it is possible to count the number of times the listener asks the talker to repeat. Subjective scaling procedures are also available, and the listener can rate different systems on the basis of "pleasantness," "naturalness," or "intelligibility." All these methods have been discussed and occasionally used, but the great bulk of experimental data have been obtained by *articulation testing methods* (Fletcher and Steinberg, 1929; Egan, 1943, 1948). An announcer reads lists of syllables, words, or sentences to a group of listeners, and the percentage of items correctly recorded by these listeners is called the *articulation score*.

Articulation tests have proved useful for comparing communication equipments, for evaluating the effects of noise on communication, for determining the basic audibility of different words, and for rating and training communication personnel. The experimental variables involve the announcer (quality and intensity of voice, pronunciation, use of equipment), the test material (phonetic composition and item difficulty), the communication link (fidelity, noise, intensity of speech, etc.), and the listener (ability to hear sound, to discriminate speech sounds, and to resist masking noises). Such

a list indicates the extensive matrix of variables that affects the results of an articulation test.

The early research is summarized by Fletcher (1929), and more recent work is

nience of training the listeners to use phonetic notation is avoided. Still higher scores are obtained with polysyllabic words. Dissyllabic words with a spondaic stress pattern (bloodhound, oatmeal, etc.) have been used

FIG. 4. Principle of the Sound Spectrograph. (From Potter, Kopp, and Green, 1947.)

discussed by Miller, Wiener, and Stevens (1946).

Test material. For most purposes it is desirable to have the test material reflect the relative frequencies of occurrence of the different phonemes in English speech. Non-

extensively because they provide lists of relatively homogeneous items. Figure 8 shows results obtained with spondaic dissyllables, unselected (trochaic or iambic) dissyllables, and phonetically balanced monosyllables. The homogeneity of the spondees

FIG. 5. Spectrogram of the words, "one, two, three, four." Horizontal and vertical directions represent time and frequency, respectively. Variations in intensity are shown by shades of gray. The heavy dark bands or bars show the frequency regions that are reinforced by the vocal resonances. (From Steinberg and French, 1946.)

sense syllables are often used for test material. They have the advantage that scores for the different speech sounds can be compared. Somewhat higher scores are obtained with monosyllabic words, but the inconve-

is reflected in the steeper slope of the function relating articulation score to intensity of speech.

Sentences present certain problems in scoring. One procedure designates key words in

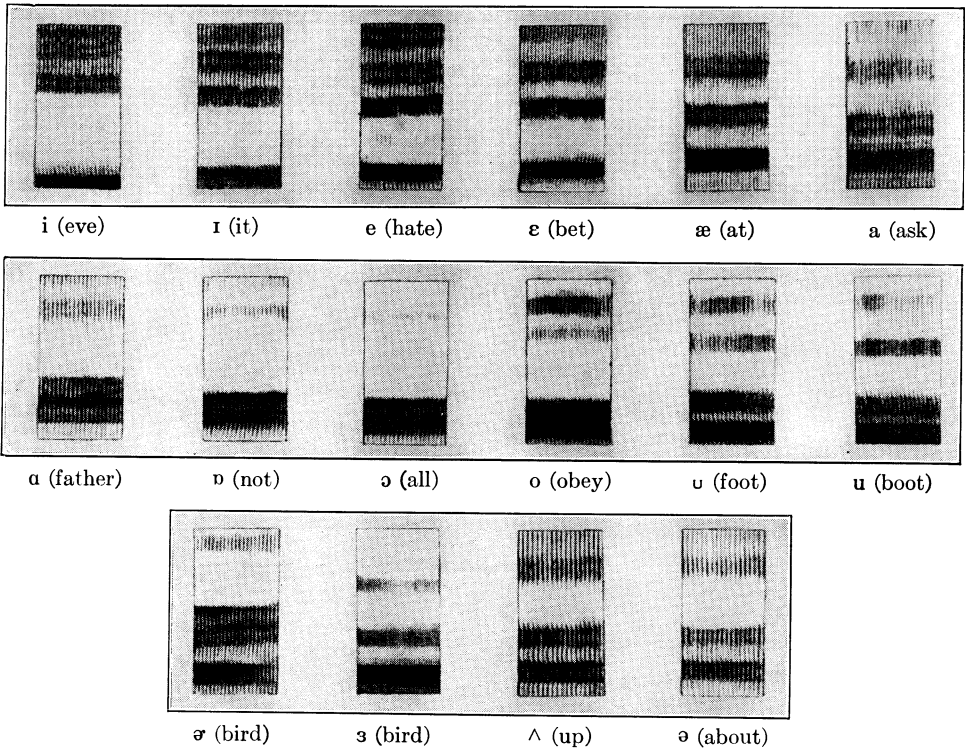

FIG. 6. Spectrograms of the vowel sounds. (From Kopp and Green, 1946.)

FIG. 7. The frequency of the lowest vocal resonance is plotted against the frequency of the second vocal resonance for ten vowels. Such a plot defines a "vowel area" for human speech. (From Potter and Peterson, 1948.)

each sentence and then scores according to the percentage of these words correctly recorded. Another procedure is to use a simple question which the listener must answer. Sentence scores are usually higher than word or syllable scores obtained under identical conditions.

When continuous discourse is used, a common procedure is to permit the listener to adjust the intensity of the continuous speech

FIG. 8. Comparison of results obtained from articulation tests conducted with three kinds of words. The percentage of items heard correctly is plotted against the relative intensity of speech in decibels. (From Hudgins et al., 1947.)

until it is just detectable (threshold of detectability), or just intelligible (threshold of intelligibility). This procedure stands in the same relation to the formal articulation test as does the method of adjustment to the method of constant stimuli in classical psychophysics.

Suitable test materials have been published by Egan (1948a) and by Hudgins et al. (1947). Collard (1929) has attempted to account for the quantitative relations among sound, syllable, and word articulation scores.

Personnel. Most experimenters have found large individual differences among talkers and listeners. Announcers should be selected who are able to enunciate the fundamental speech sounds in a "normal" manner, where the criterion for normality is one of common sense. Unless regional dialects are to be

studied specifically, talkers and listeners are usually chosen for General American pronunciation. Articulation scores obtained with inexperienced listeners show improvement with practice. Figure 9 gives a typical learning curve obtained in the presence of a loud masking noise. After 2 to 3 hours of practice each day for 5 successive days, this crew reached a relatively stable level of performance.

The number of listeners needed depends upon the reliability desired. The mean articulation score obtained from a well-trained crew of six to eight listeners will usually be sufficiently stable for most purposes. Talker variability is a more important source of instability.

Experiments designed especially to measure the effects of fatigue indicate that there

FIG. 9. Showing the effect of practice upon articulation score. Each point represents the average score on twelve tests for a crew of ten listeners. Both the announcer and the listeners were located in an intense airplane noise. (From Egan, 1948a.)

is little or no change in articulation scores obtained in the presence of intense noise over a period of several hours.

Equipment. Articulation tests are sometimes conducted with nothing but the air intervening between talker and listener, but more often the talker's speech is picked up by a microphone, amplified, modified ac-

ording to the variables being studied, and passed along to the listener via loudspeakers or headphones. Thus it is necessary to have a high-fidelity system with sufficient flexibility to permit the substitution of special components. Calibrating and monitoring equipment should be available to permit a precise description of the speech stimuli that reach the listener's ears. Test methods and equipment have been reviewed by Miller, Wiener, and Stevens (1946).

Statistical methods. A program of articulation testing should be designed in advance to permit statistical analysis. Analysis of variance can be used to estimate the potencies of the different sources of variation in the scores (Goffard and Egan, 1947). Examples of such statistical analysis can be found in a series of papers by Licklider, Bindra, and Pollack (1948), Licklider and Pollack (1948), and Licklider (1948).

RELATION BETWEEN INTENSITY AND INTELLIGIBILITY

When the announcer and the listener are linked together by an intercommunication system, it is a simple matter to control the intensity of the speech at the listener's ear by controlling the amplification in the system. As the speech level is increased above the threshold of detectability the articulation score increases, as shown in Fig. 8, until a level is reached where nearly all words are correctly heard. For greater intensities of speech the articulation score remains high until the threshold of pain is reached.

A statement of the threshold of detectability for speech should take into account the differences in the intensities of the various speech sounds (Table 1). It is customary to state the threshold in terms of an average, but, since some sounds exceed the average consistently, these sounds will determine the threshold value. Thus Fletcher (1929) estimates that the vowel ɔ is just detectable in a free field when the long-interval, root-mean-square pressure for the

speech is 0 db re 0.0002 dyne per square centimeter, but that the consonant θ does not become audible until this level is raised 25 or 30 db. Kryter (1946) reports that the presence of about half the words can be detected in a free field of 5 db. Estimates based upon the minimum audible pressure under earphones tend to run slightly higher; Hawkins and Stevens (1950) used the same criterion as Kryter but obtained 10 db as the minimum audible speech pressure at the entrance of the ear canal.

The speech level necessary in order to identify half the test items correctly depends upon the type of speech material tested. A free-field determination of 31 db for monosyllabic words has been reported by Kryter. French and Steinberg (1947) found 50 per cent of nonsense syllables correctly recorded at approximately 30 db. Davis (1947, p. 150) reported that a level of 33 db is necessary in order to hear correctly half the monosyllabic words when earphones are used, and that spondees can be heard correctly half the time at only 22 db. Shaw, Newman, and Hirsh (1947) found that spondees were reported 50 per cent of the time at 17 db monaurally, and at 14 db binaurally. Hawkins and Stevens found that connected discourse heard through earphones could be followed by the listener when the speech level was 24 db.

At the other end of the scale listening becomes uncomfortable, even for experienced listeners, when the intensity of the speech reaches 130 db, and at 135 db listeners report a tickling in their ears (Silverman *et al.*, 1946). Considering the threshold of intelligibility as about 25 db and the threshold of tickle as 135 db, the usable range of intensities is well over 100 db.

Fletcher (1929) has published curves showing the articulation scores for individual speech sounds as a function of intensity (Fig. 10). The consonants are usually harder to recognize correctly than the vowels. Fletcher estimates that the sounds v , f , and

FIG. 10. Articulation data for nonsense syllables were analyzed to determine the percentage of times each speech sound was correctly identified. Results for whole syllables and for six individual sounds are shown. The abscissa is the level of average speech, not of the individual speech sounds. (After Fletcher, 1929.)

θ count for more than half the phonetic mistakes made in listening to ordinary conversation.

THE MASKING OF SPEECH

In most situations speech is accompanied by other sounds. Masking, the shift in the threshold due to the presence of an interfering sound, is a serious problem in many situations, and the masking produced by a wide variety of sounds has been explored (Miller, 1947).

Masking by pure and complex tones. The effects of pure and complex tones upon the threshold of intelligibility have been investigated by Stevens, Miller, and Truscott (1946). They found that low-frequency tones are much more disruptive than high-frequency tones. Intense sine waves produce the most masking when their frequency is about 300 cps, whereas for weaker sine waves the most effective frequency is about

500 cps. This result is what we should expect on the basis of the results obtained in the masking of one pure tone by another: masking is greatest at and above the frequency of the masking tone.

The complex tones studied by Stevens, Miller, and Truscott included rectangular pulses and square waves. These complex waves are built up of many harmonics; consequently they mask the entire range of speech frequencies at lower intensities than do pure tones. At high frequencies, however, pure and complex tones are equally ineffective for masking speech.

Masking by noise. When a noise with a continuous spectrum throughout the range of audible frequencies is used as the masking sound, the noise must be specified in terms of the distribution of energy in the frequency range under consideration. The noise that is easiest to describe is one that has a uniform level per cycle over the range of speech frequencies. When such a *white*

noise is used to mask speech, the results shown in Fig. 11 are obtained. In this figure the shifts in the thresholds of detectability and intelligibility are plotted as a function of the intensity of the noise (Hawkins and Stevens, 1950). When the sound pressure level of the noise is greater than 40 db, the threshold shift is directly proportional to

FIG. 11. Showing the thresholds of intelligibility and detectability as functions of the intensity of the masking noise. (From Hawkins and Stevens, 1950.)

the intensity of the noise (cf. Fig. 17 in Chapter 25). Similar results were reported by Fletcher (1929) on the basis of more formal articulation tests with nonsense syllables. Kryter's (1946) experiments yielded comparable results for monosyllabic words.

This relation between masking and noise intensity is often expressed by saying that the *speech-to-noise* ratio (the ratio of the average speech power to the average noise power, which we shall abbreviate S/N) at the masked threshold is constant over a wide range of intensities. Only at the very low and possibly at very high noise levels must S/N be increased. For most noises encountered in practical situations, S/N should exceed 6 db for satisfactory communication, although the presence of speech is detectable for S/N as low as -18 db. If

the speech is distorted, higher values of S/N may be necessary.

The effects of different masking signals can be compared by stating the S/N necessary for a certain articulation score. For instance, if masking noise *A* gives the same articulation score when the speech is at *n* db as does masking noise *B* when the speech is at *m* db, then $n - m$ is the decibel difference in the masking effectiveness of the two noises.

The results obtained when speech is masked by narrow bands of noise (Miller, 1947) can be used to illustrate this kind of comparison. Highly discriminative filters were inserted into the noise channel to provide the eight adjacent pass bands indicated in Fig. 12. The narrow bands of noise were then mixed with the speech (monosyllabic words) and articulation tests were run. The results are shown in Fig. 12. Curve *A*, for a wide-band masking noise, shows the most effective masking of speech. At the low noise levels, the high-frequency bands were more effective than bands below 1000 cps. At the high noise levels, however, the low-frequency bands were more effective. The low-frequency noise, like the low-frequency masking tones discussed above, can mask the entire speech range if it is intense enough.

Lieklider (1948) has shown that the phase relations of the speech and the noise at the two ears affect the articulation scores obtained at a given S/N. These phase relations are considered in detail in Chapter 25 for the case where tones are masked by noise, and it is sufficient here to note that similar results are obtained when the masked sound is human speech. When either the speech waves or the noise waves at the two ears are 180 degrees out of phase, word articulation scores are as much as 25 percentage units higher than when both the speech waves and the noise waves at the two ears are in phase. These experiments indicate that masking is by no means a wholly peripheral process. An apparently related fact was Egan's (1948) discovery that the loudness of

FIG. 12. Articulation score as a function of the intensity of the masking noise. Filters were used to provide the narrow bands of noise. The speech was not filtered, and its level was held constant at 95 db. (From Miller, 1947.)

FIG. 13. Articulation scores obtained in the presence of noise interrupted at various rates. The noise was on half the time, off half the time. The parameter is the signal-to-noise ratio in decibels.

speech in one ear is enhanced by introducing noise into the opposite ear.

A further parameter influencing the masking effectiveness of a noise is its temporal continuity. Since many noises — static, intermittent noise of machinery, etc. — are not continuous, it is of some practical interest to determine the effect of interruptions upon masking. In general, turning the masking noise off periodically decreases its masking effectiveness, but just how much this decrease amounts to depends upon the noise-time fraction and the rate of interruption. Figure 13 summarizes the results obtained by Miller and Licklider (1950) when monosyllabic words at 90 db were masked by interrupted random noise at four intensities. The noise-time fraction was 0.50, and other noise-time fractions would give similar families of curves. When the noise is interrupted

FREQUENCY SELECTIVITY

We have considered two general ways in which the speech signal is altered during its passage from the talker to the listener. In the first instance, the speech was simply amplified or attenuated. In the second, noise was added to the speech. We are ready now to examine a third class of alterations to which the speech may be subjected, the class of distortions due to the *selective* action of the transmission system.

Three types of selective action are especially important. In each of these certain parts of the signal are favored and other parts are discriminated against. The basis upon which the signal is analyzed into parts (frequency components, amplitude levels, or temporal segments) is indicated in the first column of Table 2. The second and third

TABLE 2
CLASSIFICATION OF COMMON DISTORTIONS

Distinguishing Parameter	Discriminative Operation	Affected Parameter	Designation
Frequency	Amplification Delay	Amplitude Phase angle	Frequency distortion Phase or delay distortion
amplitude Instantaneous Rms or running average	Amplification Amplification	amplitude amplitude	Nonlinear or amplitude distortion Compression, expansion
Time	Amplification	amplitude	amplitude modulation

more than 200 times per second it is effectively continuous. Between 1 and 200 interruptions per second it is possible to patch together the bits of speech heard between the bursts of noise, and therefore the masking effectiveness of such noises is rather low. At very slow rates of interruption whole words or groups of words may be masked, and the perception is more nearly "all or none."

columns tell us what the selective operation is and what characteristic of the signal is affected by that operation. The name given to the type of distortion (last column) is the one currently used in this country. To illustrate the use of Table 2, let us consider frequency distortion. The circuit is selective on the basis of *frequency* (column 1), introducing different amounts of *amplification* (column 2) at different points along the

scale of frequency (column 1), with the effect that the pattern of *Amplitudes** (column 3) is changed.

Designations other than those given in the last column of Table 2 are often encountered, especially in the older literature.

Frequency Distortion

A system that is selective with respect to frequency is called a filter. If high frequencies are selected and low frequencies rejected, it is called a high-pass filter. Similar definitions apply to low-pass, band-pass, and band-rejection filters. With such filters it is possible to remove portions of the speech spectrum and so to evaluate the relative importance of the different frequencies to intelligibility.

French and Steinberg (1947) reported results of articulation tests with both men's and women's voices passed through various filters (Fig. 14). Orthotelephonic gain (Ingelis, 1938) is merely the transmission of a system relative to that of a standard system consisting of a talker and a listener who face one another at a distance of 1 meter in open air. For normal conversational levels, 0-db orthotelephonic gain corresponds to approximately 65-db sound pressure level at a distance of 1 meter in front of the talker.

The articulation scores in Fig. 14 rise rapidly as the orthotelephonic gain is increased. Optimal scores are obtained for each of the filter conditions at about the same point, roughly +10 db. Apparently the low frequencies contribute little to intelligibility in spite of the fact that they carry most of the speech power. When all the components of speech below 1000 cps are attenuated by a high-pass filter, the speech power is reduced approximately 80 per cent but the articulation score falls only 10 per cent. It should be noted that the frequencies above 1900 cps give approximately the same syllable

articulation as do the frequencies below 1900 cps.

These data have been analyzed to show the effects upon each of the individual speech sounds (Fletcher, 1929). Eliminating the high frequencies affects consonant articulation scores more than vowel articulation scores. Eliminating the low frequencies affects the vowels more than the consonants.

Pollack (1948) studied the effects of filtering upon word intelligibility under the special circumstance of a background of white masking noise. The noise was introduced electrically into the earphones at an overall sound pressure level of 81.5 db, and the intensity of the filtered speech was varied. For Pollack's talkers 0-db orthotelephonic gain corresponded to a sound pressure level of 68 db. In Fig. 15 the results are plotted in a form comparable to that used in Fig. 14 for quiet conditions. The effect of the noise is to shift the zero score from about -50 db to +5 db. In the presence of noise the relative importance of the different frequency components seems to shift as a function of speech level. At the lower intensities the low frequencies are relatively more important than they are at the higher intensities. It is also interesting to note that Pollack's data do not indicate that the articulation score decreases at very high intensities.

Egan and Wiener (1946) studied the intelligibility of narrow bands of speech in the presence of noise, and they summarized their results in terms of equal-articulation contours. By considering all the band-pass conditions that gave a given syllable articulation score, Egan and Wiener constructed the family of curves shown in Fig. 16. On the ordinate 0 db is the intensity of the speech in a wide-band system, and the results with the narrow-band systems are plotted relative to the level in the wide-band system. The figure is used in the following way. Suppose we wish to substitute a narrow-band system, 850 to 1700 cps, for a high-fidelity system, but must maintain a syllable articulation score of 60 per cent in the presence of white

* The maximum amplitude (Amplitude) will be distinguished from the varying instantaneous amplitude (amplitude), the capital letter being used for the former, the lower case for the latter.

FIG. 14. Functions relating syllable articulation scores for filtered speech to orthotelephonic gain, with the cutoff frequency of the filters as the parameter. (From French and Steinberg, 1947.)

FIG. 15. Functions relating articulation scores for filtered speech and orthotelephonic gain. The cutoff frequency of the speech filters is the parameter. The overall pressure level of the white masking noise (100 to 700 cps) was 81.5 db. (From Pollack, 1948.)

FIG. 16. Generalized equal-articulation contours plotted for band-pass systems all having a center frequency of 1500 cps. If the bandwidth is decreased, the intensity must be increased in order to hold the articulation score constant. (From Egan and Wiener, 1946.)

noise. Figure 16 tells us that the filtered speech must be 25 db more intense than speech via the broad-band system. In order to economize in terms of the frequency range of the system it is necessary to spend more on amplification. This generalized family of equal-articulation contours was constructed with a center frequency of 1500 cps, but to a reasonable approximation the same con-

tours can be used for other center frequencies by shifting the entire family horizontally.

PHASE OR TIME-DELAY DISTORTION

When some of the frequency components of a speech wave are delayed more than others—i.e. when the phase shifts are not

proportional to the frequencies of the shifted components—the waveform and the spectrum of the speech are of course modified. That this modification sometimes affects intelligibility was evident from experience with the early long-distance telephones. If the high-frequency *sh* of the word *shoe* is considerably delayed with respect to the low-frequency *ooh*, for example, the listener will hear the word backwards: *oosh!*

Unfortunately, we cannot yet specify the conditions under which phase distortion produces serious impairment of intelligibility. Most of the experiments that have been conducted have shown that intelligibility is highly resistant to distortion of this type (Steinberg, 1929, 1930; van der Pol, 1930). The frequency components above 1500 cps, for example, can be delayed 0.1 second relative to the components below 1500 cps without reducing the sound articulation score below 90 per cent. However, severe phase distortion has a pronounced effect upon the sound of speech (Steinberg, 1929). When different components of the speech arrive at different times, the listener frequently hears “birdies” or “tweets.” The annoyingness of phase distortion can be reduced by narrowing the range of frequencies passed by the system, but, as we have seen, narrowing the frequency range too far may seriously impair intelligibility.

EMPIRICAL EQUATIONS FOR ARTICULATION

Articulation measurement is a tedious and expensive business, and considerable attention has been devoted to the development of a computational device to replace, or at least to supplement, the laborious testing procedures. The rationale for such a device, as described by Collard (1930), involves weighting the contribution to intelligibility of the speech components as a function of their frequency and intensity. Various methods have been elaborated by Poocek (1939), French and Steinberg (1947), Beranek (1947), and

Fletcher and Galt (1950), but the basic assumptions of all these workers have been very similar.

Basic assumptions. We have seen that articulation scores depend upon the test materials used. It is desirable, therefore, to obtain a more fundamental measure of communication efficiency. Sentence, word, syllable, and sound articulation scores can then be related to this fundamental index, so that all four can be predicted once the index has been computed. Let the articulation index, A , assume values between 0 and 100, where 0 is assigned when all speech components are attenuated below the listener's threshold, and 100 is assigned to the performance of the orthotelephonic reference system. In order to divide this scale up into equal units, the articulation test is used as the operation for establishing equality; i.e. two systems have equal articulation indexes if they give equal articulation scores. Take the reference system ($A = 100$) and insert a filter that passes only the frequencies in the range from 20 to 500 cps. This system will yield a word articulation score of about 20 per cent. Next, change the filter so that it passes only frequencies in the range from 500 to 800 cps. The word articulation score will again be about 20 per cent, and by adjusting the range of the band-pass filter we can obtain exactly the same score for the two circuits. By repeating this process we can obtain n circuits such that each alone gives the same articulation score, and taken all together they constitute the original high-quality circuit. In so far as the contributions of the several bands of frequencies are equal and independent, the articulation index of each band is $100/n$.

The contribution of a given band of frequencies depends upon the intensity of the speech in the band, as well as upon the width of the band. If the intensity of the speech in a given band is below the threshold of hearing at those frequencies, the band makes no contribution to intelligibility, but as its intensity is increased the contribution in-

creases until the maximum, $100/n$, is reached. This fact is expressed by a weighting factor, w , which varies from 0 to 1.0 as a function of the sensation level of the band of speech frequencies. We can then summarize the computational procedure by

$$A = \sum_{i=1}^{i=n} w_i \frac{100}{n} = \frac{100}{n} \sum_{i=1}^{i=n} w_i$$

This equation expresses the notion that a narrow band of speech frequencies of a given

A is 50 the syllable articulation score is 68 per cent. Another point can be obtained by returning to Fig. 14 at the orthotelephonic gain that gives an articulation score of 68 per cent. If the articulation scores are now plotted as a function of filter-cutoff frequencies for this gain setting, these functions cross at a point that defines $A = 25$. By continuing this procedure the complete function relating A to syllable articulation can be plotted. This has been done in Fig. 18,

FIG. 17. Syllable articulation for high-pass and low-pass systems operating in the quiet with optimal gain. These functions are derived from the curves of Fig. 14 for an orthotelephonic gain of 10 db. (From French and Steinberg, 1947.)

intensity carries a contribution to the total index that is independent of the other bands with which it is associated, and that the total contribution of all bands is the sum of the contributions of the separate bands.

Dividing the frequency scale. French and Steinberg (1947) attempted to establish the relation between frequency and articulation index with the data shown in Fig. 14. If we cut through these two families of curves at an orthotelephonic gain of +10 db and plot articulation as a function of the cutoff frequency, we obtain the curves shown in Fig. 17. It is evident from these curves that as much of the total intelligibility is carried by frequencies below 1900 cps as is carried by the frequencies above 1900 cps. This establishes the value of 50 for the articulation index, and it appears that when

where the cumulative contribution to the articulation index is shown as a function of the upper cutoff frequency. The *slope* of this function shows the relative importance of the various frequencies in their contribution to intelligibility. With this information the range of important speech frequencies can be divided into a number of bands each of which contributes equally to the articulation index. Computations are normally made on the basis of 20 bands, each contributing a maximum ΔA of 5.

Weighting according to intensity. French and Steinberg estimate that a band of frequencies begins to contribute to intelligibility when it is about 6 db above the threshold of audibility, and that w increases linearly with a slope of 0.033 per decibel up to a sensation level, for the band, of about 30 db. The

maximum contribution is not made until the band of speech is 50 db above its threshold, but as a first approximation,

$$w_i = \frac{(\text{Sensation level of band in decibels}) - K}{30}$$

where w_i is limited to unity as a maximum value, and K is about 6 db. This approximation will tend to overestimate the contributions of bands more than 30 db above the

db. For noisy conditions, therefore, the approximated weighting factor becomes

$$w_i = \frac{(\text{S/N of band in decibels}) + 12 \text{ db} - K}{30}$$

This approximation cannot be used when the masking sound is a tone or a narrow band of noise, because these sounds spread their masking effects outside the range of frequencies of a single band.

FIG. 18. Articulation index as a function of frequency. (From French and Steinberg, 1947.)

threshold. It is usually assumed that the relation between w_i and intensity is approximately the same for all bands, although Pollack's results do not support the assumption.

When noise is present it will have the effect of raising the threshold of hearing. In this case the computations are made as before, but the masked threshold of hearing is used instead of the quiet threshold. If the masking sound is a noise with a continuous spectrum throughout the range of speech frequencies, it is possible to compute the masked threshold from the spectrum of the noise (Fletcher, 1938*a, b*; Fletcher and Munson, 1937). According to Fletcher, the masking produced by such a noise at a given frequency depends upon the intensity of the noise in the frequency region immediately adjacent to that frequency. The masking of a band of speech frequencies, therefore, will depend upon the value of S/N in that band. The sensation level of the band in the presence of the noise is 0 db when S/N is -12

Detailed examples are provided by Poocek (1939), Beranek (1947), and Fletcher and Galt (1950). The procedure is simple and straightforward once the speech spectrum and the noise spectrum at the listener's ears are known. Then S/N is stated for each band, the values of w_i are computed and totaled for the n bands, and the total is divided by $(100/n)$. The value of K seems to vary with different listeners; French and Steinberg used 6 db, but Beranek (1947) obtained more accurate predictions with K equal to 0 db. If all that is desired is a comparison of two proposed communications systems, the value of K does not affect the comparison and the computational procedure gives satisfactory results. If an accurate prediction of the articulation score is needed, however, the procedure does not seem to take sufficient account of individual differences in talkers and listeners.

The computational procedure is appropriate when the only difficulties in the com-

munication system are noise and frequency selectivity. Unfortunately, many other types of distortion occur, and for these there is at present no substitute for articulation testing methods.

AMPLITUDE SELECTIVITY

The most prevalent type of amplitude distortion is the one that discriminates against the high-amplitude parts of the speech wave.

FIG. 19. Diagram *A* is a schematic representation of the waveform of the word *Joe*. *B* shows what is left after 6-dB peak clipping, i.e. after reduction to one-half the original peak-to-peak amplitude. *C* illustrates 20-dB peak clipping. At the right, the waves of *B* and *C* are shown reamplified until their peak-to-peak amplitudes are equal to the peak-to-peak amplitude of *A*. (From Licklider, Bindra, and Pollack, 1948.)

Reduced to its simplest form, this type of amplitude distortion is called peak clipping. It is illustrated in Fig. 19. The results of a number of experiments on peak clipping agree in indicating that, although peak clipping degrades the quality and naturalness of the speech, a surprisingly large fraction of the speech wave can be eliminated before intelligibility is affected (Fletcher, 1929; Strecker, 1936; Gemelli, 1938; Licklider, 1944). This resistance to the effects of peak clipping is shown by the solid line in Fig. 20. We find, for example, that more than 95 per cent of monosyllabic words are heard correctly even after 24-dB peak clipping, i.e. after all but $\frac{1}{2}$ of the speech wave nearest the center axis has been clipped away. In fact, as indicated at the right-hand side of the figure, about 70 per cent of the words

can be understood after the speech wave has been subjected to 'infinite peak clipping,' which reduces it to a succession of rectangular waves (Fig. 21).

The opposite of peak clipping is center clipping. As is evident in Fig. 20, center clipping is disastrous. Clipping out only one-quarter of the speech wave (2.5-dB center clipping) reduces word articulation to about 30 per cent, and clipping out one-half of the wave (6 dB) leaves something that resembles static more than speech.

Comparing the effects of peak and center clipping, we are led to ask what it is about the center part of the speech wave that makes it so important for intelligibility. We do not have to go far for an answer: the center part contains the consonant sounds. Only a small percentage of our vocal energy goes into consonants, but that small portion conveys a disproportionate amount of information.

FIG. 20. The effects of peak clipping and center clipping upon intelligibility. When peak clipping is infinite, the articulation score is approximately 70 per cent.

It is evident from the observations on peak clipping and center clipping and from the results of other experiments with other types of amplitude distortion (Licklider, 1944) that the dimensions of the waveform, *amplitude* and *time*, are not, as such, the ones in terms of which the auditory system responds. If they were, we should not be able (as, e.g., by clipping off the peaks) to

render the waveform unrecognizable without impairing intelligibility more severely. Nor are the dimensions of the spectrum, *Amplitude*, *frequency*, and *phase*, the 'auditory' dimensions: the auditory system obviously analyzes along the temporal dimension, hearing "one," "two," "three," and "four" as

changed by infinite peak clipping, the general plan is by no means rendered unrecognizable. In the lowermost diagram, on the other hand, all trace of the general pattern has been lost. Clearly, the recognizability of the intensity-frequency-time pattern parallels the intelligibility of the speech.

FIG. 21. Showing how speech may be transformed into rectangular waves by means of a circuit that acts whenever the speech wave crosses the time axis. This transformation may be thought of as infinite peak clipping. (From Licklider, 1944.)

separate words, not as a steady spectrum. We turn, therefore, to *intensity*, *frequency*, and *time*, i.e. to the representation described above and illustrated by the visible speech pattern. In Fig. 23, we see an intensity-frequency-time plot of the word "shoebench," showing how it looks (1) when faithfully reproduced, (2) after infinite peak clipping, and (3) after 6-db center clipping. Comparing the middle diagram with the uppermost diagram, we see that, although many of the details of the pattern are

Amplitude selectivity and noise. When noise gets into an amplitude-selective speech transmission system, three aspects of the situation are of critical importance: (1) the characteristics of the noise; (2) the characteristics of the nonlinear circuit; and (3) whether the noise enters the system at a point preceding or at a point following the nonlinear circuit.

If the noise gets into the system at the talker's end of the line, the noise must pass with the speech through the nonlinear cir-

cuit. The resulting intermodulation is detrimental to intelligibility. Only when the noise consists of sharp pulses or clicks and the nonlinear circuit is a peak clipper is the

tortion products, and the listener judges the distortion to be less severe than it actually is.

Since every speech transmission system has an overload point where the peaks of the

FIG. 22. The diagrams illustrate various degrees of symmetrical peak clipping (left) and symmetrical center clipping (right). For each type and amount of clipping, the nonlinear input-output characteristic is shown, and opposite each nonlinear characteristic the effect upon a sine wave is illustrated. (From Licklider, 1944.)

interaction at all favorable: peak clipping then gets rid of more noise than speech.

If, on the other hand, the noise enters the system at a point following the nonlinear circuit, the noise tends to cover up the dis-

speech waves are clipped, the question arises, what is the best compromise between amplification and distortion? The answer stems from experiments on peak clipping (Licklider, 1944): if a communication system has

insufficient amplitude-handling capability to pass the peaks of the speech wave and at the same time to provide an adequate in-

(Kryter and Stein, 1944; Licklider and Roberts, 1945; W. W. Smith, 1946; Gross and Licklider, 1946; Miller and Mitchell, 1947),

FIG. 23. Intensity-frequency-time patterns contrasting the effects of infinite peak clipping and 6-db center clipping. (From Licklider, Bindra, and Pollack, 1948.)

tensity level, maximal intelligibility is obtained by clipping off the peaks and using the available power for the remainder of the wave (see Fig. 24). This principle has been applied to the design of radio transmitters

and the design of hearing aids (Davis et al., 1946, 1947). The principle appears to be of wide applicability because a considerable improvement in intelligibility can often be obtained with as little as 12-db peak clipping,

and that amount does not seriously impair speech quality.

Amplitude selectivity and frequency selectivity. When we have both frequency selec-

obtained with various arrangements of two frequency-selective circuits (differentiator and integrator) and one amplitude-selective circuit (infinite peak clipper). The differen-

FIG. 24. The advantage provided by peak clipping when the amplitude-handling capability of the communication system limits performance. When clipped and unclipped speech waves are equated in peak-to-peak amplitude, the clipped waves are much more intelligible than the unclipped waves. (From Licklider, 1944.)

FIG. 25. The effects of various combinations of differentiation, integration, and infinite peak clipping upon intelligibility. The smooth curves show the course of the articulation scores through the 25 test sessions. The heights of the bars of the inset diagram indicate the overall averages for the ten arrangements of the distorting circuit. (From Licklider and Pollack, 1948.)

tivity and amplitude selectivity in the same communication system, we face another problem of interaction. The total effect upon intelligibility is by no means the sum of the individual effects of the two distortions. Figure 25 shows, for example, the results

tiator passes the high frequencies but attenuates the low frequencies by an amount that increases 6 db per octave as we go down the frequency scale. The integrator does just the opposite. The frequency-selective circuit preceding the clipper has a marked in-

fluence upon intelligibility, whereas the one following the clipper has almost no effect upon intelligibility. It is apparent from Fig. 25, incidentally, that the listener improves rapidly in his understanding of distorted speech; only about one-third of this improvement can be attributed to increasing familiarity with the particular word lists used in the test.

TIME SELECTIVITY

Steinberg (1936) describes an experiment in which the listener was prevented from hearing the first part of the nonsense syllable spoken by the talker. Steinberg used a voice-operated relay that did not complete the communication circuit until some fixed interval after the nonsense syllable had begun. The average duration of the initial

FIG. 26. Effects of regularly repeated interruptions upon the intelligibility of speech. The percentage of the time that the speech was left on is shown by the figure adjacent to each curve.

Amplitude selectivity, frequency selectivity, and noise. Since the effect of amplitude distortion depends markedly upon the type of frequency distortion to which the speech has previously been subjected, it is reasonable to assume that some combination of the two might provide a greater advantage than that obtained with peak clipping alone. This possibility was investigated, with somewhat disappointing results, in some of the experiments already mentioned. It turns out, however, that frequency-selective circuits are useful in suppressing low-frequency noise that enters the system at a point preceding the nonlinear circuit (Kryter and Stein), and that speech in airplanes at high-altitude can be made to sound more natural by attenuating its low-frequency components (Miller and Mitchell).

consonants was normally about 0.16 second. When the first 0.08 second of this consonant was lopped off, the listeners still recorded the sound correctly about half the time. With the first 0.12 second gone the listeners were right about 25 per cent of the time.

Several investigators have performed the experiment of turning speech on and off periodically and noting the effect upon intelligibility (Poirson, 1920; Marro, 1936; Montani, 1946; Miller and Licklider, 1950). As shown in Fig. 26, the effect of the interruptions upon intelligibility depends upon the two variables, *interruption rate* and *speech-time fraction*. If the rate of interruption is sufficiently high, almost all the words can be understood even though the speech-time fraction is very low. This result may appear surprising at first thought, but it is exactly what amplitude-modulation

theory predicts, and we need appeal to no unusual properties of the auditory mechanism to understand it. The part of the signal that falls within the frequency range important for intelligibility is, in fact, essentially undistorted. The dip in the curve between 100 and 3000 interruptions per second (ips) is also to be expected on the basis of modulation theory. The plateau between 10 and 100 ips, however, tells us something about the dynamics of auditory perception. We find that, under certain conditions, the auditory mechanism is capable of getting the whole story even though it hears the speech only half the time, provided only that the interruptions are so spaced in time that few of the fundamental speech sounds are entirely eliminated. When the interruptions occur at a rate of 15 per second, for example, the loudness of the signal fluctuates in step with the interruption. The 'sense' of the interrupted speech, however, is perceived quite independently of the loudness. In fact, intelligibility remains high even when the gaps in the speech are filled with intense bursts of noise that sound much louder than the speech.

Observations have been made also with aperiodic or random interruptions (Miller and Licklider, 1950). These observations show that, if the average rate of interruption and the average speech-time fraction are held constant, changing from regular to random interruption has relatively little effect upon intelligibility. The subjective sound of the interrupted speech, however, is quite different: regularly interrupted speech seems to be heard against a somewhat tonal background; irregularly interrupted speech seems to be heard against a background of white noise or static.

PRACTICAL APPLICATIONS

Three quantities of great economic importance in the communication world are frequency, power, and time. Since power is proportional to the square of amplitude,

it is evident that these quantities are essentially the ones we have been discussing. The practical utility of frequency, amplitude, and time selectivities may be judged, therefore, in terms of the savings that they may permit us to achieve in frequency, power, and time.

The way to save space along the frequency scale is, of course, to minimize the bandwidth of the transmitted signal. We have seen that intelligibility is impaired only slightly by the elimination of the very high and the very low frequency components of speech. Advantage is taken of this fact in practical telephone and radio communications: the speech spectrum extends from below 100 to above 7000 cps, but only those parts between about 250 and 3500 cps are usually transmitted. This frequency selectivity permits a saving of approximately one-half in bandwidth.

As we saw in Fig. 24, 24-db peak clipping allowed us to achieve a given level of intelligibility with about 13 db less peak signal power than would be required if we insisted on distortionless transmission. We can therefore substitute a 1-watt peak-clipping amplifier for a 20-watt linear amplifier. Advantage of this fact is taken in military and commercial communication by building pre-modulation clippers into the radio transmitters. In broadcast work, simple peak clipping cannot be used because it impairs the quality of music; compression or volume-limiting amplifiers (which preserve quality better, but provide a less marked saving in power) are used instead.

A possible application of time selectivity, suggested by Marro, takes advantage of the high intelligibility of speech interrupted at a low rate in such a way that it is on only half the time (cf. Fig. 26). By alternating between two conversations 15 times per second, it is possible to provide intelligible two-way communication on a single channel, thereby achieving double use of the communication facilities, which is in a sense equivalent to halving the bandwidth of the signal.

OTHER TYPES OF DISTORTION

Of considerable practical interest are several special types of distortion that we should consider briefly. These are the distortions due (1) to reverberation in enclosures with reflecting walls, (2) to expansion, contraction, or modulation of the time scale, and (3) to displacement of the speech spectrum along the frequency scale.

tailed analysis. Steinberg found that the sounds most affected were short vowels, nasal consonants, and stop consonants. Long vowels and sustained fricative consonants were, as might be expected, considerably less affected.

We should not conclude, however, that because extreme reverberation impairs intelligibility all reverberation is undesirable. (Note the maxima in the curves in Fig. 27.) Anyone who has listened inside an anechoic

FIG. 27. The effect of reverberation upon the intelligibility of speech. The data were obtained with nonsense-syllable tests in a series of auditoriums having about the same shape and volume, but different reverberation times. (From Knudsen, 1929.)

Reverberation. The reverberation of sound in a 'live' room leads to a piling up of echoes in such a way that both frequency and phase distortion are introduced. The individual speech sounds tend to lose their individuality, to run together into an unintelligible blur. The effect is especially pronounced in the waiting rooms of railroad stations.

The impairment of intelligibility caused by reverberation has been measured by Knudsen (1929) and by Steinberg (1929). Knudsen's results are shown in Fig. 27. The reverberation time is the length of time required for the sound to decay to $\frac{1}{1000}$ of its initial rms amplitude (60 db). Clearly, severe reverberation is highly deleterious to intelligibility. Knudsen's results are confirmed, in the main, by Steinberg's more de-

tailed analysis. Steinberg found that the sounds most affected were short vowels, nasal consonants, and stop consonants. Long vowels and sustained fricative consonants were, as might be expected, considerably less affected.

chamber knows the oppressive feeling of 'acoustic deadness' and remembers the unfamiliar sound that familiar voices have when there is no reverberation.

In an effort to express in a quantitative way the characteristic of a room or auditorium that determines the naturalness of speech or music, Maxfield and Albersheim (1947) developed a formula for liveness. According to this formula, liveness is proportional to the square of the reverberation time, to the square of the distance between the sound source and the listener, and, inversely, to the volume of the enclosure. One of the principal advantages of liveness over reverberation time is that the optimal liveness is a constant, whereas the optimal reverberation time increases, approximately as the $\frac{1}{6}$ power of the volume of the room.

Time-scale distortion. We ordinarily think (or at least Newton thought) of time as flowing by at a constant rate. Neverthe-

FIG. 28. The effect upon intelligibility of compressing or expanding the time scale. The data were obtained by recording speech and playing it back faster or slower. (From Fletcher, 1929.)

less we can change the time scale by recording a signal and playing it back at another rate. This operation also affects the frequency scale, of course: when we increase the record speed by a factor N , all frequencies of the signal components are multiplied by N .

The relation between intelligibility and the factor N is shown in Fig. 28. Ordinary speech has, we see, a fairly high tolerance for distortion of this type. The tolerance is by no means so high, however, as the tolerance for the speeding up or slowing down that the talker can achieve simply by altering the rate at which he talks (cf. Fig. 30).

Probably the most drastic form of time-scale distortion is produced by making time, i.e. a phonograph record, run backwards. Backward speech is so completely unintelligible at first hearing that it makes good nonsense material for experiments on learning (Lewis, 1946). English sounds like Chinese. The words seem to follow one another at a rapid pace. The talker is surprised to find that he has generated *h*'s during what he thought were pauses between words (Kellogg, 1939). These unfamiliar effects occur, of course, despite the fact that the Amplitude-frequency pattern is not changed by reversing the time scale. There is perhaps no more convincing evidence that the auditory mechanism "perceives phase" (cf. Chapter 25).

Frequency-shift distortion. When speech is sent from one point to another by means

FIG. 29. The effect of frequency-shift distortion upon the intelligibility of speech. The speech spectrum was shifted bodily along the frequency scale by the number of cycles indicated on the abscissa. (From Fletcher, 1929.)

of single side-band transmission, an unusual effect is produced in the received speech if the two stations are not precisely synchronized. The whole speech spectrum is shifted bodily up or down the frequency scale, a constant number of cycles being added to or subtracted from the frequency of each component. The effect of this frequency-shift distortion upon intelligibility is shown in Fig. 29. We see that the auditory mechanism can tolerate an upward frequency shift of 100 cps with an articulation loss for nonsense syllables of less than 10 percentage units. Because frequency-shift distortion changes harmonic relations into inharmonic relations, however, it is highly deleterious to music.

INDIVIDUAL DIFFERENCES

If the talker and the listener both speak the same language, word articulation measured in the quiet and in the absence of distortion is almost always above 90 per cent. We should be careful, however, not to jump to the conclusion that individual differences among talkers and among listeners are therefore small. We need only apply a little stress in the form of noise or distortion to make it apparent how great the variations among talkers actually are. In one experiment the average articulation scores of twelve representative talkers in the presence of simulated airplane noise with standard military communication equipment were found to range from 44 to 85 per cent (Abrams et al., 1942).

The question naturally arises, what are the characteristics of the talkers, or of their speech waves, that determine the differences? This question was studied by Abrams et al. (1944) in the following way: First, they used word and sentence articulation tests to determine intelligibility scores for each of 47 talkers. Then, from phonographically recorded samples of their speech they made measurements of (1) speech intensity, (2) the distribution of speech en-

ergy along the frequency scale, (3) the 'pitch' of the voice (fundamental frequency of the vowel sounds), and (4) the 'peak factor' (peakedness) of the speech waveform. In addition they had a group of five judges make subjective ratings of (1) consonant strength, (2) consonant precision, (3) appropriateness of rate of speaking, (4) duration of words, (5) steadiness of rate of speaking, (6) steadiness of level and

FIG. 30. The relation between the rate of speaking and average sentence intelligibility. (From Abrams et al., 1944.)

emphasis, (7) noise-penetrating quality, (8) deviation from General American dialect, and (9) overall intelligibility. Finally they determined the degree of correlation between measured intelligibility and each of the parameters just mentioned. Besides intensity, which is almost always the most important variable determining intelligibility in noise, the important factors proved to be the noise-penetrating quality (which itself is a function of intensity, pitch, and peak factor), the strength and precision of the consonants, and the dialect.

It is perhaps surprising that normal variations in rate of speaking do not have much effect upon intelligibility. As shown in Fig. 30, sentence intelligibility fell off only slightly as the rate was increased until the talker was emitting almost 160 words per

minute; approximately 120 words per minute was rated optimal by five judges.

One of the psychologist's contributions to communication theory is the idea that the talker and the listener are parts of the communication system. Directly from this notion stems the question: can we train talkers to speak intelligibly? Black and Mason (1946) have answered it in the affirmative; they found that they could do more to improve communication by training the talker than the engineers could do by developing new and better microphones. In order to improve a talker's intelligibility over an interphone or radio link operating in a noisy location, they simply taught the talker (1) to handle his microphone properly, (2) to get his speech level up as high as he could without straining his voice, and (3) to articulate precisely. In an hour they found it possible to improve the intelligibility of aviation personnel talking over an aircraft interphone system by about 7 percentage units (a control group improved less than 1 percentage unit). A 4-hour course led to improvements ranging from 12 to 24 percentage units.

Variations among listeners. It goes almost without saying that a good listener understands the language and has normal auditory acuity. (See Carhart, 1946, on the relation between the audiogram and the capacity to hear weak speech.) The other characteristics of the listener that determine his ability to understand speech, however, are difficult to elucidate. The principal trouble is that, whereas we can analyze the speech wave that the talker produces, the only thing that we can do with the listener's response is to check it to see whether or not it is correct. The role of the listener must be studied, therefore, by varying the stimulus and/or by varying the listener.

Here again, most of the interest has been in the ability to understand speech in noise. That there are wide individual differences in this ability was shown by Abrams et al. (1942). Karlin et al. (1944) studied the

nature of these individual differences by varying the nature of the speech material, the equipment over which it was transmitted, and the noise against which it was heard. Using a large number of subjects, they found that there was only one significant factor in the situation. This factor, surprisingly, is uncorrelated (actually, $r = -0.17$) with ability to receive telegraphic code in noise. Moreover, the correlations between listening ability and intelligence, memory span, and speaking ability are all quite low.

We have already seen (Fig. 25) how markedly listeners improve with practice in their understanding of distorted speech. Similar results have been obtained with undistorted speech heard in the presence of noise (cf. Fig. 9). There appears to be no better way to teach listeners than to motivate them and have them listen. Even after extensive training, however, normal listeners differ considerably in their ability to understand speech under difficult conditions.

DISCUSSION

The preceding summary has shown that vocal communication is highly resistant to distortion. Apparently no single dimension of the speech is critical. Speech power can be varied over a range of a billion to one. Conversations are intelligible with only the upper half of the speech spectrum, but there is nothing unique about this half because we can throw it all away and get along equally well with only the lower half. The waveform can be distorted to a series of square waves or turned off half the time without severe effects. The listener does not seem to depend upon amplitude alone, nor upon frequency or time alone. The fundamental acoustic determinant of his response is the distribution of energy at the different frequencies as a function of time: the intensity-frequency-time pattern. Types of distortion that alter the listener's ability to respond correctly are those that change the

intensity-frequency-time pattern. Changes in the intensity, the fundamental frequency, the waveform, the envelope of the wave, or the spectrum do not affect intelligibility until the change is so great the spectrographic pattern is markedly altered. The resistance of this pattern to the commonly encountered distortions makes vocal communication possible under adverse circumstances.

It is interesting to note that the attempts to translate speech into tactual or visual patterns for the benefit of the deaf have not succeeded unless they have presented intensity-frequency-time patterns to the new modality. An oscillogram of the waveform, for example, presents speech to the eye in a graph of amplitude versus time, and quite different oscillograms can have very similar spectrographic patterns. If the waveform is applied with a vibrator to the skin, the subject can discriminate changes in the envelope of the wave, but the complete pattern is not available (Gault, 1926; Gault and Goodfellow, 1937; Weichbrodt, 1932). The pattern must be presented in the appropriate dimensions before we recognize it readily.

Since speech can be severely distorted without becoming unintelligible, it is reasonable to suppose that the normal stream of speech contains many more discriminative clues than are necessary. If distortion removes or confuses some of these clues, the others carry the message. An important aspect of any message is the extent to which the component elements are interrelated. As long as each element is unrelated to the others, each element can carry a separate parcel of information, but the listener is required to make no mistakes. If some relation exists, the amount of information per element of the message is reduced, but the listener's job is simplified. If the listener hears any one of the related elements, he knows something about the others. By sending related elements in the message the talker is, in effect, repeating himself. From

the point of view of efficiency, human speech seems a poor device, but what is lost in efficiency is regained in resistance to distortion. If the speech stimulus contains many more discriminative clues than the listener really needs, distortions in the stimulus must be extreme in order to obliterate all traces of the message.

In almost all the work on the perception of speech, the yardstick has been a scale on which 100 per cent represents a perfect echo: the listener writes down or repeats what the talker says. Currently, however, communication theorists are developing a more elegant yardstick (see Chapter 21). The new standard of performance is perfect reproduction, not of what a talker says, but of the information he might transmit if he generated a white noise of the same bandwidth as the speech. In order to make this notion seem reasonable, it is necessary to consider that the information contained in a message does not depend upon what the talker says, but upon what he might say.

In the simplest formulation of the theory, the amount of information contained in one message is equal to the number of decisions, D , between equally probable alternatives that the listener must make correctly in order to tell which of the M possible messages was sent.

$$\text{Amount of information} = D = \log_2 M$$

If there are two possible messages, the listener must make one correct decision. If there are four possible messages, two correct decisions are necessary. Eight possible messages require three decisions, etc.

Now it is possible to estimate how rapidly information, so defined, could be transmitted by a 'white noise' talker to an ideal listener over a reasonably good communication system. Assume (1) that the system passes all the component frequencies within a frequency band B cycles wide and suppresses all others, (2) that the ratio of the talker's speech power to the interfering noise power

is 1000/1 (i.e. 30 db), and (3) that in all other respects the system transmits the speech faithfully. The amount of information — number of decisions — that the system can handle in a length of time T is given by the formula *

$$D = BT \log_2 (S/N + 1)$$

Substitute the values of bandwidth (5000 cps), time (1 second), and signal-to-noise ratio (30 db). The system is capable of transmitting

$500 \log_2 (1001) \approx 50,000$ decisions per second

For this representative set of conditions the yardstick places perfect performance at 50,000 bits of information per second.

When normal speech communication is evaluated by this yardstick (cf. Chapter 21), we find that it carries less than 50 usable bits of information per second. Relative to the theoretical ceiling of the system, human beings are less than 0.1 per cent efficient. And if the listener is expected to retain what

* Here we accept the formula with only a suggestion as to its derivation. Although the talker's message is only T seconds long, we can imagine a wave of infinite duration made up of endless repetitions of his message. The fundamental frequency of this recurring wave is $f = 1/T$ cps, and the spectrum consists exclusively of integral multiples of f . In the B cycles passed by the system there are $B/f = BT$ harmonics. Associated with each harmonic are two magnitudes, one designating Amplitude, the other phase angle (or two Amplitudes, one of a sine component, the other of a cosine component). Thus $2BT$ numbers are necessary to specify the message completely. Because of the noise these magnitudes cannot be determined exactly. We have, as it were, a scale s units long, but we can read it only to the nearest n units. We can do no more than select the proper mark out of $(s/n + 1)$ alternatives. This selection supplies us with $\log_2 (s/n + 1)$ units of information about each of the $2BT$ magnitudes. Now s and n are linear quantities (like inches), but we want to use quadratic quantities (S, N) in the formula. We therefore note that, if $S/N \gg 1$, $\log_2 (s/n + 1) \approx \frac{1}{2} \log_2 (S/N + 1)$. In all, then, we have $2BT \log_2 (s/n + 1) \approx BT \log_2 (S/N + 1)$. More detailed discussions are given by Shannon (1948) and Wiener (1948).

he recognizes, the rate at which information is transmitted must be reduced even further.

It is reasonable to ask why we are so inefficient. A principal reason is that our sensory channels, although sensitive to small differences, do not identify stimuli in an absolute way. The ideal decoding machine would have a capacity not just to detect differences but to identify the frequency components of the messages, their Amplitudes, and perhaps their phases. This capacity is poorly developed in the human listener. In lieu of an absolute calibration, the auditory system must respond to relations. Nevertheless, from the point of view of information theory, response to relations is highly inefficient. If the parts of the signal must form a pattern, if they must be intercorrelated, the total amount of information carried by the signal is necessarily reduced. The necessity for relations among the elements of the signal greatly reduces the number of degrees of freedom in the system.

One final point is of interest here. A spoken message carries information about the talker as well as about the things the talker refers to. Numerous studies (Bonaventura, 1935; Cantril and Allport, 1935; Eisenberg and Zalowitz, 1938; Fay and Middleton, 1939-1943; Herzog, 1933; Pear, 1931; Stagner, 1936; Taylor, 1934) have tested the reliability and validity of personality judgments based solely upon the voice. Table 3 summarizes the results according to the accuracy of the listener's opinion. The listeners often agree among themselves that a talker should be what he is not, and several studies report results significantly different from chance, but in the wrong direction. In other words, stereotypes are common. Not all the listener's information depends upon the talker's choice of words. Whether or not the listener's impression is accurate, it is quite simple to show that he perceives and evaluates vocal information that does not appear in the results of an articulation test.

The Mechanical Properties of the Ear

GEORG VON BÉKÉSY and WALTER A. ROSENBLITH
Harvard University

Many theories have been proposed to account for the phenomena of hearing. Theorizing has flourished principally because the location and the size of the various parts of the ear make it difficult to measure their physical properties with accuracy. Consequently our knowledge of the mechanical properties of the ear is sketchy, and even more fragmentary is our understanding of the translation of mechanical processes into neural stimuli.

In the following pages we shall be concerned primarily with those phenomena that are accessible to physical measurement. We shall attempt to separate the function of the ear, as a mechanical transducer, from the function of the nervous system, and to examine the mechanical processes in the ear that relate to the theory of hearing. We must, however, point up the danger of generalizing about the whole process of hearing on the basis of measurements made in one range of frequencies. Our measurements demonstrate that the auditory systems of man and higher animals function in many respects as if they were governed by the same general principles. Yet a more detailed quantitative study often brings out important differences in the functioning of cer-

tain parts of these systems. It would appear unwise, therefore, to try to generalize too freely about the workings of the various elements of human and animal auditory systems from certain similarities in their overall response.

GROSS ANATOMY OF THE EAR

Figure 1 represents a schematic drawing of the human ear. (Unless otherwise noted, all drawings and measurements presented in this chapter represent the human ear.) An incident sound wave exerts a pressure upon the drum (tympanic membrane) which sets the three ossicles — the hammer (malleus), the anvil (incus), and the stirrup (stapes) — into motion and thereby transfers the pressure to the inner ear. The air-filled space containing the ossicles is called the middle ear. Since gas inside the body is absorbed by the blood stream, the pressure in the middle ear would gradually fall below normal, were it not for the Eustachian tube which connects the middle ear with the pharynx. The Eustachian tube is usually closed, but it opens when we swallow or yawn. The middle ear pressure and the atmospheric pressure are thereby equalized. This is very important whenever the atmospheric pressure changes rapidly, as in airplanes and elevators. In certain pathological cases the

This chapter was prepared at the Psycho-Acoustic Laboratory, Harvard University, under contract with the U. S. Navy, Office of Naval Research (Contract N5ori-76, Project NR142-201, Report PNR-80).

FIG. 1. Schematic drawing of the human ear. Sound waves enter the external meatus, and move the tympanic membrane which sets the three ossicles in motion. When the stapes footplate moves inward, the perilymph inside the cochlea flows in the direction of the helicotrema and makes the round-window membrane bulge outward. All these movements can be observed with the aid of a microscope. (Békésy, 1935.)

FIG. 2. Schematic cross section of the cochlear channels. When a pressure (direction of arrow) is applied, the ductus cochlearis is bulged into the scala tympani (shown by the dotted lines). (Békésy, 1941b.)

Eustachian tube remains continuously open, and sound then travels directly from the mouth to the middle ear. An unpleasant rumble known as autophony ensues.

The inner ear is filled with liquid. It consists of two parts: the vestibular apparatus

and the cochlea. The cochlea is coiled in the manner of a snail shell (hence the name).

By means of an elastic partition, the cochlea is subdivided into two principal perilymph-filled channels (see the dotted area in Fig. 2). This partition contains the

ductus cochlearis, which is filled with a highly viscous, almost gelatinous substance called endolymph. The partition contains the auditory nerve endings and many other structures whose function is connected with the translation of mechanical into neural

liquid does not flow through the helicotrema and back to the round window. Instead it deforms the cochlear partition as shown by the dashed lines in Fig. 2.

Figure 3 shows an actual section of the human ear. The sound impinges from the

FIG. 3. Middle ear in man. (After Békésy, 1949.)

stimuli (for details see Chapter 28). In spite of its rather heterogeneous inner structure, the partition can, to a first approximation, be treated as a single elastic layer. The helicotrema (see Fig. 1) protects the cochlear partition from one-sided, static pressures. When the stapes moves slowly inward, the liquid flows along the upper channel and through the helicotrema into the lower channel where it finally produces a deformation of the round window. At higher audible frequencies of vibration of the stapes the

back of the figure upon the drum and sets the handle of the malleus into motion. The interlocking of the head of the malleus and the incus is visible, as are also the various ligaments that fasten the ossicles to the middle ear wall. We see a tendon leading to the tensor tympani, a muscle that contracts when the ear is stimulated by a sound. Another muscle, the stapedius, the smallest muscle in the human body, is fastened to the stapedial joint. The stapes footplate is attached by means of very tenuous fibers to

the bony wall. This insures a pistonlike motion of the stapes. Figure 4, a histological section of the middle ear of a cat, shows the piston "packing" as well as the stapedius muscle.

Only the outer edge of the cochlear partition is elastic; the inner edge is a bony shelf known as the lamina spiralis ossea (see Fig.

Mangold, 1926). The external ear can be compared to a funnel. For higher frequencies the funnel acts in two different ways: (1) it brings about a pressure transformation making the pressure at the drum greater than the pressure in the free sound field, and (2) it has directional properties such that sounds from one direction are

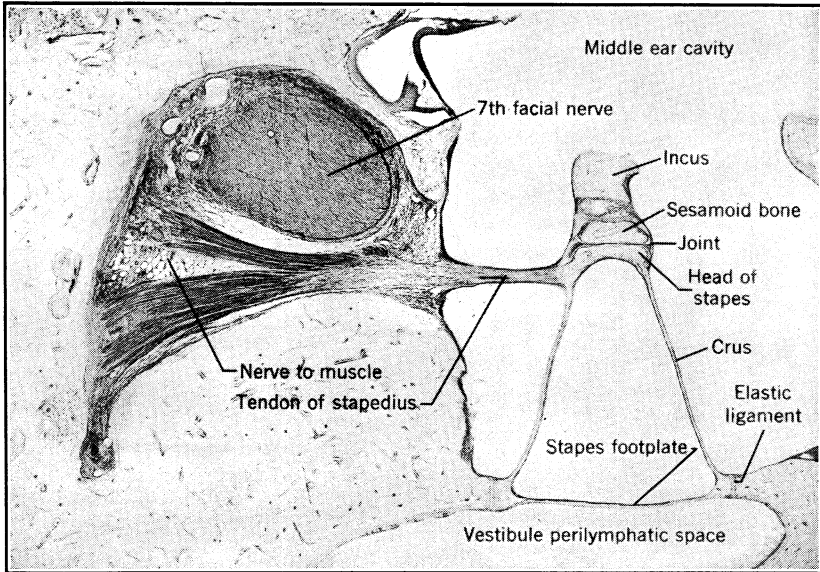

FIG. 4. Cross section of the stapes of a cat. In otosclerotic patients the tenuous elastic ligaments that attach the stapes footplate to the bony capsule of the cochlea become ossified and the stapes becomes immobilized. (We are indebted for this figure to Dr. M. H. Lurie.)

2). The width of the elastic part of the cochlear partition increases uniformly as we go from the stapes to the helicotrema. Since the width of the cochlear partition as a whole remains rather constant, the width of the bony part decreases as we recede from the stapes. To give the reader a feeling for the dimensions and masses in the human ear, the best available data have been summarized in Table 1.

The outer and the middle ear. Many animals possess rather large pinnas which affect particularly their reception of high-frequency sounds. The horse, for instance, has seventeen different muscles that permit him to orient his pinna in different direc-

amplified while sounds from other azimuths are attenuated. Both these properties come into play for wavelengths that are of the order of magnitude of the dimensions of the external ear funnel (the wavelength of a 3000-cycle tone in air is about 11 centimeters). Mach and Fischer (1873) have given a particularly clear and thorough discussion of this matter.

The second half of the nineteenth century produced a whole series of experiments dealing with the modifications of the sound field due to irregularities in the human meatus. The experimenters (Schneider, Kuepper, Harless, Rinne, Kessel, and others) used great ingenuity to get a smooth sound path

TABLE 1

AVERAGE DATA FOR HUMAN EARS (RESULTS OF MEASUREMENTS BY MANY AUTHORS)

Auditory Meatus	Middle Ear
Cross section, 0.3–0.5 cm ²	Total Volume, about 2 cc
Diameter, 0.7 cm	Malleus: weight, 23 mg
Length, 2.7 cm	length, 5.5–6.0 mm
Volume, 1.0 cc	Incus: weight, 27 mg
	Stapes: weight, 2.5 mg
	length of footplate, 3.2 mm
	width of footplate, 1.4 mm
	area of footplate, 3.2 mm ²
	width of elastic ligament, 0.015–0.1 mm
Tympanic Membrane	Cochlea
Area, 0.5–0.9 cm ²	Length of cochlear channels, 35 mm
Thickness, about 0.1 mm	Height of scala vestibuli or scala tympani, about 1 mm (great variability)
Volume elasticity for 10 cps, equivalent to about 8 cc air	Round window: area, 2 mm ²
Displacement amplitude 1000 cps tone (at threshold), 10 ⁻⁹ cm	Basilar membrane: width at stapes, 0.04 mm
Displacement amplitude for low-frequency tones (threshold of feeling), about 10 ⁻² cm	width at helicotrema, 0.5 mm
	Helicotrema: area of opening, 0.25–0.4 mm ²

to the drum. They introduced glass tubes and filled the hollows of the external ear with wax, oil, or bread dough. Their final conclusions show a good measure of agreement: although the threshold for sounds in the middle range is not much affected, localization suffers when the shape of the external ear is altered. In particular it becomes less easy to distinguish noises originating in front from those in back of the head.

The meatus functions also as a protective device against foreign bodies. Since the thin membranes of the middle ear are very sensitive to changes in humidity, the meatus also serves the purpose of making the humidity in the vicinity of the drum reasonably independent from the humidity of the atmosphere. The same holds for temperature: because of the length of the meatus we find that the temperature close to the drum is independent of the atmospheric temperature and is even 0.2 to 0.3 degree C higher than the temperature in the armpit.

The meatus is a resonator about 2.7 centimeters long. The natural frequency of the resonator is near 3000 cps. Consequently,

for frequencies close to the resonant frequency the sound pressure at the drum is greater than the free-field pressure, but, since this resonator is terminated by a flexible drum and since its outside opening is relatively large, the resonance is not sharp. Even at the resonant frequency the increase in sound pressure is small: in most cases the maximum increase is about 10 db. To this increased sound pressure due to the meatus are added the effects on the sound field produced by the presence of the head and the body.

These phenomena were predicted on theoretical grounds by Ballantine (1930) and Békésy (1932*b*). Experimental evidence substantiating them came from Wiener and Ross (1946) and Wiener (1947). In order to perform such measurements a probe is inserted close to the drum and the measured sound pressure is compared with the pressure at the entrance of the meatus. Figure 5 shows the most recent results.

The drum and the ossicles. Although with the aid of an ear speculum we can see the drum very clearly, it is not easy to measure

its vibratory pattern because the amplitude of vibration of the drum is very small.

In 1872 Mach and Kessel put some shell gold on the drum and succeeded in observing the drum vibrations through a microscope. Similar observations can be made more easily with modern ear microscopes (Waar, 1923). When low frequencies are used, greater amplitudes are obtained, and it becomes simpler to make these observations stroboscopically. Wilska (1935) determined the amplitude of vibration of the

The question is often asked whether the ear responds mainly to pressure changes or mainly to changes in the velocity of the vibrating air particles. In a standing wave pattern a tone is heard loudest when the ear is located at a pressure antinode, while nothing is heard at a velocity antinode. The ear behaves therefore, at low frequencies, as a pressure receiver. For frequencies near 1500 cps, the vibrations of the ossicles give rise to rather irregular resonance phenomena. In this frequency range the drum

FIG. 5. Effects of resonance in the external meatus. The ordinate shows the ratio in decibels between the sound pressure at the eardrum and the sound pressure at the entrance to the auditory canal. (Wiener, 1947.) For the effects of sound diffraction around the head, see Wiener and Ross (1946).

drum at the threshold of audibility for various frequencies. He glued a light stick directly to the eardrum and then measured the amplitude with which the stick vibrated (Fig. 6).

A series of measurements (West, 1928; Tröger, 1930; Békésy, 1932*a*, 1936*a*; Sivian and White, 1933; Geffcken, 1934; Waetzmann and Keibs, 1936*a, b*; Metz, 1946) were carried out in order to determine the mobility of the drum. More specifically, these workers measured the volume displacement of the drum for pressure changes inside the meatus. The importance of these so-called impedance measurements stems from the fact that once we know the impedance of the drum we are able to calculate how much sound energy is transferred to it (Fig. 7). These impedance measurements show that, at low frequencies, the drum behaves like an elastic membrane whose displacements are proportional to the incident pressure.

reflects practically none of the energy that impinges upon it. Its sensitivity is maximum. It is, however, no longer exclusively a pressure receiver. At the higher frequencies the situation is complicated by the fact that the eardrum vibrates in segments, so that no simple generalizations can be made. The pattern of segmental vibration changes drastically with frequency.

The natural frequency of vibration of the middle ear depends upon the ossicular masses and also upon the elastic properties of the various ligaments that keep the ossicles in place. The small bumps in the curves representing the threshold of hearing would seem to be attributable to small frequency-dependent variations in drum mobility. In 1936 Langenbeck drew attention to the fact that threshold curves for both ears of a given individual show a high degree of similarity, as would be expected from the bilateral symmetry of the face.

FIG. 6. Amplitudes of vibration of the drum at the threshold of hearing. The circles show the amplitudes determined by Wilska. Békésy measured the amplitude of vibration of the basilar membrane at the threshold of feeling (solid square). The amplitude of the basilar membrane at the threshold of hearing (open square) is an extrapolation, as were Wilska's points. The curve shows the amplitude of vibration of air molecules in a sound wave at threshold as calculated by Stevens and Davis. This curve and Békésy's data are in reasonable agreement with Wilska's findings if allowance is made for the different impedances involved.

FIG. 7. Transmission of energy at the eardrum. The ordinate values were computed from impedance measurements. They indicate the percentage of the incident sound energy transmitted to the middle ear. The circles refer to the left and the crosses to the right ear of the subject. The difference between the ordinate values and 100 per cent is the amount of energy reflected at the eardrum. (After Waetzmann and Keibs, 1936a.)

Since the shape of facial bones is presumably inherited, we may also assume that the shapes of the ossicles, and hence of the fine structure of threshold curves, are likewise inherited. This was shown by Waetzmann and Keibs (Fig. 8). Threshold curves on identical twins confirm this notion.

be thought of as a piston with a cross section of about 85 square millimeters, out of which about 55 square millimeters are rigidly attached to the handle of the malleus. The pressure upon this piston is finally transmitted to the stapes where the effective area amounts to only 3.2 square millimeters.

FIG. 8. Family similarities in audiograms (right and left ears). The "control" is for one of Waetzmann's three unrelated subjects. Waetzmann stresses (1) that audiograms tend to be similar for both ears, (2) that audiograms for members of a family are similar, and (3) that unrelated subjects show significant differences. (Békésy, 1935, after Waetzmann, 1935.)

Since the auditory nerve endings are immersed in a liquid, a transducer problem arises: how is the acoustic energy transferred from the air to the liquid? Air, a very light and compressible medium, has a small impedance compared to that of the practically incompressible cochlear liquid. Hence the necessity for a system of levers whose function consists in transforming the large displacements of the air into small displacements of the liquid, while at the same time transforming the small forces acting upon the drum into larger forces acting upon the cochlear liquid.

The anatomical structure of the middle ear seems extremely appropriate for this purpose (Helmholtz, 1868). The drum can

The ossicles are pivoted in a manner that provides a small additional mechanical advantage (about 1.3). From these figures we can calculate that the pressure at the stapes should be about 22 times as large as the pressure at the drum. Frank (1923) made some detailed computations concerning this point. More recently van Esser (1947) re-examined the problem.

Work by Backhaus (1928) on condenser microphones led to a technique that makes it possible to observe in detail the vibrations of the various parts of the middle ear. In a Backhaus microphone one plate of a condenser is fixed while the other plate is attached to a vibrating body (e.g. the eardrum). The fixed plate does not come into

contact with the vibrating body. The vibration itself alters the distance between the two plates and produces thereby a change in

ments on very light, soft bodies without modifying the way in which they vibrate. It is even possible to dispense with the condenser plate usually attached to the vibrating body and to reduce the surface of the fixed plate to a diameter of 2 to 3 millimeters. Hence the displacement amplitude of vibrating bodies can be easily measured without interfering with their motion (Békésy, 1941a).

This method was used to determine how the drum vibrates. Figure 9 shows that for a frequency of 2000 cps the drum vibrates like a solid plate pivoted on an axis (upper right corner). In man the drum vibrates with its greatest amplitude near the lower edge. Detailed anatomical investigations have shown that the great mobility of this part of the drum is made possible by the presence of a small fold. The pattern of vibration remains the same for frequencies up to about 2400 cps. At higher frequencies the drum vibrates in segments.

The same method can be used to measure the vibrations of the stapes footplate after the ear has been opened from the cochlear side. It is also possible to measure the pressure transformation of the middle ear by a null method. A known pressure is applied to the drum and balanced by a pressure on the cochlear side of the stapes footplate so that the latter remains motionless. Figure

FIG. 9. Vibration of the human eardrum for a 2000-cycle tone. The closed curves represent contours of equal displacement amplitude on a relative scale. The eardrum moves like a rigid body around the axis of rotation. (Békésy, 1941a.)

the capacity of the condenser. The variable capacitance is used in a circuit to modulate the frequency of a high-frequency signal, and we are thereby able to make measure-

FIG. 10. Pressure transformation in the middle ear. The pressure at the stapes is increased over the pressure at the meatus (and at the drum) by the ratio shown. This pressure transformation helps to match the impedance of the air to the impedance of the cochlea. At the higher frequencies the ratio of transformation between stapes and meatus is enhanced by the resonance of the meatus (cf. Fig. 5). (Békésy, 1941a.)

10 shows the ratio between the pressure that acts upon the stapes footplate and the pressure acting on the drum (the dashed curve shows the ratio of the pressure at the stapes to the pressure at the entrance of the meatus). As can be seen, the average transformation ratio is 15:1. The agreement with the previously calculated transformation

FIG. 11. Response of the malleus handle to a sharp click presented to the ear. The displacements were recorded by means of a light beam reflected from a mirror glued to the handle. It is possible to calculate the natural frequency and the degree of damping from the recorded curve. (Békésy, 1936c.)

ratio could easily be "improved" by using different data for the area of the drum (see, for instance, Stuhlman, 1943, who cites a range of 52 to 90 square millimeters with a mean of 66 square millimeters).

An important datum for the understanding of the functioning of the middle ear is its natural frequency. If a sharp click is produced by means of a spark and the oscillations of the malleus handle are recorded by an oscillograph, we find that the natural frequency lies in the neighborhood of 1300 cps (Fig. 11). There is a good deal of damping in the mechanism of the middle ear, which tends to reduce the distortion of the on-and-off transients of speech waves.

THE MIDDLE EAR AS A PROTECTIVE DEVICE

The structure of the middle ear is rather complicated. One bone, the stapes, would suffice to bring about the appropriate pressure transformation. In birds we find merely this one bone. The presence of three ossicles in mammals is not too easy to understand, and many investigators have been concerned with this problem.*

At first sight it would seem absurd that both the malleus and the incus should be endowed with so much mass (Figs. 12 and 13). But, as Bárány (1938) has pointed out, the symmetrical arrangement of the mass of these ossicles with respect to the axis of rotation contributes to the minimization of bone-conducted sound.

For low frequencies the ligaments are certainly sufficient to keep the axis of rotation

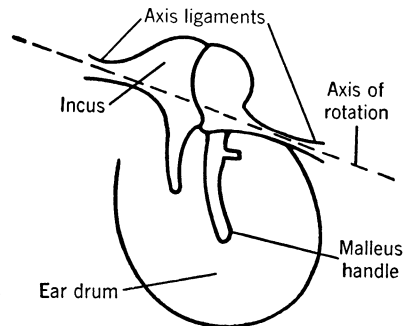

FIG. 12. Arrangement of the ossicles, showing how the mass is distributed around the axis of rotation. As shown in Fig. 9 the maximum displacement of the eardrum occurs at its lower edge. (Bárány, 1938.)

of the ossicles fixed, guaranteeing thereby pressure transformation. At higher frequencies, however, the acceleration forces (which are proportional to the square of the frequency) increase so much that the elastic ligaments tying the ossicles to the membranous wall are no longer able to keep the ossicles precisely in their normal loca-

* For a detailed description of the middle ear, see Fumagalli (1949).

tion. The pivot, however, remains fixed (theorem of the center of mass).

There are also two small muscles in the middle ear. One of them pulls the drum inward in reflex response to an incident sound; the other muscle pulls the stapes out of the

FIG. 13. For lower frequencies the human eardrum is rigid and turns on an axis at its upper rim. A fold on the lower rim permits movement of the rigid eardrum cone. Since the center of gravity is at the point of rotation of the malleus, no bending force acts to deform the eardrum, unless the malleus head is missing. (Békésy, 1941a.)

cochlea. In patients with perforated drums the activity of both muscles is easily observed (Lüscher, 1929). In 1864, Politzer expressed the opinion that the pull exerted by these two muscles reduces the displacement amplitude of the drum. In other words the effect of these muscles is presumably analogous to that of the iris in the eye, in that they protect the cochlea from excessively loud sounds. Many animal experiments (in particular those that make use of cochlear microphonics) support this

view. Under normal circumstances the sound pressure is not reduced as much in man as it is in animals. Kato (1913) showed that the muscles in both ears contract, even if the sound is present in one ear only. Thus it becomes possible to expose one ear to a high-frequency tone and then to examine what happens to the loudness of a low-frequency tone in the other ear. The changes that occur are of the order of 5 to 10 db.

When impedance measurements are used to determine the mobility of the drum in the presence of voluntary muscle contractions, no significant changes in drum mobility are found (Geffcken, 1934).

In any case, the muscles do not seem to offer protection against sharp clicks because their reaction time is about 10 milliseconds, and as war injuries have demonstrated it is during this interval that the damage occurs.

According to Helmholtz there is a mobile joint between the head of the malleus and the incus. This joint loosens up if the malleus vibrates too strongly, and the transmission is reduced. Békésy was, however, unable to observe such a loosening either in fresh post-mortem preparations or during operations on living subjects.

Measurements with very low-frequency tones have shown that there is another effective mechanism at work that protects the inner ear to a certain extent. Beyond a certain point an increase in the sound pressure of a 10-cycle tone does not produce an increase in its loudness. On the contrary, the loudness of the tone decreases suddenly (Békésy, 1936b). When the loudness starts to decrease the subject has a pricking sensation in the middle ear. Closer investigation shows that the whole mode of motion of the ossicles changes at that time, as indicated by Fig. 14. The stapes stops rotating about a vertical axis and no longer presses the fluid into the cochlea. Instead, the stapes footplate turns now about an axis at right angles to the previous axis. This causes the

fluid to flow only from one edge of the footplate to the other. Such an arrangement is a really effective protective device. The complicated structure of the ossicular chain now becomes understandable. We are here in the presence of a mechanical system able

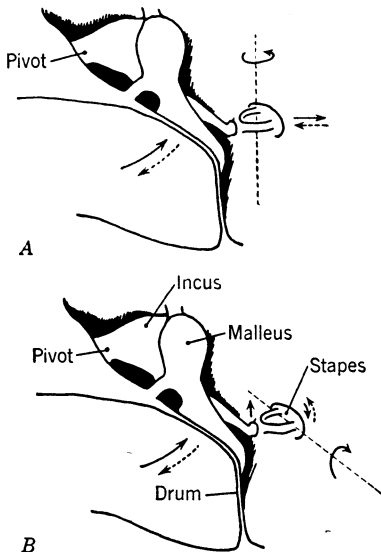

FIG. 14. The two modes of vibration of the stapes. *A.* Rotation of the footplate about a vertical axis through its far edge occurs in response to weak sounds. The fluid is pressed into the scala vestibuli by the motion of the edge of the stapes nearest the reader. *B.* For intensities above the threshold of feeling, the axis of rotation coincides with the longitudinal axis of the footplate, and the actual volume of fluid pressed into the scala is reduced. (Békésy, 1936c.)

to vibrate in two different modes with a sudden transition from one mode to the other for displacement amplitudes greater than a critical value.

NONLINEAR DISTORTION

Hooke's law states that a deformation is proportional to the force producing it. But this law holds only for small deformations, and as the force increases the deformation deviates from the value predicted by the law. This phenomenon, called nonlinearity, is encountered whenever an elastic system

is investigated over any appreciable range of forces. If tones of two frequencies f_1 and f_2 act simultaneously upon a nonlinear system, harmonics ($2f_1$, $3f_1$, etc.; also $2f_2$, $3f_2$, etc.), difference tones ($f_1 - f_2$, $2f_1 - f_2$, etc.) and summation tones ($f_1 + f_2$, $2f_1 + f_2$, etc.) will make their appearance. Nonlinearity thus gives rise to frequencies previously not present in the stimulus. If the system is one-dimensional and deviates from Hooke's law in a known manner, the amplitudes of the difference and summation tones are related in a lawful manner to the amplitudes of the harmonics (cf. Fig. 27 in Chapter 25).

The ear is apparently not so simple a system, however. Let us consider, for instance, the semihypothetical case of an eardrum connected to a single ossicle. If the eardrum is under negative pressure, so that the eardrum and the ossicle are pulled outward, the system has only one degree of freedom. For a positive pressure, however, the ossicle is in an unstable equilibrium, and it can tilt in various directions so that it has at least three degrees of freedom. The eardrum moving in from left to right tilts the ossicle upward from the middle position. With the movement of the eardrum out to the left, the ossicle comes back to the midline. The next inward movement of the eardrum causes the ossicle to move downward because its kinetic energy carries it through the middle position. Therefore it is evident that, during a full period of the eardrum, the ossicle makes an excursion to only one side. It moves with the half frequency of the eardrum (this gives rise to what are called undertones).

Such a system, having three degrees of freedom, cannot be represented by a single characteristic function describing the relation between input and output, and it is not possible to use the relation among harmonics and difference tones to determine the shape of the input-output function.

Nevertheless the appearance of "new" tones can still be used to determine whether

nonlinearity is present in the ear and what type of nonlinearity we are dealing with. If two tones ($f_1 = 2000$ cps, and $f_2 = 2260$ cps) are presented to the ear, a tone corresponding to $f_1 - f_2 = 260$ cps can be heard and clearly distinguished from the two primary tones. (For some frequencies the loudness of the difference tone may equal the loudness of the primary tones.) We can make it easier to detect the difference tone if a search tone of frequency, $f_3 = 261$ cps, is added. This results, of course, in beats between the difference tone and the newly added tone of 261 cps. We must bear in mind, however, that the introduction of a search tone gives rise to new distortion products.

Once the existence of nonlinear distortions in the ear has been established, the question arises: where are they generated? Possibilities of mechanical nonlinearity exist in the drum, in the ossicular joints and ligaments, in the cochlear fluid, and in the cochlear partition.

Is the drum the source of difference tones? This question can be decided in the following manner: two intense tones are presented to the ear, at about 20 db below the threshold of feeling. A very strong difference tone is heard. If this difference tone owes its existence to distortion in the drum, it should be radiated from both sides of the drum and be detectable in the external meatus. Experiments of this kind (Békésy, 1934) led to the conclusion that the difference tones we hear when the primary tones are about 20 db below the threshold of feeling are not generated by the drum. The same negative conclusion applies to the generation of harmonics by the drum.

If we assume that the difference tones originate in the middle ear, their intensity should change when the ossicles are displaced from their normal position (such a displacement would cause the ossicles to vibrate in a mode other than their normal mode). This displacement can be accomplished if a pressure

is exerted upon the drum at the same time as a tone is presented.

As shown in Fig. 15, the greatest change in the loudness of difference tones occurs during the time interval in which there is a change in the added pressure, i.e. while the ossicles are being displaced from their normal position. It would therefore appear that

FIG. 15. If the pressure in the meatus is increased by the equivalent of 6 centimeters of water, the changes in the loudness of three primary tones are not striking, but the loudness of the 260-cycle difference tone (2260 minus 2000 cps) increases considerably while the pressure is changing. (Békésy, 1934.)

the origin of difference tones is to be sought in the nonlinearity of the middle ear, at least part of which may be due to the ligaments holding the ossicles in place. It is most probable that these distortion phenomena are in particular related to the vibrations of the stapes footplate.

The origin of the harmonics cannot be localized in this same manner. Application of a unidirectional pressure does not influence their loudness to the same extent.

It seems at present difficult to determine the exact part played by rectification phenomena inside the cochlea in the production of nonlinear distortions. This rectification

is probably achieved by means of eddies in the vicinity of the stapes footplate and also further along the cochlear partition.

It seems very surprising that the drum does not give rise to observable nonlinear distortions, for we might expect it to on the basis of its anatomical structure. In particular, we should expect a funnel-shaped membrane to exhibit more distortion than a flat membrane (Fig. 16). On the other

FIG. 16. Vibration of flat and conical membranes (schematic). The flat membrane is deformed symmetrically by positive and negative pressures. The eardrum is like a conical membrane. Positive and negative pressures produce different deformation patterns, thus giving rise to nonlinear distortion. (Békésy, 1939a.)

hand, the actual drum displacements are determined principally by the elastic properties of the volume of air in the middle ear (which acts like an air cushion) and not by its own elastic properties. Since in the human ear the stiffness of the air cushion exceeds that of the membrane (Békésy, 1936a) the nonlinearity of the drum itself is not an appreciable factor. (This same principle of "cushioning" is made use of in the condenser microphone, where a thin aluminum foil is given great stiffness without being put under tension.)

The situation changes if relatively large pressures are exerted upon the drum. Kobrak (1949) has studied the effects of such pressures by measuring the displacements of the round-window membrane for various static pressures in the external meatus.

Figure 17 shows the lack of proportionality between pressure and displacements; it also points up the fact that the displacements are different for positive and negative pressures.

For large alternating pressures the presence of harmonics can be easily detected, especially at low frequencies. Figure 18 shows the waveform present in the meatus for a tone of 20 cps at a pressure of 10^4 dynes per square centimeter (approximately 154-db sound-pressure level). This considerable amount of nonlinear distortion is due to the fact that the ossicles now vibrate in their second stable mode (see Fig. 14). Stuhlman's enlarged model of the ossicles (1937, 1943) permitted him to investigate in detail the nonlinearities that arise when the

FIG. 17. The effects on the round window of static pressures in the ear canal of a fresh human cadaver. Note the asymmetry of the displacements: negative phases of pressure in the external auditory canal produce greater displacements than positive phases. (Kobrak, 1949.)

ossicles undergo rotational motion of appreciable amplitude.

A question of particular interest is whether nonlinear phenomena can be demonstrated in the vibration of the cochlear partition. Actual measurements (Fig. 19) show that the movement of the basilar membrane is not a linear function of the movement of the stapes when the amplitude is

above the threshold of feeling. This non-linearity is not present, however, at sound intensities below the threshold of feeling.

FIG. 18. Waveform generated in the meatus by a tone of 20 cps at a sound-pressure level of 154 db. The upper curve represents the stimulus, and the lower curve shows the waveform, containing a large third harmonic, reradiated from the drum. Part of the fundamental was canceled out in order better to display the distortion. (Békésy, 1936a.)

Among other things the linearity of the movement of the cochlear partition under the impact of moderate sound intensities

FIG. 19. Amplitude of vibration of the basilar membrane as a function of the amplitude of the stapes. At values far above the threshold of feeling the movement of the basilar membrane ceases to be proportional to the movement of the stapes. (Békésy, 1947.)

rules out nonlinearity as an explanation of the fact that pitch is observed to change with intensity.

THE INNER EAR: HYPOTHESES AND THEORIES

Does the cochlea perform a mechanical frequency analysis so as to translate differ-

FIG. 20. Models representing fluid motion in cochlea. The series of U-shaped tubes (top figure) are filled with fluid up to the level OO' and form resonating systems one of which responds preferentially to an alternating air pressure in channel AB . The system is thus capable of frequency analysis. In the middle figure the tubes have now been collapsed into a single vessel with several openings; gravity still provides the restoring force in this frequency-analyzing system. In the cochlea (bottom figure), the mass of the resonating system is given by the thread of fluid ABC ; and the restoring force comes from the elastic membrane. (After Lux, Budde, and Wilkinson.)

ent tones into different "spatial" stimuli for the nervous system? Helmholtz, in 1863, assumed the presence of a series of reso-

nators in the ear, each tuned to a different frequency, and he thought he was able to explain Ohm's acoustic law according to

there must be present a membrane characterized by a much larger tension crosswise than in the longitudinal direction.

In the absence of anatomical evidence for such a piano-chord structure of the cochlear partition, Lux developed his hypothesis (described by Budde in 1917) according to which there is a series of U-shaped threads of liquid in the cochlea. All these threads

FIG. 21. Ewald's camera acustica designed to reproduce the vibrations of the cochlear partition, represented by a thin rubber membrane fastened in the frame *e*, contained in a water-filled box. The opening *d* represents the round window. The sound enters through the opening *f* (the oval window) and sets the rubber membrane into vibration, which brings about changes in the reflection pattern observed through a microscope *m*. (Ewald, 1903.)

FIG. 23. The deformation patterns of the basilar membrane for one complete cycle of a 1000-cycle tone. The instantaneous patterns of the membrane are for intervals separated by $\frac{1}{8}$ of a period. Each wave of vibration passes along the membrane away from the oval window. For 1000 cps the amplitude of vibration is greatest at a location 16 millimeters from the oval window. (After Fletcher, 1930.)

FIG. 22. Typical standing wave patterns observed by Ewald are different for different frequencies. The distance between nodes of the standing waves decreases as the frequency increases. (Ewald, posthumously published.)

which the ear tends to hear the individual components of a complex sound, regardless of their phase relations. The search for these resonators ran, however, into certain difficulties. According to Helmholtz the cochlear partition has what might be called a "piano-chord" structure. This means that

represent resonant systems: the fluid in the thread furnishes the mass, and the elastic cochlear membrane furnishes the elasticity. Figure 20 shows the transition from this system of U-tubes, in which gravity supplies the restoring force, to the cochlea, where

the restoring force is the cochlear membrane. Roaf (1922) and Wilkinson (1922) carried this theory further.

We could also have started, however, from an entirely different conception. The cochlear scalae are essentially elastic tubes since they are bounded on one side by the elastic

gated along the membrane. Reflection from the far end of the membrane will then give rise to standing waves, with a different standing wave pattern for each frequency. Ewald (1899, 1903) built a detailed theory along this line. He demonstrated his patterns by experiments with models (Figs. 21 and 22).

FIG. 24. Deformation of the basilar membrane, according to Ranke. This figure should be compared with Fig. 23. The four different patterns are separated by $\frac{1}{8}$ of a period. The envelope shows the maximum amplitude obtained at each point. The wave travels from the stapes to the helicotrema, pushing the fluid ahead of the wave front. This gives rise to eddy formation as indicated by the arrows. (Ranke, 1942.)

cochlear partition. Then by analogy with the concepts that have proved useful in work on blood vessels, we can assume that an inward motion of the stapes will give rise to a traveling wave along the cochlear partition. Hurst (1895), Bonnier (1895), and ter Kuile (1900) constructed theories along these lines. They assumed appropriate values for the damping and the wavelength of these traveling waves so as to obtain different loci of maximum displacement on the cochlear partition for different frequencies. It is also possible to assume that the number of waves simultaneously present along the partition is large, and that there is not much damping as they are propa-

If still other assumptions are made concerning the elastic properties of the cochlea, the forms of vibration depicted in Figs. 23 and 24 can be deduced.

In the extreme we could consider the cochlear partition as being very stiff. The wavelength then becomes so large that the entire partition will vibrate in phase in the manner of a telephone diaphragm (Rutherford, 1886).

Wever and Bray (1930) examined the possibilities of combining resonance and frequency theories.*

* Since this chapter was written, Wever (1949) has given a detailed account of his resonance-volley theory.

Measurement of mechanical properties. The various mechanical theories of hearing differ from one another at essentially one point: each of them assumes different values for the elastic properties of the cochlea. The actual measurement of these mechanical characteristics constitutes, therefore, a stepping stone to further progress.

Ewald (1914) was the first who tried to observe the vibrations of the basilar membrane itself. However, his short account of the work does not allow one to draw any conclusions.

When we try to measure the properties of the cochlea, the first question is whether the measurements have to be made in a living animal or whether a post-mortem preparation will suffice. Hence the first step in such an investigation is to determine how the elastic properties of tissues vary post mortem. The eardrum is a very thin membrane and is easily accessible to measurement. The following experiment was therefore performed: The middle ear of a living cat was opened up, and the displacements of the drum for certain sound pressures were measured. After death, observations were made to determine whether there had been any changes. It was possible to show that the drum's mobility can be kept the same throughout several days, provided the ear is kept in a moist chamber. (The elastic properties are definitely affected by the drying-out process.) The preparations were maintained at a temperature of approximately 5 degrees C.

The elasticity of the cochlear partition also remains unchanged for 2 or 3 days, compared with its value 1 hour after the death of the animal. Precautions must of course be taken; i.e. all preparations have to be kept cool, in physiological saline solution, with air excluded. The salt solutions have to be degassed beforehand. Otherwise gas bubbles of microscopic size may form inside the cochlea and hamper the motion of the liquid. Since the elastic properties remained apparently constant for at least 1 day, it ap-

peared possible to measure the properties of the human cochlea during the first hours after death.

In order to make it possible to prepare human cochleas quickly, a special micro-anatomical technique was developed (Békésy, 1941b). The whole procedure takes place

FIG. 25. Setup for the measurement of the amplitude of vibrations of the cochlear partition for known volume displacements of an artificial stapes. The cochlea is mounted under water in plaster and is opened at the apex. A small metal tube *R* is fastened in place of the stapes and covered with a rubber membrane that is driven with a known amplitude by an electrodynamic unit. With a water immersion microscope and stroboscopic illumination it is possible to observe the vibrations of silver crystals dropped on the cochlear partition. (Békésy, 1943.)

under water. The bony parts are removed by means of a dental burr and then carried away by flowing water. It is relatively easy to distinguish the cochlear canal since the bone changes color in the vicinity of the canal. The finer structures are then examined by means of a water-immersion microscope with magnifications ranging from 30 to 70.

The whole setup is portrayed in Fig. 25. After the cochlea has been removed from the skull by means of a cylindrical drill, it is imbedded in gypsum. The place of the stapes is taken by a tube with a small piston

in it; and this piston can be driven electro-dynamically in a measureable way. Thus the experimenter can measure displacements of the cochlear partition that correspond to a given displacement of the stapes. In preliminary experimentation the maximum permissible size of the openings was determined. Their presence did not give rise to a modification in the pattern of vibration.

PROPERTIES OF THE COCHLEAR PARTITION

The cochlear partition is made of an almost completely transparent jellylike substance. It tears when touched only lightly. Berendes (1934) was the first experimenter who tried to determine its elastic properties.

Elastic properties. The following procedure may be chosen for such an investigation. If a short hair is cemented to a handle and used to exert a pressure upon a surface up to the point at which the hair bends, a certain maximum pressure is produced. A known pressure of a few milligrams produces a certain deformation of the underlying tissue, which permits a determination of the elastic properties of the tissue.

Observations with these hairs show that, near the helicotrema where the basilar membrane is broad, the area of deformation is circular, even when the pressure is not exerted at the center of the membrane. Near the stapes, the deformed area is generally elliptical with the major axis parallel to the longitudinal axis of the cochlear canal. The ratio of the major and minor axes of the ellipse is 2:1, at most. Very thin hairs must be used here, so that the deformed area will remain small compared with the width of the membrane. A microscopic enlargement of about 30 \times is most suitable.

It follows that the most flexible part of the cochlear partition displays essentially the same elastic properties in the longitudinal and in the transverse directions. This independence of direction in elastic properties of the basilar membrane is partly due to the

existence, in addition to the known radial fibers, of a layer lying upon the basilar membrane (the tympanic covering layer) whose fibers extend longitudinally along the membrane. As W. Roux (1895) has demonstrated, such sets of fibers at right angles to each other occur very often in nature as, for example, in the eardrum.

FIG. 26. Deformation patterns in membranes. A shows a uniformly stretched, thin, elastic membrane. Note the fairly steep gradient near the point at which pressure is applied. B shows the basilar membrane near the helicotrema when the same pressure is applied. The difference between these two patterns shows that the basilar membrane is not like a thin, stretched membrane. (Békésy, 1941b.)

If the hair probe is used not on the basilar membrane but near the bony edge of the cochlear partition, a considerable section of this zone, up to $\frac{1}{8}$ of a turn, is displaced simultaneously. At the same time, the basilar membrane is also bent for the same large distance. Therefore the cochlear partition possesses near its bony edge considerable rigidity in the longitudinal direction.

If a rod is pushed into a stretched membrane under uniform tension, the area of deformation that results is illustrated in Fig. 26A. Displacement of the membrane increases sharply near the point of pressure. Nothing of the kind is observed in the case

of the basilar membrane (Fig. 26B), where the deformed area is much the same as that produced when a pencil point is pressed into the skin.

The basilar membrane, therefore, does not seem to be a membrane under tension, for a large part of its elasticity, when deformed, arises in some other way. The question is whether the basilar membrane at rest exhibits any tension at all.

as free from tension when there was no effective external stimulation.

Had the theory of hearing not started with the notion of a vibrating piano string, the basilar membrane might never have been regarded as under lasting tension at all.

The fine structure of the various parts of the cochlear partition can be examined by the method of pressure deformation patterns. In Fig. 27 the upper portions of the draw-

FIG. 27. Relative stiffness of different membranes belonging to the cochlear partition. The upper parts of the figures show schematic cross sections through the cochlear partition at different distances (10, 20, and 30 millimeters) from the stapes. Below is shown the elasticity for each of the structures as a function of distance across the cochlear section.

Both the tectorial and basilar membranes vary in stiffness across the cochlear partition. The basilar membrane alone shows a large variation in elastic properties as one proceeds from the stapes to the helicotrema. (Békésy, 1947.)

When a slit is cut in any elastic material or tissue that is under tension, the cut edges gape apart in a lens-shaped opening. But, when very fine cuts are made in the basilar membrane, transversely or longitudinally, the cut surfaces cannot be observed to draw apart.

These observations indicate that the basilar membrane is apparently not under tension and that it can best be likened to a gelatinous sheet covered by a thin, homogeneous layer of fibers. The complete lack of tension in the cochlear partition would appear to be important physiologically, inasmuch as the inner structure of the cochlea may, as a consequence, be treated as analogous to the other parts of the labyrinth where the tissues have always been regarded

as free from tension when there was no effective external stimulation. The upper parts of the figures show schematic cross sections of the cochlear partition of man at positions 30, 20, and 10 millimeters from the stapes. The lower part of each figure presents the depth of impression, expressed in centimeters per dyne, for the positions across the membranes corresponding to the section shown immediately above. A comparison of the three figures shows that Reissner's membrane has the same elasticity throughout its entire length.

If Reissner's membrane is removed and the material within the cochlear duct is washed away, the elastic properties of the tectorial membrane can be investigated in the same way. As has been previously indicated, all measurements must be carried out in a physiological saline solution in order to avoid

the effects of drying and of capillary forces. The values obtained for the tectorial membrane show that its stiffness is not great and that it increases only slightly in the neighborhood of the stapes. This membrane is noteworthy for the ease with which it may be moved in a direction perpendicular to the basilar membrane. Together with its supporting structure it represents essentially a flat, delicate, very thin-walled tube filled with liquid, which can be rotated about the edge that is attached to the bony shelf of the cochlear partition. The decrease in elasticity at the end near the stapes is a result principally of its narrow breadth.

The values for the elasticity of the organ of Corti (including the hair cells) indicate no dependence whatsoever on location. On the other hand, it can be seen that there are marked differences in the stiffness of the basilar membrane from one position to another. These changes in the basilar membrane produce a continuous change in the volume elasticity along the cochlear partition. These measurements show that it is not the tectorial membrane but, as Hensen and Helmholtz have argued, the basilar membrane that determines the movement of the cochlear partition and the location of the point of maximum vibration.

Except for the tectorial membrane, all the surfaces investigated show circular symmetry in the depressions produced by the test hair. The surface of the tectoria presents a much elongated hollow (Fig. 28). It must therefore be concluded that the tectorial membrane exhibits different elasticities in different directions. In some directions it possesses a substantial stiffness. This may also be recognized from the fact that upon tearing it away from its attachment a considerable segment comes off, whereas the other membranes may be removed in quite small sections.

Microscopic observations of the various parts of the cochlear partition show that they tend to move together. As Fig. 27 indicates, there are relative displacements of

these structures, but as a first approximation we may assume that they all move with the same phase. If one then wants to assess the combined elastic properties of the cochlear partition it becomes necessary to determine the volume displacements for a given pressure difference across the partition. Figure 29 shows how many cubic centimeters of liquid are displaced by a section of the cochlear partition 1 millimeter long for a pressure difference across it equivalent to

FIG. 28. Depression patterns at the surface of the tectorial membrane. The only noncircular patterns observed are found at the surface of the tectoria. The contour lines indicate equal amounts of depression. (Békésy, 1947.)

1 centimeter of water. As we can see, the volume displacement at the widest part of the cochlear partition is 200 times the volume displacement at a point 3 millimeters from the stapes.

Since the cochlear partition is bony at the inner edge and soft at the outer edge, the greatest displacements of the partition occur at the outer edge of the cochlea (see Fig. 2).

Vibration pattern. Before describing how the volume displacements in the liquid produced by the stapes vibrations affect the various sections of the cochlear partition, let us determine the transfer characteristic of the entire cochlea as a function of frequency. Figure 30 shows the ratio of the volume displacement of the round window to the sound pressure at the eardrum. The transmission is fairly constant up to 4000 cps. The lower curve in Fig. 30 shows that the structures between the drum and the round window behave like a spring for frequencies below 500 cps, whereas above

FIG. 29. Overall elastic properties of the cochlear partition. The ordinate scales indicate the volume displaced by a segment of the cochlear partition 1 millimeter long, and also the depth of the bulge, for a difference of pressure across the cochlear partition equivalent to 1 centimeter of water. (Békésy, 1941b.)

FIG. 30. Overall transfer characteristics of the mechanical structures between the eardrum and the round-window membrane. The upper curve shows the displacements of the round-window membrane for a given sound pressure at the eardrum. The crosshatched area indicates the range of dispersion of the data for ten temporal bones. The lower curve represents the phase angle between the displacement and the applied pressure. At low frequencies the displacement has the same phase as the pressure, and the mechanical structure behaves as a spring whose elastic forces come from the ligaments attached to the stapes footplate and the round window. (Békésy, 1942.)

FIG. 31. Resonance curves for six points on the cochlear partition. The solid curves are measured values (Békésy, 1943); the dashed curves are theoretical values calculated by Zwislocki (1948).

1000 cps frictional forces determine the excursions of the round-window membrane.

If the stapes is vibrating sinusoidally with constant amplitude and if the displacements of various points along the cochlear partition are examined under the microscope as a function of frequency, the curves of Fig. 31 are obtained for human ears. We can see quite clearly that each different point on the membrane undergoes its maximum displacement for a particular frequency. And the behavior of the point as a function of frequency resembles a resonance curve.

If we now cut windows into the human cochlea at appropriate places, the vibration pattern of the entire partition can be determined for selected frequencies. Figure 32 shows the results obtained. It is obvious that the maximum response is displaced towards the stapes as the frequency increases. A number of experiments were carried out in order to verify that the windows made in the cochlea had no influence upon the locus of this maximum. If we plot the distance from the stapes of the point of maximum displacement versus frequency, the curve obtained has the general form of the curves that can be inferred from psychophysiological data (Fig. 33). Many measurements have shown that there is little variability in the curves one obtains from different subjects. The structure of the cochlea shows great stability in this respect, in marked contrast to the elastic properties of certain parts of the middle ear, for instance.

It was also possible to measure the phase difference between the movement of the stapes and the movement of the membrane. From these data and from the data on displacement amplitudes the deformation pattern of the membrane can be determined.

It is necessary first to determine the amplitude of vibration at a given place along the partition for various frequencies, and then, in a second series of measurements, to measure for each frequency the phase difference between the movement of the stapes and that of the observed point. By combining the

two series of measurements, the displacement (deformation) of the cochlear partition can be determined for the various vibratory states.

Since the cochlear partition cannot be loaded with a measuring instrument because

FIG. 32. Displacement amplitudes along the cochlear partition for different frequencies. The stapes was driven at a constant amplitude and the amplitude of vibration of the cochlear partition was measured. The maximum displacement amplitude moves toward the stapes as the frequency is increased. (Békésy, 1943.)

of its delicacy, an optical method of measuring phase is the most useful. Further, since the entire cochlear partition in fresh condition is almost transparent, very small crystals of silver were strewn over it to improve its visibility. Stroboscopic observation shows that these flat crystals follow the movement of the partition quite exactly up to 4000 cps, the highest frequency that was investigated. With the proper illumination on the partition one sees a large number of bright, shiny

dots, which spread out into a band when the basilar membrane is in vibration. In order to carry out the measurement accurately, the crystals of silver were made so small that even when enlarged more than 100 times they appeared as quite sharp dots.

zero. The measurement of phase is therefore particularly suited to test the degree to which the cochlea resembles a simple resonant system.

When the phase relations in the movement of the cochlear partition are observed, it can

FIG. 33. Position of maximum vibration of the cochlear partition as observed in ears and in models (Békésy, 1942). The curve relating pitch to frequency (Stevens and Volkman, 1940) is drawn for comparison. The form of this curve is in agreement with "maps" of the basilar membrane derived from several sources: (1) position of maximal electrical activity (Culler et al., 1943); (2) impairment of cochlear microphonic by localized lesions (Stevens, Davis, and Lurie, 1935); (3) degeneration in human cochleas associated with deafness (Crowe, Guild, and Polvogt, 1934); (4) integration of pitch jnd's (Stevens, Davis, and Lurie, 1935); (5) width of critical band in masking (Fletcher, 1940); (6) contribution of various frequencies to total loudness (Fletcher); (7) contribution of various frequencies to speech intelligibility (French and Steinberg, 1947).

The phase relations in the movements of the cochlear partition possess a significant theoretical interest. If we trace, for a given position along the cochlear partition, how the amplitude changes with frequency, a curve is obtained that resembles a resonance curve. Such measurements seem to support the notion of an aural resonator. In a simple resonant system like a pendulum or an inductive-capacitive circuit, however, the phase angle must change from $\pi/2$ through zero to $-\pi/2$, as the driving frequency is changed continuously. Furthermore at the point of resonance the phase angle will be

be determined first of all that there are, as stated previously, no microscopically observable phase differences among the movements of the basilar membrane, the organ of Corti and the tectorial membrane. In a fresh preparation, Reissner's membrane also vibrates in phase with the other parts of the partition. At the higher frequencies it may happen that Reissner's membrane does not undergo a simple movement; rather, it may vibrate in sections.

In Fig. 34 is presented the amplitude of vibration for a point along the cochlear partition 30 millimeters from the stapes. The

amplitude of vibration is shown in the dashed line as a function of frequency when the stapes undergoes movement of constant amplitude. The form of the curve shown is similar to a resonance curve. The solid line

made, and it can be seen that their wavelength decreases as the frequency increases.

The distribution along the cochlear partition of displacement amplitude and phase angle are shown for various frequencies in Fig. 35. Below 50 cps the movement of the entire cochlear partition is practically in phase; above 150 cps the traveling wave can be demonstrated. The measurements are quite reproducible in a given cochlea.

The curve for 200 cps in Fig. 35 was used to calculate the detailed form of vibration of the cochlear partition for two different instants in time corresponding to a separation by a phase angle of 90 degrees. The two curves that result are shown in Fig. 36. The measured values compare favorably with those calculated by Ranke (cf. Fig. 24).

Transient response. The Helmholtz resonance theory has stimulated discussion of a controversial problem, namely, the time constant of the so-called resonators in the ear. Many authors have been concerned with this question: Waetzmann (1912, 1922), Meyer and Waetzmann (1925), Hartridge (1921), Hallpike and Rawdon Smith (1934), Hunt (1942) and Pumphrey and Gold (1947, 1948). The difficulties that have arisen are

FIG. 34. Resonance curve and phase displacement for a position along the cochlear partition 30 millimeters from the stapes. The phase angle is relative to the movement of the stapes. Its variation from 0 to 3π indicates that we are not concerned with a simple resonating system but with some kind of traveling waves. (Békésy, 1947.)

in this same figure presents measurements of the difference in phase angle between the movement of the stapes and that of the point on the basilar membrane. The phase angle changes, as the resonance curve is traversed, from $\phi = 0$ to $\phi = 3\pi$. These facts, taken together, indicate clearly that we are not dealing with a simple resonance, but with some sort of traveling waves. These waves pass the point at which observations are

FIG. 35. Amplitude and phase angle of the cochlear partition at various distances from the stapes. For frequencies above 100 cps the difference in phase may exceed π . At 50 cps the membrane vibrates in phase. (Békésy, 1947.)

due largely to the fact that we are dealing with "time constants" obtained by various techniques of measurement: physical, physiological, and psychological. All these different time constants may be presumed to be involved in an auditory sensation. But the fact that they are really different phenomena

the stapes to the helicotrema, and during this time interval there will be stimulation of the nerve endings, provided the wave has not spent too much of its energy.

In order to measure the transient response of the cochlear partition the cochlear liquid is set into vibration and the transients on

FIG. 36. Traveling wave along the cochlear partition for a 200-cycle tone. The solid line indicates the deformation pattern at a given instant. The line with the short dashes shows the same traveling wave $\frac{1}{4}$ of a period later. The envelope shows the maximum displacement at each point. Compare this figure with Fig. 24 calculated by Ranke. (Békésy, 1947.)

warns us to proceed cautiously when we examine the conclusions that have been drawn.

We are concerned here only with the mechanical contributions to this composite time constant. They are essentially two:

the cochlear partition are then observed directly. This experiment can be carried out by again scattering small silver crystals on the partition, illuminating them so that they stand out as very brilliant points, and then observing them, through a moving micro-

FIG. 37. Decay process in the displacement amplitude of a point of the cochlear partition 30.5 millimeters from the stapes. (Békésy, 1943.)

(1) one arising in the middle ear, which contributes a damped transient close to its own natural frequency (around 1500 cps), and (2) one constituting a damped traveling wave along the cochlear partition, initiated whenever there is displacement. This wave takes a certain length of time to get from

scope, at a point where a given frequency will produce maximum displacement amplitude. The microscope is made to move at right angles to the direction of the displacement so that the displacements appear spread out, as in Fig. 37. This figure shows the decay curve obtained when the vibra-

tion of the stapes footplate is brought to a sudden halt. The values for the decrement agree satisfactorily with values calculated from Fig. 31. This confirms that the inner ear, as a mechanical system, is less than critically damped. Hence it can act as a frequency-analyzing system.

Traveling waves along the cochlear partition. Let the stapes be set into sinusoidal vibration, and let us observe microscopically the vibrations of a sizable section of the cochlear partition under stroboscopic illumination. We then get the impression that the section of the cochlear partition in the immediate vicinity of the stapes is vibrating in the same phase as the stapes. In the vicinity of the region of maximum displacement amplitude we observe traveling waves propagated toward the helicotrema. These waves are so damped that after one or two cycles they are no longer visible. But we can see them clearly enough to detect that the wavelength decreases markedly as they proceed toward the helicotrema. This situation is quite understandable if we remember that near the stapes the stiffness of the partition is relatively great, and that it decreases toward the apical end. The velocity of propagation is much greater for a stiff partition than for a soft one; the decrease in the wave velocity is responsible for the decrease in wavelength [λ (wavelength) = c (wave velocity)/ ν (frequency)].

In 1933 Békésy established the existence of this travel time by a subjective method. He exposed one ear to a low-frequency tone and the other ear to a high-frequency tone, so as to desensitize the section of the partition close to the helicotrema in one ear and close to the stapes in the other ear. When both ears were then exposed simultaneously to a click, the difference in travel time along the partition led the observers to judge the clicks as "localized" to one side instead of in the median plane.

In order to measure travel times objectively, a small mirror was put on the cochlear partition, the stapes was set into motion,

and the time difference between the onsets of the vibrations of the stapes and of the partition was recorded by means of an oscillograph. An electric spark was used to ini-

FIG. 38. Propagation times along the cochlear partition. When the stapes is suddenly displaced, a bulge travels along the partition toward the helicotrema. The time intervals plotted are those between the onset of the motion of the stapes and the first detectable displacement at a given point along the partition. The propagation velocity near the stapes is high and is much reduced near the helicotrema. (Békésy, 1943.)

tiate the sudden pressure change with the correct amount of energy.

In Fig. 38 we find plotted the propagation time of the traveling wave. On the abscissa both the distance from the stapes and the

FIG. 39. A sudden displacement of the stapes gives rise to a traveling bulge along the cochlear partition. The dashed line indicates the position of the bulge at a later time. The bulge pushes fluid ahead along the surface of the partition. The bulge disappears at the helicotrema and the fluid flows back to its original position, creating eddies (dotted ellipses). (Békésy, 1933.)

equivalent frequency (taken from the solid curve of Fig. 33) are indicated. The ordinate represents the travel time. As can be seen, it takes the wave about 5 milliseconds to reach the helicotrema.

Figure 39 gives a schematic representation of the way the partition is deformed when there is a sudden short outward movement of the stapes. In a brief interval of time the wave progresses from the position shown by the solid line to that shown by the dashed

increase in length of the basilar membrane, or whether there is an improvement with increase in length. It would be particularly interesting to know whether increased length corresponds only to an extension of the auditory range, so as to include lower and higher

FIG. 40. The membranous labyrinth of (A) turtle, (B) bird, and (C) mammal. The vestibular organ is fully developed in fish, and there has been no further evolution in higher animals. The dotted ellipses represent the otoliths. In higher animals the length of the basilar membrane shows a decided increase as we go from the turtle to the mammal. (Békésy, 1944.)

line. If there are repeated displacements of the stapes to the right and the left, there is an eddy formation in the liquid channel, as shown by the lighter dashed lines in Fig. 39.

frequencies, or whether there is an increase in the resolving power of the ear.

This problem was attacked by the same direct microscopic observation previously

FREQUENCY ANALYSIS

Analysis in the cochleas of various animals. Figure 40 shows the membranous labyrinth of a turtle (A), a bird (B), and a mammal (C). The three semicircular canals are clearly visible. The dotted ellipses indicate the otoliths. The short lines represent the auditory nerve endings along the basilar membrane.

When we compare these three steps in the evolution of the membranous labyrinth, we are struck by the apparent invariance of the semicircular canals, in contrast to a decided increase in the length of the basilar membrane. This increase in length pushes the lowest otolith to the end of a tube (in the bird), until it finally vanishes in the labyrinth of mammals.

The question then arises, to what extent improved hearing ability is related to the

FIG. 41. Projection of the mouse cochlea upon a horizontal plane. The numbers on the curve give distances from the stapes in millimeters. (Békésy, 1944.)

used in man. Fortunately we find that the dimensions of the cochlea do not vary nearly as much from animal to animal as do the body dimensions. Figure 41 shows a map of the cochlea of the mouse, and Fig. 42

gives a map of the cochlea of an elephant. In both cases the projection is in the direction of the axis of the cochlea. The cochlear diameters are in a ratio of 1:7.

For the elephant a change in frequency from 30 to 40 cps produces a shift in the position of the maximum displacement am-

FIG. 42. Projection of the elephant cochlea upon a horizontal plane. The numbers give distances from the stapes in millimeters. (Békésy, 1944.)

plitude (Fig. 43). For the mouse this lower limit lies at 400 cps. For frequencies lower than 400 cps the entire cochlear partition of the mouse vibrates in phase.

If the curves of displacement amplitude for different frequencies are plotted along the cochlear partitions of various animals in the manner of Fig. 32, the curves look very much alike for all animals, except that those for the elephant are more pointed. We can therefore use the shift of the point of maximum response along the partition (Δl) for a given ratio of frequency change ($\Delta n/n$) as a measure of the mechanical frequency analysis. This mechanical resolving power

$$\frac{\Delta l}{\frac{\Delta n}{n}} = \text{MRP}$$

has been plotted in Fig. 44. As we would expect, the hen possesses the least developed cochlea. In general we can say that the mechanical resolving power increases with the size of the animal. Also, for the higher frequencies this resolving power is practically independent of frequency in most animals. The one exception is the human ear, where the resolving power shows an abrupt change between 500 and 1000 cps. This fact is possibly related to the findings in articulation tests, that the speech sounds below 300 cps are relatively unimportant.

The lower frequency limit for mechanical frequency discrimination has been chosen as

FIG. 43. Locus of maximum displacement amplitude for various frequencies in the elephant. Compare with Fig. 33. (Békésy, 1944.)

the point at which there is no shift in the pattern when the frequency is further decreased.

Figure 44 shows clearly how this lower frequency limit is shifted downward as the animals increase in size. These shifts are not due so much to changes in elastic constants (since practically all the animals examined show the same range of variation of volume

elasticity, namely, from 10^{-9} to 10^{-5} cubic centimeter) as to the effective mass that loads the cochlear partition.

The wisdom of nature is evident in all this, because it is certainly important for large animals to hear over great distances. If the sound is propagated along the ground, the absorption will in general affect low-frequency sounds less than high-frequency

The preceding pages contain most of the data necessary to build an uncoiled model of a cochlea having approximately the correct characteristics. Such a model (Fig. 45) shows satisfactory agreement with the actual situation. (The uncoiling of the cochlea seemingly does not influence the vibration along the membrane.) The model is made essentially of three microscope slides, two

FIG. 44. Mechanical resolving power in the cochlea of man and various animals. The mechanical resolving power is here defined as the shift of the locus of maximum response for a given relative shift in frequency. (Békésy, 1944.)

sounds. Hence the usefulness of favoring the low frequencies.

Frequency analysis in cochlear models. Ear models have been used on several occasions (Ewald, 1914; Wilkinson, 1922; Meyer, 1928) in order to investigate the vibration pattern inside the cochlea. These experiments were, however, based on rather arbitrary assumptions; since most of the relevant mechanical data were unknown at the time. But when use is made of the hydrodynamical laws of similitude—a common procedure in the designing of ships—a good approximation to the real situation can be obtained (Békésy, 1928). In this manner it becomes possible to build an enlarged model of the cochlea.

razor blades, and a rubber membrane. The volume displacement of this rubber membrane, in response to a given rise in pressure in the channel, corresponds to the volume displacement for the same pressure change in the human cochlea. If the channel is filled with a liquid in which small silver crystals are suspended, it becomes possible to observe the motions of the liquid by means of a microscope. If a glass tube is cut lengthwise, and one-half is used to cover the basilar membrane of the model shown in Fig. 45, a more perfect imitation of the actual situation in the cochlea is obtained. This was done in several experiments. Comparing data collected with the two types of models, we find that the only change is a

shift in the locus of the maximum response. This shift can be compensated for by a frequency change of about $\frac{1}{2}$ octave.

Although it is true that we are at present able to perform satisfactory measurements on a real ear, models similar to the one described are still very useful, because they

tude is a maximum (see also Fig. 47). The locus remains unchanged when the dimensions of the channel are increased or when the introduction of foreign bodies has made the channel considerably narrower. It was furthermore found that the vibrations of the membrane are largely independent of the

FIG. 45. Model of the uncoiled cochlea. Three microscope slides are set to form a trough having a cross section of 1 square millimeter. A solution of rubber is applied to the V-shaped opening formed by the two razor blades, producing a 'basilar membrane' whose volume displacement corresponds to that measured along the human cochlear partition. The fluid column in the cochlear channel is set in motion by a small metal tube. The other end of the channel, the 'helicotrema,' can be left open because capillary forces keep the fluid (water, or water mixed with honey) in the channel. (Békésy, 1942.)

permit us to investigate the factors that are responsible for the vibration pattern of the cochlear partition. The models also show very clearly the presence of a small eddy at the locus of maximum response (Békésy, 1928). This eddy moves toward the stapes for high frequencies and toward the helicotrema when the frequency is lowered. Since it is possible to observe the center of the eddy with great accuracy, each change in the vibration pattern of the membrane can be determined with satisfactory precision.

Figure 46 illustrates a striking conclusion to be drawn from experiments with ear models: it is extremely difficult to influence the location at which the displacement ampli-

location of the "round" and "oval windows" in the model.

All the experiments with ear models show that even perfectly sinusoidal vibrations of the liquid are accompanied by a "rectified" or unidirectional flow. Any irregularity in the structure of the cochlear model leads to the presence of one or more additional eddies. The eddies that occur regularly at the locus of maximum deformation of the cochlear partition are particularly striking; they change position along the membrane when the frequency changes.

Eddies also occur in the vicinity of the stapes footplate under the influence of strong vibrations. As a matter of fact, a circular

eddy occurs at any opening in the cochlear canal or in the semicircular canals. Since the vestibular apparatus is so close by, these eddies may lead to disturbances affecting the

feeling that one's head is pulled over to the side. These motions have been recorded (Fig. 48) for monaural beats between tones around 1000 cps at a sound pressure of about 120 db (Békésy, 1935).

Frequency analysis in the human cochlea. The measurements of the displacement amplitude along the cochlear partition demonstrate some kind of preliminary mechanical frequency analysis. In particular, they establish two facts: (1) there is a position of maximal stimulation along the cochlear par-

FIG. 46. Measurements on an ear model with the same elastic properties as the human ear showed that the vibration pattern and the location of the eddy do not change under the modifications shown. (Békésy, 1942.)

sense of equilibrium. This effect can be demonstrated very easily with pigeons: if an opening is made in the labyrinth, it becomes possible to produce head motions by means of sounds (Tullio, 1929).

Even for the normal human ear there are noticeable vestibular effects when fairly loud tones are turned on or off. One has the

FIG. 47. Under these alterations in the ear model, there is a slight change in the locus of the eddy, which can be restored by lowering the input frequency 15 to 25 per cent. When the fluid in a canal is replaced by air, the model may be driven by airborne sound via the tube shown at the left. Removing the fluid from one channel reduces the model to a one-channel variety. (Békésy, 1942.)

tion, and (2) the location of this maximum sensitivity shifts with frequency.

The curve for man in Fig. 44 subdivides the audible frequencies into essentially four subregions. The first lies to the left of the starting point: there is no mechanical fre-

quency discrimination for tones lower than about 25 cps. For frequencies lower than this, the analysis must be purely neural. Incidentally, man can hear tones as low as 1 cps (Békésy, 1936). The second subregion extends from 25 to about 300 cps. Here we find a moderate amount of mechanical frequency analysis, but probably not enough to account for the precision found in judgments of pitch discrimination. The next region, from about 300 to about 1000 cps is

It was never really possible to throw the entire burden of pitch discrimination on mechanical analysis alone, because, as both Wien (1905) and Fischer (1908) have already pointed out in the case of pure tones, the mechanical excitation falls off much too slowly on both sides of the maximum (i.e. the resonance curve for pure tones is much too flat). It is still not clear by what processes the nervous system increases the apparent sharpness. Gray's (1900) view is

FIG. 48. Head motions induced by loud sounds (about 120-db sound-pressure level). If beats (lower tracing) between two tones of about 1000 cps are presented to one ear, lateral head motions can be recorded from most listeners. (Békésy, 1935.)

a region of transition where mechanical frequency analysis improves rapidly. In this subregion pitch discrimination likewise improves. Unfortunately, for most of the fourth region (the part above 4000 cps) mechanical measurements are not available. For the highest audible frequencies it becomes impossible to observe the vibration pattern on the partition, because amplitudes involved are too small. In models, however, the eddy moves toward the stapes end of the membrane as the frequency increases, and remains there for further increases in frequency.

This summary has attempted to fit together the different observations and measurements made. We are, at present, far from a definite solution of the problem of pitch discrimination. What was attempted here was to demonstrate the possibilities of a purely mechanical frequency analysis in the ear.

slowly gaining, according to which only the position of maximum stimulation counts. The positions that have been stimulated less than maximally are apparently subject to some sort of nervous inhibition in the manner of the law of contrast (Békésy, 1928). In any case, the fact that mechanical time constants are very small compared with overall auditory time constants, as found in psychophysical experiments, must eventually be fitted into the picture of a frequency- and time-analyzing system for which equivalent linear circuits with simple time constants and resonance curves cannot be readily established.

The auditory system includes both mechanical and neural transducers. We know that the latter behave in a radically nonlinear manner. This reason alone would seem to be sufficient to discourage the setting up, for the entire auditory system, of an equivalent circuit made up of passive,

linear, time-invariant elements—i.e. a circuit that obeys the principle of superposition. This does not mean, however, that it is impossible to find an equivalent circuit for parts of the auditory system. If we restrict the range of variables sufficiently, we might even imitate the behavior of the entire system by an equivalent circuit. We must, however, constantly remain aware of the limitations of such an equivalence.

HEARING BY BONE CONDUCTION

There are two principal ways in which sound can reach the inner ear. The first is by air conduction: the drum is set into

vibration, and these vibrations are transmitted via the ossicles. The second involves a direct contact between the human head and a vibrating body. The vibration of the skull produces compressions in the bones, and we might very plausibly assume that these compressions stimulate the auditory nerve directly. If this were so, the vibration pattern of the cochlear partition would lose its importance, and we would find ourselves in the presence of a type of hearing radically different from hearing by air conduction.

It can be shown, however, that for both types of hearing an identical vibration pattern of the cochlear partition is obtained. This can be demonstrated by canceling a tone heard by bone conduction by means of

FIG. 49. Vibration pattern of the skull when the forehead is in contact with a vibrating body. Below about 200 cps the skull behaves as a rigid body. Near 800 cps the forehead vibrates in the opposite direction from the back of the head—a type of resonance of the skull with a nodal line of compression. Above 1500 cps the skull vibrates in sections separated by nodal lines. Variations in the thickness of the skull produce variability in the resonance frequency. (Békésy, 1932a.)

another tone (in proper phase and amplitude) heard by air conduction. If the vibration patterns for air and bone conduction were not exactly alike, such a cancellation would prove impossible (Békésy, 1932*a*; Lowy, 1942).

If a body vibrating at low frequency touches the forehead, the head will undergo displacements that are parallel to those of the vibrating body, i.e. the compression of the skull is very small. But for higher frequencies the back of the head does not follow the vibrations of the forehead because of its inertia. Hence the middle of the head is compressed. The elasticity of the middle of the head and the mass of the back of the head constitute a system that may resonate at a certain frequency. This skull resonance is most easily measured by determining the phase of the vibration at different places on the skull. The phase pattern makes it possible for us to see which part of the bony wall is moving inward and which outward (Békésy, 1948).

For low frequencies the movements of various parts of the head are simple parallel movements in the same direction. Around 800 cps the skull goes through a kind of resonance. The forehead moves forward as the back of the head moves backward, and vice versa. Above about 1500 cps the skull vibrates in several sections very much like a bell (Fig. 49). If the source of vibration is moved to different locations on the head, this pattern rotates with it to some extent.

Figure 50 shows the mandibular joint of the lower jaw in the immediate vicinity of the meatus. If we insert a finger into the meatus, we are able to feel displacements of the lower jaw. When the head and the lower jaw are displaced with respect to each other, the auditory meatus finds itself compressed and dilated. Consequently, if the meatus is plugged by means of a stopper, the loudness of a bone-conducted tone will increase because of the compression of the meatus due to the relative movements of the

skull and the jaw. This is known as Weber's experiment. If the stopper is located inside the bony part of the meatus (as indicated by the stopper in Fig. 50), the vibration of the mandible does not compress the meatus to the same extent as before and the loudness of a bone-conducted sound increases very little.

The inertia of the ossicles prevents them from following the vibrations of the skull.

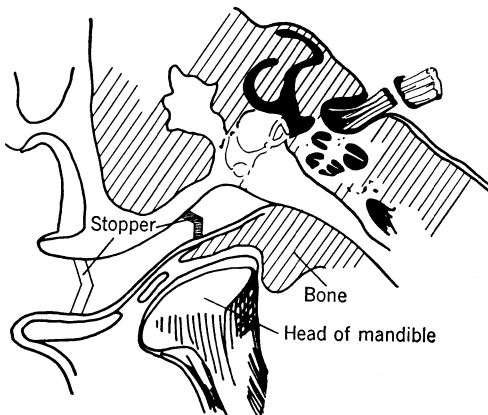

FIG. 50. Schematic longitudinal section through the meatus and the temporal bone. The head of the mandible is close to the ear canal, and its movement produces a deformation of the wall of the meatus. Stoppers at the two positions indicated have different effects. (Békésy, 1941*c*.)

The ossicles then undergo displacements relative to the bony wall of the middle ear. These relative vibrations are transmitted in the usual manner (i.e. by means of the stapes) to the cochlea.

The bending of the skull capsule results in compressions of the cochlea. Figure 51*A* shows that this compression would produce no motion of the cochlear partition if both windows were equally mobile (Rejtő, 1914; Herzog, 1930). Actually the membrane of the round window moves more easily than the stapes footplate in the oval window. The basilar membrane is therefore deformed in the manner indicated in Fig. 51*B*. Deformation of the bones produces a compression, not only of the cochlea, but also of the other parts of the labyrinth. This compression

forces liquid into the cochlea close to the stapes footplate, so that the vibration pattern of the cochlear partition is identical

phone on one ear produces a sound pressure that is heard by air conduction. But at the same time the vibrating membrane of the earphone sets the housing of the earphone into vibration, and these vibrations are transmitted to the bony part of the skull and heard by bone conduction. Bone-conducted sounds are very easily transmitted from one ear to the other ear, and we have, therefore, the problem of finding out what fraction of the sound energy delivered to one ear by means of an earphone is transmitted to the opposite ear by air conduction and how much is transmitted by bone conduction. For an ordinary earphone, the measured transmission loss from one side of the head to the other is between 40 and 50 db for the frequencies between 100 and 10,000 cycles. By measuring the vibrations of the head produced by an earphone it was possible to show that the loss in cross-hearing by bone conduction is of the order of 90 db (Békésy, 1948). In other words, in order to minimize cross-hearing we should provide the greatest possible insulation for airborne sounds, since the air provides the path of least attenuation.

The construction of an earplug assuring a maximum of acoustic insulation also leads to the problem of distinguishing between air and bone conduction. During the second World War many experimenters came to the conclusion that it was impossible to construct earplugs with an acoustic insulation greater than about 40 db. Therefore it was assumed that the sound waves striking the forehead set the skull into vibration and that these vibrations are heard by bone conduction. If this were the case, above a certain value the amount of mass closing the ear canal would be of no importance. It was, however, possible to increase the insulation provided by earplugs by covering each ear with a cotton-filled tube (Fig. 52). This can be interpreted only by saying that the reduction of the sound field near the ear canal made it possible to improve the insulation. In other words, when we listen to airborne

FIG. 51. Compression of the inner ear by bone-conducted sound leads to movement of the basilar membrane. The dashed lines indicate the positions of the various membranes during compression by a sound wave in the skull. A. Hypothetical case of symmetrical compression of the cochlea and equal yielding of the membranes of the oval and round windows. No movement of the basilar membrane occurs. B. The round window actually yields more than the oval window to equal pressures. The basilar membrane is moved slightly toward the scala tympani. C. The semicircular canals are also compressed, and fluid forced into the scala vestibuli causes greater movement of the membranes. (Békésy, 1932a.)

with that obtained when the stapes itself is displaced in the usual manner (Fig. 51C).

In many cases it is difficult to evaluate the relative importance of hearing by bone and by air conduction. For instance, an ear-

sounds the limiting factor is the sound attenuation of the earplug for these same sounds. Bone conduction plays little or no role in the maximum insulation provided by an earplug, as can be shown by increasing the surface of the head as much as ten times without changing the amount of insulation. The lower drawing in Fig. 52 shows how the effective surface of the head hit by the sound may be increased by biting on a board.

FIG. 52. The upper drawing shows two tubes filled with cotton and pressed upon the ears to improve the acoustic insulation provided by earplugs. In the lower drawing the surface exposed to the sound is enlarged without changing the insulation provided by the earplug. (Békésy, 1948.)

Bone conduction is of considerable importance in the hearing of one's own voice. If the vibrations of the surface of the skin are recorded by means of a pickup at various body locations while the subject sings a vowel, we find (Fig. 53) that the displacement amplitude in the vicinity of the ear is only $\frac{1}{20}$ of the amplitude recorded near the vocal cords. The vibrations of the air in the oral cavity are transmitted to the cheeks and from there to the lower jaw. The attenuation between the oral cavity and the ear canal is about 40 to 50 db. If we introduce a sound into the closed oral cavity through a tube, the sound pressure in the mouth must be about 47 db higher than the sound pressure in the ear canal in order to be heard with equal loudness. From this

we can see that, in the hearing of our own voices, the sound transmitted to the ear by bone conduction and that transmitted by air conduction are of about the same magnitude. Herein lies the explanation for the well-known difference between our speech as heard by ourselves and our speech as heard by others. If we record speech on a phonograph disk, the speaker does not recognize his own voice, since there is a great difference in the timbre of bone-conducted and air-conducted sound, and only air-conducted sound has been recorded.

Middle-ear infections have little influence upon hearing by bone conduction. A pathological condition of the acoustic nerve, on

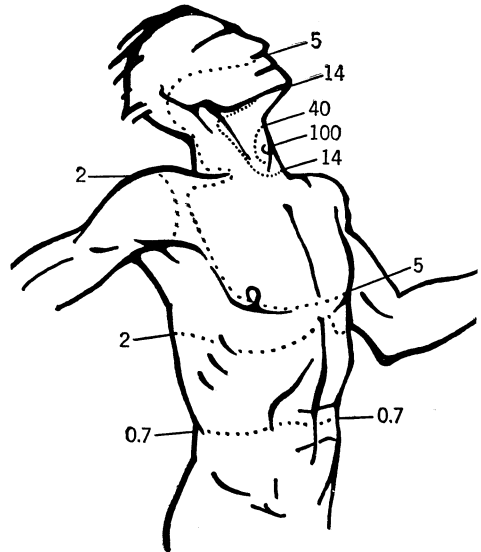

FIG. 53. The decrease in amplitude as the vibrations from the vocal cords travel over the surface of the body. The numbers give relative amplitudes along the dotted contours of equal amplitude. (Békésy, 1939b.)

the other hand, affects the hearing by air conduction and bone conduction in identical manner. Therefore, if a hard-of-hearing individual's hearing by bone conduction remains unchanged, we may conclude that we are dealing with a middle-ear disease. But, if his hearing by air and bone conduction are both affected, we can conclude that we are

FIG. 54. Bone-conduction thresholds. A vibrating body with a surface area of 0.8 square centimeter was pressed against the forehead. Two sets of threshold curves were obtained: A, the effective amplitude of the forehead; B, the rms force applied to the bone. An occlusion of the ear canal lowered the threshold by about 10 db for frequencies below 2000 cps. (Békésy, 1941c.)

FIG. 55. Amplitudes of vibration of the human head, stapes, and basilar membrane, and also of air and water particles, in response to sound waves having a pressure of 10^3 dynes per square centimeter (134-db sound-pressure level). The lowest curve shows the amplitude of the head at the threshold of hearing by bone conduction. (Békésy, 1948.)

concerned with a nerve condition. Hence the importance of the measure of the bone-conduction threshold for diagnostic purposes.

If bone-conduction thresholds of audibility are measured, two different curves may be obtained, depending upon the type of measurement: in one case the displacement amplitude of the forehead is measured; in the other the alternating force applied to the bone is determined (Fig. 54). It is also of some practical interest to note that the bone-conduction threshold is lowered if the outer ear is stopped off. As shown in Fig. 54, this effect amounts to about 10 db for frequencies below 2000 cps.

A FINAL WORD ABOUT SENSITIVITY

In the preceding pages we have attempted to describe the vibratory phenomena encountered in hearing. Figure 55 presents a quantitative summary of the displacement amplitude of various structures important or related to the process of hearing.

Findings such as those summarized in Figs. 6 and 55 pose a problem. What physical meaning are we to attach to displacements as small as the threshold values in the region of greatest sensitivity of the ear? It would appear from extrapolation that in the case of a very good observer we might be dealing with threshold displacements that are only about tenfold removed from what according to Gamow (1949) might turn out to be a new universal constant of elementary length. In other words, the ear would appear to be responding to displacements not much bigger than the smallest numerical values of distance that can be used in a physical sense to characterize the space separation of two elementary particles. This is an astonishing and baffling conclusion!

It would lead us too far to discuss here the related question of the signal-to-thermal noise ratio at the absolute threshold. Sivian and White (1933) have carried out certain

calculations, and more recently the whole subject has been reviewed by de Vries in a series of articles (1948a, b, c) to which the reader may refer.

Psychophysiology of Hearing and Deafness

HALLOWELL DAVIS, M. D.

*Central Institute for the Deaf
and Washington University*

The external ear delivers sound waves through the external auditory canal to the middle ear, and thence they pass to the inner ear. There, in the cochlea, the sensory cells of the organ of Corti are stimulated and initiate nerve impulses in the fibers of the auditory nerve. The impulses pass through a series of nuclei and fiber tracts in the medulla and midbrain to the auditory area of the cerebral cortex; and there, somehow, they generate the sensations that we know subjectively as "sounds."

NEUROANATOMY OF THE AUDITORY SYSTEM

The gross anatomy of the inner ear has been described in the previous chapter. There special attention was given to the cochlear partition, consisting of the spiral lamina and the basilar membrane. The basilar membrane is a structure of special interest because on it rests the organ of Corti, which contains the specialized sensory cells of audition. Somehow these cells, when agitated by the movements of the basilar membrane, set up nerve impulses in the fibers of the auditory nerve.

The author gratefully acknowledges the assistance of Robert Galambos in the writing of various sections, and in the preparation of Figures 4 and 14.

Microscopic Anatomy of the Ear

A typical cross section of the organ of Corti, as seen under the microscope, is shown diagrammatically in Figs. 1 and 2 (Rasmussen, 1943). At the junction of the basilar membrane with the bony spiral lamina, and projecting into the scala vestibuli, stand two relatively stiff structures, the rods of Corti. The rods converge and, with the segment of basilar membrane beneath them, enclose the "tunnel," triangular in cross section, that runs from end to end of the organ of Corti. The rods are about 50 microns in length near the round window and increase progressively to about 90 microns in the apical turn. Internal to the rods, i.e. toward the modiolus and over the edge of the spiral lamina, is located a single row of sensory cells, the internal hair cells. One internal hair cell is seen in a typical cross section of the organ. External to the pillars are three or four rows of external hair cells. The supporting structures, like the rods of Corti, increase progressively in size from the basal to the apical end of the basilar membrane.

Two accessory structures worthy of mention appear in Figs. 1 and 2. The tectorial membrane, attached by its inner edge to the epithelium of the limbus, is located just above the hair cells. In fixed sections it appears homogeneous and fairly dense, but

during life it is a soft, delicate, semigelatinous, tubelike mass that seems to be lightly attached to the organ of Corti. The attachment appears to be chiefly through delicate hairlike structures, several of which project from each hair cell into the endolym-

ner's membrane. The canal enclosed by it, the basilar membrane, and the stria vascularis is called the ductus cochlearis or scala media. These structures taken together are called the cochlear partition. The scala media ends as a closed sac at the helico-

FIG. 1. Diagrammatic cross section of a cochlear canal. The ductus cochlearis (or scala media) contains the organ of Corti with its hair cells, the ultimate end organs of hearing. (From Rasmussen, 1943.)

phatic space. The hairs, entangled in the tectorial membrane, probably excite the sensory cells when they are bent or pulled by movement of the hair cells relative to the tectorial membrane. The tectorial membrane is thus analogous to the cupola of the cristae and maculae in the vestibular portion of the inner ear. (The vestibular structures of the inner ear, i.e. semicircular canals, utricle, and saccule, are concerned with orientation relative to gravity and acceleration. There is no good evidence, in spite of many theoretical suggestions, that they are in any way concerned with the sense of hearing.)

Above the tectorial membrane is a thin, flexible, dividing partition known as Reiss-

ner's membrane. The canal enclosed by it, the basilar membrane, and the stria vascularis is called the ductus cochlearis or scala media. These structures taken together are called the cochlear partition. The scala media ends as a closed sac at the helico-

truma, an opening that connects the scala vestibuli and the scala tympani. The scala media forms part of the membranous labyrinth and is continuous with the vestibule, the saccule, the utricle, and the membranous semicircular canals. The sensory structures of all the sense organs of the inner ear lie inside this inner membranous labyrinth. The membranous labyrinth is filled with endolymph, and another fluid, the perilymph, surrounds the membranous labyrinth. These structures act as a single homogeneous medium in transmitting the movements of the stapes to the basilar membrane.

The ultimate sense organ of hearing, the hair cells of the organ of Corti, forms a

long narrow sensory surface, four or five cells wide, and running the length of the basilar membrane. Each inner hair cell is about 12 microns in diameter (viewed from the scala vestibuli) and the external hair cells are about 8 microns in diameter. There are

recognized in this ganglion. Auditory nerve fibers make uninterrupted anatomical and functional connections between the hair cells of the organ of Corti and nerve cells inside the central nervous system. One peculiarity of the neurons of the auditory nerve is that,

FIG. 2. Diagrammatic cross section of the organ of Corti. The outer hair cells are supported by their respective phalangeal cells, which rest in turn on the movable basilar membrane. The phalangeal cells supporting the inner hair cells rest on bone. Motion of the basilar membrane presumably distorts the hair cells. (From Rasmussen, 1943.)

about 3500 inner hair cells and a total of about 20,000 external hair cells.

The Innervation of the Organ of Corti

The eighth cranial (auditory) nerve consists of a vestibular portion and a cochlear portion. The latter, serving the sense of hearing, runs down the center of the spiral core or modiolus of the cochlea. The cell bodies of its nerve fibers are located within the modiolus and form a long spiral ganglion. This spiral ganglion of Corti contains about 27,000 cells and is analogous to the dorsal root ganglia of the spinal nerves. Its cells are bipolar, and no synaptic connections are

contrary to the usual law of Wallerian degeneration, when the fibers are severed between the medulla and the spiral ganglion the fibers do not regenerate from the cell bodies, but all of each injured neuron, including the cell body, degenerates. As a rule the hair cells innervated by the injured neurons also ultimately degenerate.

The cell bodies of the spiral ganglion are more densely grouped (900 to 1100 per millimeter) along the basal and lower middle turns of the cochlea than along the upper middle and apical turns (about 500 per millimeter), with a gradual transition in the middle turn (Guild, 1932).

The inner hair cells are each innervated by one or two nerve fibers, and each fiber connects with one or two hair cells. The innervation of the external hair cells is more complicated, however, as most of the fibers turn at right angles near the external hair cells and run for a half turn or farther toward the round window. Each fiber makes connections with many external hair cells, as

of the basal turn. The fibers running to the more apical region twist around the core in one direction, those running to the basal end, in the opposite direction. This arrangement results from the fact that, in embryological development, the nerve fibers are dragged after the organ of Corti as the latter grows out and assumes its ultimate spiral form.

The auditory nerve is short. The distance from the internal auditory meatus to the point of entrance of the nerve into the medulla is only about 5 millimeters. The nerve enters the lower brain stem (medulla oblongata) at the inferior border of the pons, and there its fibers promptly divide. One branch of each primary afferent fiber runs to the dorsal, and the other to the ventral portion of the cochlear nucleus. Here are the first synapses of the auditory system. The fibers of the auditory nerve, and also the cells in the cochlear nucleus on which they impinge, preserve more or less completely the orderly arrangement of the corresponding sensory cells on the basilar membrane. The same general tendency to an orderly arrangement, with its implications for a segregation of high-tone, middle-tone, and low-tone fibers, seems to be maintained throughout the auditory system.

FIG. 3. Innervation of the organ of Corti (cat). Auditory nerve fibers (AN), with their cell bodies in the ganglion of Corti (GC), end in the organ of Corti (OC). Internal hair cells (IHC) receive radial fibers (RF) and collaterals from internal spiral fibers (ISF). External hair cells (EHC) receive collaterals mainly from external spiral fibers (ESF). An external hair cell is innervated by many fibers; an internal hair cell by a few. The function of the internal spiral and centrifugal (CF) fibers is unknown. (From Stevens and Davis, 1938, after Lorente de N6, 1933.)

is shown in Fig. 3 (Lorente de N6, 1933). There is also a bundle of internal spiral fibers that parallels the organ of Corti just internal to the internal hair cells, and additional fibers running lengthwise of the organ of Corti within the spiral ganglion have also been described. The origin and connections of the fibers in these spiral bundles, as well as of others in the auditory nerve, are still unknown.

The Auditory Nerve

The fibers in the auditory nerve are arranged in an orderly but complicated fashion. They twist like the strands of a rope around a central core. This core contains the fibers that originate at about the middle

Auditory Pathways and Nuclei of the Brain Stem

The general arrangement of the auditory pathways and nuclei is shown in Fig. 4. The system may be divided into four levels: (1) the group of nuclei in the lower brain stem (including those of the superior olive, the trapezoid body, and the lateral lemniscus), (2) the cerebellum, (3) the inferior colliculus at the upper pontine level, and (4) the medial geniculate body (in the thalamus) and the auditory cortex at the highest level.

Second-order neurons* from the two cochlear nuclei pass by different pathways

* By "second-order" we mean fibers separated by at least one synapse from the sense organ, but we disregard possible longer alternative routes

to other nuclei of the lower brain stem and to the inferior colliculus. From the brain stem nuclei (of the trapezoid body and the superior olive) third-order neurons pass up the lateral lemniscus. Many terminate in

In addition to the main pathways from cochlea to cortex, three others of known or potential functional importance to the animal may be pointed out.

Some neurons arising from the superior olive ultimately connect with the motor nuclei controlling eye movements, the middle ear muscles, and other reflex responses to sound. Also, neurons from the inferior colliculus pass to the near-by superior colliculus which is an important nucleus of the optic system. Visual and auditory activity may be coordinated here, but this plausible suggestion has not been substantiated experimentally.

Finally, Snider and Stowell demonstrated, in 1944, a strong projection of the auditory system to the vermis of the cerebellum. The vermis responds when visual, tactile, or auditory stimuli are presented to the anesthetized cat, and also when the visual or auditory cortices are stimulated electrically (Hampson, 1949). How the cerebellum is involved in hearing is not at all clear, but speculations that it coordinates impulses from the different sense modalities are not out of order.

In contrast to other sensory systems, each ear appears to be represented bilaterally in the auditory pathway from at least the level of the superior olive upwards. The relative importance of the homolateral and contralateral pathways to the auditory cortex has been variously estimated, both from anatomical and from physiological evidence. At the cortical level the contralateral ear evokes stronger electrical responses than does the homolateral ear in cats (Bremer, 1943) and dogs (Tunturi, 1946). Cats with one cochlea destroyed and one cortex removed show a definite loss in auditory sensitivity. Yet the sensitivity is the same, regardless of whether the homolateral or contralateral cortex has been spared (Brogden et al., 1936). Apparently, then, each ear projects about equally to the two hemispheres. This bilateral projection is accomplished in the numerous places where the auditory tracts

FIG. 4. The afferent acoustic pathways (based mainly on the cat). The locations of important synapses are indicated in capital letters on the right. The "order" of each neuron is indicated by a number. (Cf. Ades; Barnes, Magoun, and Ranson; Cajal; Rasmussen; Cheng and Niemer.)

the inferior colliculus, but a significant fraction also sends collaterals to the medial geniculate body (Cajal, 1909; Ades, 1944). Other third-order neurons originate in the inferior colliculi and pass to the medial geniculate bodies where at least one additional synapse is located. The auditory radiations to the cortex are therefore at least fourth-order neurons.

with more synapses by way of neurons with short axons that lie entirely within a single nucleus.

cross as they ascend the brain substance. Important crossings occur at every level except the thalamic (medial geniculate), and opportunities for interaction between the two ears are correspondingly numerous. Such interactions are presumably significant for integrating functions, like localization, which depend upon slight differences in the neural inflow from the two ears.

In this connection the inferior colliculus appears to be an important center for auditory reflexes in some forms. It attains a relatively enormous development in bats (Kappers et al., 1936); and in these animals the ability to recognize the direction of incoming sounds, notably the echoes of their own ultrasonic cries, is developed to such an extent as to enable the bats to avoid obstacles while flying in the dark (Galambos and Griffin, 1942). The fact that some authors depreciate, with good reason, the role of the inferior colliculi as reflex centers illustrates our lack of understanding of many aspects of the auditory system (cf. Barnes, Magoun, and Ranson, 1943).

The Auditory Area of the Cortex

The auditory cortex may properly be considered an outgrowth from the medial geniculate body of the thalamus. The auditory radiations to the cortex are the chief outgoing pathway from the medial geniculate nucleus. Nearly all the cell bodies of this nucleus show signs of retrograde degeneration after the auditory cortex has been surgically removed. If only part of the auditory cortex is removed, a corresponding portion of the medial geniculate body shows degeneration (Walker, 1937).

The auditory projection area, where the auditory radiations are distributed in the cerebral cortex, lies in the posterior portion of the superior temporal convolution in man. Most of it is hidden deep in the sylvian fissure. Accurate information concerning both its location and its organization in monkeys, dogs, and cats has been derived from studies of its electrical responses when

FIG. 5. Auditory areas of cat, monkey, and rat, as determined by the electrical response of the cortical mantle following stimulation of the cochlea. Base (B), mid (M), and Apex (A) refer to regions responding when, in the cochlea, electrical stimuli were applied to the basal, middle, and apical turns, respectively, of the cat and monkey. Circles indicate where electrical responses were evoked by clicks to the ear of the rat, with diameter of circle roughly proportional to amplitude of response (maximum = 2500 microvolts). The active area measures about 4 by 4 millimeters. (From Woolsey, 1947; LeMessurier, 1948.)

the organ of Corti is stimulated electrically or by sound (Bremer and Dow, 1939; Ades and Felder, 1945; Walzl and Woolsey, 1946; Woolsey and Walzl, 1942; Tunturi, 1944, 1945, 1946). Walzl (1947) and Woolsey (1947) have both written useful summaries of this work.

sylvian fissure. There it comes into close relation with somatic sensory area II. Figure 5, from Woolsey, shows the auditory cortical areas for cat, monkey, and rat.

Each projection system in the cortex seems to arise independently from the medial geniculate body. Fibers from the small-cell

FIG. 6. The voltage of the aural microphonics is plotted as a function of intensity in linear and in double logarithmic coordinates. Corresponding points on the two curves are connected by broken lines. These microphonics were obtained from the round window of a guinea pig and measured with a sharply tuned wave analyzer. (From Stevens and Davis, 1938.)

The auditory area, like other sensory cortical areas that have been similarly analyzed, shows two systematic projections of the sense organ. In the monkey (macaque) one of these projections (auditory area I) lies along the posterior half of the lower bank of the sylvian fissure. Stimulation of nerve fibers from the apical turn of the cochlea gives responses in the anterior lateral part of the area. Stimulation of fibers from the basal turn gives responses in the posteromedial part. In the adjacent auditory area II, the relations are reversed. Apical fibers activate the posteromedial region, and basal fibers the anterolateral. Area II extends to and includes part of the upper bank of the

part of the nucleus (in the cat) apparently go to area I, and fibers from the large-cell portion go to area II (data of Waller, quoted by Woolsey and Walzl, 1942).

In the dog a third auditory area, occupying the ventral end of the anterior ectosylvian gyrus, has been described by Tunturi (1946), who presents some physiological evidence for separate fiber connections from local parts of the cochlea to this area. The localization of responses to high and to low tones is not so clear as in the other two areas, however. The existence of a third cortical projection area is apparently unique among the sensory systems. Many investigators suspect that this third area is an as-

sociation area rather than a true primary projection area.

THE AURAL MICROPHONIC

If one electrode is placed on the round window of an animal and another anywhere on the tissues of the head or neck, an electrical potential can be measured between the two electrodes when sound waves fall on the animal's ear. The time course of this potential follows closely, although not always precisely, the changes in sound pressure. Thus a pure tone may produce an alternating electrical potential that is very nearly sinusoidal in form. A transient sound, such as a click, produces a train of electrical waves that starts in either the positive or the negative direction, depending on whether the initial sound wave is a wave of positive or of negative pressure. Over a considerable range of pressure the electrical potential is nearly proportional to the sound pressure (Figs. 6 and 7). Usually, however, the slope of the line plotted in double logarithmic coordinates is significantly less than 1.00 (Wever and Bray, 1938). At high sound intensities the potential increases less and less rapidly and finally reaches a maximum. The maximum voltage varies with frequency, and under favorable conditions it may approach as much as a millivolt in the cat or the guinea pig.

This electric response of the cochlea or *aural microphonic* is generated within the cochlea. It is strong at the round window, at the oval window, at the internal auditory meatus, along the auditory nerve, and, in the guinea pig, all over the thin, bony shell that covers the cochlea. It still appears when sound is transmitted to the cochlea by bone conduction, even after surgical removal of eardrum, malleus, and incus, and after the auditory nerve has degenerated following its transection at the internal auditory meatus. The microphonic appears without any apparent latency except for the time required for transmission

of the sound waves into and along the cochlea. The microphonic spreads from the cochlea through the tissues of the head, according to their configuration and electrical conductivity. Its polarity at the round window is opposite that at the oval window, as

FIG. 7. The voltage of the aural microphonics (cat) plotted against the intensity of a 1000-cycle tone. The numbers on the curves indicate tension in grams applied to the stapedius muscle. Increased tension reduces the response, but the shape of the curve and its slope ($= 1$) remain constant. (From Wever and Bray, 1942.)

though the 'generator' were located on, and oriented perpendicular to, the basilar membrane.

The aural microphonic does not disappear immediately on the death of the animal, although it begins to fall off rapidly in intensity soon after the blood supply has been interrupted in any way. At a much reduced level the microphonic may persist for several hours after death (Wever, Bray, and Lawrence, 1941a).

The aural microphonic was first detected in 1929 by Wever and Bray when they placed an electrode on the auditory nerve of a cat. The microphonic was combined with the action potentials of the auditory nerve, and at first it was not recognized as a separate phenomenon; but soon the dual nature of the electric response (nerve impulses plus aural microphonic) became clear. The microphonic, or, more accurately, the mixture of microphonic and action potentials, is often known as "the Wever-Bray phenomenon." The term *aural microphonic* for the cochlear response (as distinguished from action potentials of the auditory nerve) has been advocated by Stevens and Davis (1938).

Nearly all the characteristics mentioned above serve to differentiate the aural microphonic from the action potentials of nerve. The behavior of the microphonic suggests a purely biophysical phenomenon such as a piezoelectric effect or the movement of an electrically charged structure. The acoustic energy of the sound wave seems to be sufficient to account for the electrical energy that is developed. The microphonic seems to be a pure transduction of acoustic to electrical energy, not a physiological response in the proper sense of the term, which implies a release of stored energy.

Possible Origins of the Aural Microphonic

The mechanism of the aural microphonic is still uncertain. It has been ascribed, by one investigator or another, to nearly every anatomical structure within the cochlea as well as to physical artifacts. Reviews dealing with aural microphonics have been written by Wever (1939), Walzl (1939), Walzl and Bordley (1942), and Stevens and Davis (1938).

The aural microphonic may arise from the movement of a polarized membrane. The generation of the potential would then be very much like the action of a condenser microphone. Reissner's membrane, the basilar membrane, and even the tectorial

membrane have been suggested as the polarized structure, and the difference in chemical composition between endolymph and perilymph has been postulated to account for the assumed polarization (Hallpike and Rawdon-Smith, 1934*a, b*). The polarized-membrane theory has not been completely disproved, but it is rendered improbable by the absence of the aural microphonic in congenitally deaf animals that lack an organ of Corti but have apparently normal basilar and Reissner's membranes. It is still possible that the electrically charged structure is the organ of Corti, and that the charge depends on the integrity of the sensory cells. This is the writer's present working hypothesis.

In a closely allied theory the microphonic is attributed to "streaming potentials," i.e. the potential generated when fluid is forced through small channels in a filter or membrane (Eyster, Bast, and Krasno, 1935). If such movement is to generate a potential, there must be a surface charge between the fluid and the solid. Such a charge is usually present in biological systems. The arguments for and against this theory are very similar to the arguments concerning the movement of polarized membranes, and the theory is not generally accepted.

In considering the various hypotheses, however, we must remember that they need not be mutually exclusive. The aural microphonic may be generated by several different mechanisms simultaneously. In fact, the long persistence of a weak microphonic many hours after death suggests the presence of a second mechanism that is less directly dependent on an adequate oxygen supply than the mechanism that is responsible for most of the microphonic during life.

The most generally accepted hypothesis of the origin of the aural microphonic attributes it to the organ of Corti, and specifically to the hair cells. These cells, oriented nearly perpendicular to the basilar membrane, are thought to develop a difference of electrical

potential between their hair-bearing ends and the ends that are in contact with the terminal nerve fibers. The potential is thought to depend on pressure (or deformation or movement or acceleration) in some simple and direct fashion and has been compared with the piezoelectric effect in a quartz crystal (Stevens and Davis, 1938). No more detailed explanation of the transformation of acoustic to electrical energy by the hair cells has been proposed.

An extension of the hair-cell theory makes the aural microphonic the mechanism whereby the sensory cell initiates a nerve impulse in the contiguous basket-like termination of the auditory nerve fiber. The microphonic would thus be analogous to a synaptic potential or, still more accurately, to the local potential that is the electrical aspect of the local excitatory process in a nerve or muscle cell (see Chapter 2). This extension of the hair-cell hypothesis is attractive in its simplicity, but some authors have specifically rejected it in favor of a theory of chemical mediation between the hair cell and the nerve (Derbyshire and Davis, 1935). It is possible that the microphonic originates in the hair cells, and that it plays no part in the initiation of the nerve impulses.

The hair-cell theory rests largely on a general correspondence between the integrity of the hair cells and the presence of the microphonic. For example, in one set of experiments, local degeneration of the hair cells in one region along the basilar membrane, caused by long exposure to a loud tone, was associated with a weakening of the microphonic generated by a particular band of frequencies (Davis et al., 1935). Again, the development of the organ of Corti in the pouch-young opossum begins at the upper end of the basal turn, and in such young opossums the microphonic is present for only a restricted range of medium frequencies (McCrary, Wever, and Bray, 1940). Similar evidence has been found in studies of deaf (or partially deaf) albino cats, waltzing guinea pigs, and Dalmatian dogs (cf. Wever,

1939). The hair-cell theory offers a reasonable explanation of the depression of the aural microphonic by the injection into the cochlea of narcotics and of salt solutions of varying composition, by deprivation of oxygen (Wever, Bray, and Lawrence, 1941a), by partial injury by very small surgical lesions (Walzl and Bordley, 1942), and by exposure to loud tones.

On the other hand, there is evidence that the degree and location of injury to hair cells, particularly the injury caused by brief exposure to loud tones or noise, does not correspond accurately to the frequencies for which the microphonic is impaired. Although in some instances the behavior of the microphonics agrees well with prediction from theory, the exceptions (Bast and Eyster, 1935; Dworkin et al., 1943; Lurie, Davis, and Hawkins, 1944) are too numerous and too well substantiated to be lightly ignored. Although explanations of the exceptions may yet be forthcoming, the hair-cell theory of the origin of the microphonic is still only a theory.

Species differences. The microphonic has been demonstrated in the ear of every species of animal in which it has been sought, but there are great differences in its strength from one species to another. Particularly interesting in this respect is the weakness of the microphonic in monkeys and especially in man. It has been successfully recorded from the round window of human beings, but the strongest reported is less than 50 microvolts. (For references, see Lempert, Wever, and Lawrence, 1947.) As much as 1000 microvolts may be found in cats and guinea pigs.

Parameters of the Aural Microphonic

Frequency. Whatever its origin, the microphonic is closely related to the mechanical events within the cochlea. The microphonic generated by low tones is relatively much stronger at the apex (in the guinea pig) than at the round window, but for high tones it is stronger at the round

window. The frequency limits of the microphonic are at least as wide as the range of audible tones, and probably wider. The slow changes of pressure produced by contraction of the intra-aural muscles give a strong microphonic although they do not seem to excite nerve impulses (Wiggers, 1937).

Intensity. At low sound intensities the microphonic seems to reflect quite faithfully the mechanical movements of the basilar membrane. Its relation to sound intensity is nearly linear (see Fig. 6) up to about 40 per cent of its maximum voltage. The microphonic has been used to study the characteristics of the transmission system of the middle ear, the effects of the contractions of the intra-aural muscles (Fig. 7), and the generation of aural harmonics. It has been found, for example, that nonlinear distortion of the ear may be influenced by the contraction of the intra-aural muscles (Stevens and Newman, 1936; Newman, Stevens, and Davis, 1937; Wever and Bray, 1942), but it is also clear that nonlinear distortion of the microphonic takes place in the inner ear (Wever, Bray, and Lawrence, 1940a, b, c, and 1941a, b; Wever and Lawrence, 1949).

As the intensity of the sound is increased, the microphonic ceases to increase proportionately, and finally reaches a maximum. This suggests a mechanical 'overload' of the vibrating system. The situation is more complicated, however, for further increase in the intensity of the sound causes a *decrease* in the aural microphonic; and after exposure to intense sounds the microphonic produced by a weaker sound is also reduced for some time. This effect has been termed *hysteresis* (Hughson and Witting, 1935; Stevens and Davis, 1938). This phenomenon suggests a biological 'fatigue' or perhaps a mild injury (followed by recovery) of the elements that transform the mechanical into electrical energy.

Interference. A phenomenon called *interference* is closely related to overload, hysteresis, and injury. If a fairly strong stimu-

lating tone is sounded and then a second tone of different frequency is added, the response to the second tone is less than it would be if the second tone were sounded alone. Many details of this interference have been described (Wever, Bray, and Lawrence, 1940b; Wever and Lawrence, 1941), and the phenomenon is presumably the same as that reported by Newman, Stevens, and Davis (1937), who found that the presence of a second tone decreases the aural harmonics of a first tone. Wever, Bray and Lawrence (1940a, b) interpret their data as showing that interference precedes overloading in the chain of events in the inner ear and thereby tends to protect the hair cells against overload.

ACTION POTENTIALS OF THE AUDITORY NERVE

The human auditory nerve is composed of about 30,000 individual fibers, and the activity of each fiber presumably consists of the familiar all-or-none nerve impulses. All the information transmitted from the ear to the brain must pass through this bottleneck, and a fundamental problem of the neurophysiology of audition is to 'break the code' of the auditory nerve. At the psychophysiological level every auditory discrimination must depend on a corresponding difference in the space-time pattern of nerve impulses in the auditory nerve. Consequently the aspects of neural response that we seek to relate to the parameters of the stimulus are (1) the rates of discharge of impulses in various fibers and (2) the time relations of the impulses in one fiber with respect to the stimulus and to the impulses in other fibers.

Observation of auditory nerve impulses. The electric responses of the auditory nerve as a whole may be studied by means of an electrode inserted into or hooked beneath the eighth nerve where it emerges from the internal auditory meatus of the experimental animal. Unfortunately, the action potentials

of the nerve fibers are mixed with the aural microphonic from the cochlea and perhaps also with the responses of cell bodies in the spiral ganglion and in the cochlear nucleus. The unwanted microphonic potentials can be almost completely eliminated by the use of coaxial electrodes (Derbyshire and Davis, 1935b), but the remaining composite potentials are still difficult to interpret in detail.

Action potentials in the nerve are also detected by an electrode placed on the round window. In response to a faint or moderate click they may be large and distinct, but, if a continuous tone is used or if the click is made strong, the neural responses are almost completely obscured by the aural microphonic.

A third type of recording has employed a microelectrode (a very fine pipette with an opening only a few microns in diameter) inserted into the eighth nerve (Galambos and Davis, 1943; Galambos, 1944). With such electrodes unitary neural responses were obtained which were interpreted as action potentials of the axons of first-order neurons running from the cochlea to the medulla. It now appears, however (Galambos and Davis, 1948), that the observed potentials actually originated *in cell bodies of second-order neurons* (see below). We still lack, therefore, direct observations of the activity of single first-order neurons which we would like to relate to the parameters of the stimulus.

From the observations of composite potentials at the round window and from the eighth nerve and from the activity of the second-order neurons we shall draw several inferences as to the activity of the first-order neurons. Many of the following propositions must still be regarded as tentative, however.

Synchronization with the stimulus. The organ of Corti tends to excite nerve impulses during one-half of the cycle of movement of the basilar membrane. Apparently excitation occurs only during the phase of movement of the basilar membrane toward (or the phase of displacement into) the

scala vestibuli. This corresponds to movement of the stapes outward. The result is that for low and medium frequencies the nerve impulses are synchronized with the

A

B

FIG. 8. Synchronization of neural response. Each record is the photograph of many sweeps across the oscillograph. The neural responses are downward excursions from the undulating baseline, which is the aural microphonic. The neural responses, from cell bodies of the second order (in the cochlear nucleus), are relatively few in number compared with the sound-wave cycles photographed. The grouping of the neural responses indicates a synchrony that is approximate, but imperfect. The stimulating frequency is 1050 cps in A, 500 cps in B. (From Galambos and Davis, 1943.)

stimulating sound waves, and therefore with one another. At high frequencies the refractory period of the nerve prevents the fiber from responding to every sound wave, but the tendency toward (nearly) synchronous response to a pure tone in the auditory fibers as a group is very strong. A series of well-

defined action-potential waves appears in the auditory nerve and reproduces, up to 2000 or 3000 cps, the frequency of the stimulating tone. This synchronization at the higher frequencies presumably depends upon the ability of the individual nerve fibers to take turns responding to alternate sound waves, or to every third or fourth sound wave.

The approximate synchronization of nerve impulses is carried over into the second-order neurons, but variations in the synaptic delay apparently make it a little less pre-

in the fine, nonmedullated terminals of the fibers, or it may be a true latency at the junction between hair cell and nerve fiber.

ACTION POTENTIALS IN SINGLE SECOND-ORDER NEURONS

The observations of Galambos and Davis (1943, 1944), made with microelectrodes inserted into the eighth nerve of anesthetized cats, were originally interpreted as action potentials of the axons of first-order neurons

FIG. 9. Response of a single cell body in the cochlear nucleus (cat) to words spoken about 20 feet from the preparation.

cise than in the first-order neurons. Figure 8 shows the impulses in a single (second-order) neural unit synchronized with the stimulating tone in an approximate but imperfect manner. The responses occur at about the same phase in each cycle, when they do occur, but they vary over a range of about ± 0.13 millisecond. From this figure it is also clear that the responses of a given unit do not occur after every sound wave by any means.

Latency. Stimulation with transient sounds (clicks) causes the appearance of impulses in the auditory nerve at the internal auditory meatus about 0.4 to 1.0 millisecond after the arrival of the sound wave at the oval window (Derbyshire and Davis, 1935b). Not more than 0.1 millisecond of this latency can be attributed to conduction time in the large medullated portion of the nerve fibers. Much of the latency of the later waves can be explained as the time required for the mechanical wave to travel up the basilar membrane. But even the earliest (high-tone) component of a composite action potential has an unexplained latency of about 0.3 or 0.4 millisecond. This part of the latency may be due to slow conduction

running from the cochlea to the medulla. These authors later assumed (1948) that their unitary action potentials were recorded from cells of the cochlear nucleus separated from those of the spiral ganglion in the cochlea by at least one synapse. We therefore call the neurons of Galambos and Davis "second-order neurons." The response of such a cell body is shown in Fig. 9.

Relation to frequency. Each second-order neuron is 'tuned' to a particular frequency. Less acoustic energy is required at this frequency than at any other to set up impulses. Near threshold the tuning is very sharp, but the neuron responds to a broader and broader band of frequencies as the intensity is increased. If the response area of a fiber is plotted against logarithmic scales of intensity and frequency, the area is unsymmetrical (Fig. 10). It invariably extends more octaves into the lower frequencies than into the higher frequencies as intensity is increased. Also, on this scale, the tuning of the high-frequency neurons tends to be sharper than the tuning of the low-frequency neurons.

Even for fairly strong tones the tuning of each neuron to a particular frequency is still

FIG. 10. Response areas of four different neurons in the cochlear nucleus in the cat. The frequency at which the minimal acoustic energy was required for producing discharges is indicated. Energies greater than the minimal elicited discharges over wider frequency ranges. The lower borders of each of the areas represent the threshold curve of response for the neuron. (From Galambos and Davis, 1943.)

FIG. 11. Number of neural discharges plotted against sound frequency at various intensities (cat). More discharges appear at 7000 cps than at any other frequency. Each point represents the total number of discharges counted in the first second after the start of the tone. The reference level for intensity is the same as in Fig. 10. (From Galambos and Davis, 1943.)

apparent. At its characteristic frequency the neuron discharges more impulses per second than at any other frequency, provided, of course, that intensity is constant (see Fig. 11).

Neurons with characteristic frequencies as low as 200 cps and as high as 50,000 cps have been identified in the cat (Galambos, un-

The greater the intensity of a stimulating tone, the higher the rate of discharge in the cells of the cochlear nucleus (Fig. 13). A rate of 400 to 500 discharges per second is the highest attained by most neurons, and intensities of 30 db above the threshold for the neuron are sufficient to produce the maximum rate. Not infrequently, at high

FIG. 12. Sensitivity of 42 neurons in the cochlear nucleus of 12 cats. Each symbol marks the frequency and intensity at which a particular neuron began to respond. The solid line is the aural microphonic "threshold" for the animal whose neural thresholds are indicated by open squares. Some neurons respond at intensities well below that at which the microphonic can be just detected; others are relatively insensitive. (From Galambos and Davis, 1943.)

published). Neurons tuned to frequencies below 1000 cps are rarely encountered in the cochlear nucleus of the cat, but this may be due to a systematic anatomical distribution of cell bodies that favors isolation of high-frequency rather than of low-frequency neurons (Lorente de Nó, 1933).

Relation to intensity. The thresholds for different neurons tuned to the same frequency differ by as much as 60 db (Fig. 12). The most sensitive neurons begin to respond at levels below that at which the aural microphonic can be detected at the round window. The less sensitive neurons seem to be neither more nor less sharply tuned than the most sensitive neurons.

stimulus intensities, one discharge follows another with an interval of about 1 millisecond, but intervals shorter than this are not seen.

Relation to duration. Under the influence of a steady tone the frequency of discharge from a second-order neuron soon falls off to one-half, or less, of its initial rate. Most of this 'adaptation' takes place within the first fifth of a second. Most neurons, when adapted, maintain a steady discharge of between 100 and 200 impulses per second.

Inhibition in the cochlear nucleus. About half of the cells in the cochlear nucleus discharge at a slow rate in the absence of any known acoustic stimulus. This 'spontaneous'

discharge can often be checked or *inhibited* by a tone of the proper frequency (Fig. 14A). The most effective inhibitor is usually

Similarly, a discharge of impulses in response to a tone of moderate intensity may often be inhibited by a second tone sounded

FIG. 13. Relation of neural discharge to sound intensity in three different neurons in the cochlear nucleus (cat). The rate of discharge was established by counting the number of spikes appearing in the first $\frac{1}{10}$ second. (From Galambos and Davis, 1943.)

FIG. 14. Inhibition of single neuron responses in the cochlear nucleus. A. The notched white line indicates the presentation of a faint tone of 9400 cps to the ipsilateral ear of a cat. This tone inhibits the spontaneous discharge of the neuron. B. The lower white line marks the duration of a faint 1300-cycle tone, which excites the neuron. The line above it indicates a 2400-cycle tone which inhibits the discharge resulting from the 1300-cycle tone. Records A and B are from different cats.

a tone that is slightly *higher* in frequency than that by which the neuron is most easily stimulated, but lower frequencies or noises also sometimes produce inhibition.

simultaneously (Fig. 14B). Not every neuron is subject to inhibition, and the effect usually occurs only when both tones are moderate or weak. Increasing the intensity

of an inhibiting tone sometimes shifts the effect abruptly from inhibition to excitation. Also the response to a strong tone is difficult to inhibit.

It is noteworthy that facilitation of the central effect of one tone by another is not described. If it occurs it probably is not very dramatic, at least at the level of the cochlear nucleus.

The mechanism of the inhibition is not a physical interference or cancelation of sound waves. The effect is certainly neural and almost certainly occurs at the first synaptic junctions of the auditory tract. As Lorente de N6 has pointed out, each second-order cell body is connected to a large number of auditory nerve fibers by the fine terminal endings of those fibers. Each nerve fiber innervates hundreds of cell bodies, he says, and each cell body is innervated by many nerve fibers. Such a complicated set of synapses should show the properties of all synapses in the nervous system, including the phenomenon of inhibition. We must admit, however, that both the mechanism and the functional significance of central inhibition are still obscure.

ELECTRICAL RESPONSES OF THE CENTRAL AUDITORY SYSTEM

The latency of impulses in the midbrain nuclei and pathways increases systematically as we go from first-order to second-order and then to third-order neurons. The increase in latency associated with each additional synapse is about 1 millisecond and is a little shorter for strong than for weak stimuli (Kemp, Copp6e, and Robinson, 1937; Kemp and Robinson, 1937).

The impulses in response to sustained tones do not appear to be so accurately synchronized in the higher auditory pathways as in the auditory nerve. Although isolated clicks may yield brief, clearly defined action potentials from the fourth-order

neurons in the cortex, synchronized impulses at frequencies above about 70 or 100 cps have not been found in the cortex (Bremer, 1943, 1947).

An absolutely unresponsive period of 20 to 100 milliseconds followed by gradual recovery during 100 to 250 milliseconds was found by Tunturi (1946) in the auditory cortex, the auditory radiations, and the medial geniculate bodies of dogs. Stimuli applied to one cochlea rendered the cortex refractory to stimuli applied to the corresponding region of the opposite cochlea. Below the medial geniculate body, however, the unresponsive period lasted only 1 to 2 milliseconds. The evidence suggests that there is a neuron, activated from symmetrical points in the two ears, that runs from the medial geniculate body to all three auditory areas in the cortex.

The electrical response of the cortex to auditory stimulation (even to sharp clicks) is difficult to demonstrate unless cortical activity is reduced or simplified by anesthesia or by sleep (Bremer, 1947). Small action potentials definitely associated with acoustic stimuli have been identified in the waking human electroencephalogram (P. A. Davis, 1939). These responses may, however, represent secondary reactions in large areas of the cortex (and presumably subcortical structures as well) outside the auditory projection area. Similar widespread cortical reactions in anesthetized animals have been produced by electrical stimulation of other sensory nerves (Forbes and Morison, 1939). The clearest generalized cortical response in man is the *K-complex* evoked during sleep by auditory stimulation (Loomis, Harvey, and Hobart, 1938; Davis et al., 1939). This combination of beta and delta waves probably represents a partial and transient arousal or awakening of the sleeping brain, and perhaps also a synchronous activation of whatever neural elements are responsible for the large slow waves of sleep.

Acoustic stimuli may also cause a transient suppression of the alpha waves in the wak-

ing human brain. This effect is apparently related to startle, to the attracting of attention, or even to the specific emotional value of the sounds or words.

Bremer and his colleagues have studied the reactions of the auditory area in the unanesthetized isolated brain of the cat (1947). Disturbing sensory impulses are largely eliminated by cutting the medial lemnisci, and the simplified regularized electrocorticogram suggests a state of normal repose bordering on sleep and alternating with periods of actual sleep. In the state of waking repose the suppression of regular slow (alpha) waves in all parts of the cortex by acoustic stimuli is very clear. In addition, the auditory cortex, but not other areas, shows an increase of waves (beta) that are faster but still fairly regular. The maximum frequency of the latter is 70 per second. The frequency depends on the intensity, *not* on the frequency, of the stimulating tone. Clicks, up to about 70 per second, give very clear diphasic "primary responses" (Bremer, 1943), followed by an acceleration and regularization of the electrical activity of the auditory area. The first phase of the primary response is surface-positive, and the latency is about 8 milliseconds. Both of these features are compatible with a response in fourth-order neurons of the thalamocortical radiations. Natural sleep and barbiturate anesthesia (unlike ether) depress the after-discharge selectively. They also reduce, slow, and simplify the spontaneous resting activity of the cortex. (Most of the mapping of the auditory cortex mentioned in an earlier section was done with barbiturate anesthesia.) Tonal localization was not observed by Bremer and his associates in the unanesthetized cortex (1943).

Audiogenic seizures. Epileptiform reactions are produced in some rats by acoustic stimuli. The reactions, including tonic seizures, clonic seizures, and racing seizures, resemble those produced by electrical stimulation of the cortex at appropriate intensities (Golub and Morgan, 1945). Generalized

electrical seizure patterns have been recorded from the cortex during audiogenic seizures (Lindsley, Finger, and Henry, 1942), but their origin is not specifically from the auditory cortex.

General emotional reactions. The fact that human brain waves are altered by sounds illustrates the general arousing or alerting action of auditory stimuli. In addition, emotional effects of loud sounds (startle, fright, fear) are seen even in newborn infants. A very different emotional reaction is the depression that is characteristic of adults who have suddenly been deprived, by disease or injury to the ear, of normal continual auditory stimulation (Ramsdell, 1947).

AUDITORY REFLEXES

Some of the phenomena mentioned above, such as the startle reaction, general alerting, and possibly audiogenic seizures, are akin to reflex responses. There are other more specific types of auditory reflexes.

Protective auditory reflexes. The tensor tympani and the stapedius muscles contract reflexly when the ear is stimulated by a strong sound. The latent period is about 10 milliseconds (Perlman and Case, 1941). The contraction takes up any slack in the ossicular chain. In more precise terms it adds both stiffness and damping to the transmission mechanism of the middle ear (Wever and Bray, 1937). The net effect of these changes, inferred from observations on cats and guinea pigs, is to raise slightly the natural period of the transmission system, and to reduce considerably the transmission for low tones (Wever and Bray, 1942; Wiggers, 1937). The transmission for high tones is unaffected or slightly reduced. For a band of middle frequencies, near 2000 cps, transmission may be slightly improved. A very vigorous contraction of the stapedius muscle, however, may greatly reduce transmission for all frequencies (Wever and Bray, 1942; cf. also Fig. 7). The reduced transmission

of low tones, which are mechanically dangerous because of their greater amplitude, justifies our classifying the reflex as "protective." The reflex is also elicited by tickling the skin in or near the external end of the ear canal.

A twitch of the pinna in response to a sudden sound is characteristic of many small animals, notably the guinea pig. The reaction has frequently been used as a rough test of the ability of the animal to hear. Its functional significance is uncertain, but it may represent a reflex closing of the external canal which protects the ear much as an eye-blink protects the eye.

Conditioned Auditory Reflexes

An effective method of conditioning cats for auditory studies is to place them in a rotating cage and deliver a shock after an auditory stimulus. The animal soon learns to move the cage and thereby avoid the shock whenever he hears the tone. Reliable 'audiograms' and measures of intensity discrimination have been made in this way (Kryter and Ades, 1943; Raab and Ades, 1946).

Complete bilateral removal of the auditory cortex causes total loss of auditory conditioned reflexes. If only a small portion of one auditory area remains, however, the simple avoidance reaction to a pure tone is retained. Raab and Ades consider this function of the cortex to be all-or-none in character.

After removal of the auditory cortex the CR can easily be reestablished, although a few more trials may be necessary than for an intact animal. The relearned response is not abolished by removal of the medial geniculate body, which, by this criterion, seems to have no reflex function. It is, however, abolished by removal of the inferior colliculi or their efferent pathway through the superior colliculi. But removal of the colliculi alone, leaving the lateral lemniscus, the medial geniculates, and the auditory cortex does not abolish the reflex. Apparently the

midbrain centers do not mediate the CR normally, but they can be trained to do so after removal of the cortex. The difference limens for intensity are as small for reflexes mediated at the midbrain level as at the cortical level.

Even after the cortex and the midbrain centers have been removed, auditory CR's can still be established. They are, however, less precise, and the latency of response is longer. The threshold is elevated, and intensity discrimination is impaired. The threshold of auditory acuity is elevated about 15 db after removal of the inferior colliculi (Kryter and Ades, 1943). If only the brain stem nuclei below the level of the inferior colliculus remain, the thresholds for motor CR are elevated about 40 db above the normal level.

In a study of auditory conditioned reflexes of dogs, Allen (1945) found that correct conditioned differential responses were abolished after bilateral destruction of all or part of the auditory cortex. They could be reestablished if only the projection areas I and II had been removed bilaterally or if all three areas were removed unilaterally (including Tunturi's area III or C). Bilateral destruction of all three did not prevent the reappearance of correct *positive* responses, but these dogs seemed to lack the ability to make correct *inhibitions*. A similar lack of correct inhibition in differential responses with two sets of general *cutaneous* stimuli was also observed after removal of Tunturi's third auditory area. The full functional significance of the two (and perhaps three) auditory areas is still uncertain, but we may hope for rapid clarification now that the areas have been defined.

A study of auditory conditioned reflexes by Neff (1947) is particularly interesting. The hearing of 11 cats was measured by CR before and after partial section of the auditory nerve on one side and complete destruction of the cochlea on the other. After the operation no hearing losses were detected, at octave frequencies from 125 through 8000

cps, unless at least half of the nerve was sectioned. All losses that were found were extensive high-tone losses, beginning at or (usually) above 1000 cps. These systematic hearing losses resulting from presumably varied lesions are surprising, but they correspond to some very similar clinical observations by Dandy on patients operated for Ménière's disease.

The ears of several of these same cats were studied electrically (5 animals) and histologically (7 animals) by Wever (Wever and Neff, 1947). The aural microphonics were normal for 4 of the 5, and depressed for high frequencies in the fifth. Only in this last animal had any of the hair cells degenerated, and here only in the basal turn. All the ears showed degeneration of some or many nerve fibers, but in all ears that had given evidence of any hearing (by CR) there was at least a short stretch of intact nerve supply at the apical end. This situation corresponds to their retention of normal hearing for the low tones. The data also show that tones below 1000 cycles were heard normally by a cat in which only the last few millimeters at the apical end were normally innervated. The question why the apical nerve fibers were systematically spared remains unanswered.

IMPAIRMENTS OF HEARING

Five main types of auditory impairment are recognized (Davis et al., 1947). We shall consider each of them in turn.

Conductive Deafness

Conductive deafness usually depends on an obvious mechanical abnormality of the conductive system, such as plugging of the external ear by wax, restriction of the movement of the ossicles by abnormal tension on the ear drum (barotrauma) or by pus or fluid or scarlike adhesions (otitis media), loss of drum and/or ossicles (chronic otitis media and radical mastoidectomy), or pathological fixation of the stapes in the oval win-

dow (otosclerosis). The hearing loss is in general fairly uniform as a function of frequency, a "flat hearing loss," but either the high or the low tones may be selectively impaired. The conductive impairment may also be analyzed in acoustic terms by measuring the acoustic impedance of the ear (Metz, 1946; Perlman, 1946) and by interpreting the abnormality in terms of changes in the mass, the stiffness, and the resistance of the ear as an acoustic load.

The bones of the skull, as well as the specialized conductive mechanism of the external and middle ear, conduct sound to the inner ear. Even if the acoustic energy is not delivered preferentially to the skull, as by a bone-conduction receiver of an audiometer or a hearing aid, the skull is set in vibration to some extent by airborne sound waves from a headphone or in a free field. The basilar membrane is set in motion by the bone-conducted sound by mechanisms described in the previous chapter, and therefore conductive hearing loss can never be complete.

The movements of the basilar membrane induced by bone conduction may be opposite in phase to those produced by air conduction (Békésy, 1941). It has been suggested, therefore, that at some stage in the development of conductive deafness in otitis media and particularly in otosclerosis there should be a stage of total deafness when the reduced air conduction exactly balances the bone-conducted waves of opposite phase. Clinically such an intermediate stage of very profound deafness is not seen. The suggestion is naïve, however, for it assumes that the relative efficiency of pickup of acoustic energy by bone and by air conduction is constant in amplitude and phase regardless of the orientation of the head to the sound source (cf. Lowy, 1942).

Nerve Deafness

Nerve deafness has both physiological and anatomical bases. The thresholds of some or all of the essential sensory cells of the organ of Corti may be temporarily elevated by

fatigue or partial injury; and the sensory cells, auditory nerve fibers, or both, may degenerate entirely. Degeneration may be spontaneous, as in hereditary nerve deafness or the partial high-tone nerve deafness of old age. It may depend on, or be accelerated by, toxic agents (quinine and the toxins of certain diseases such as scarlet fever, measles, etc.). Infection may attack the inner ear directly (meningitis), or the auditory nerve may be mechanically compressed by a tumor. Once a fiber of the auditory nerve has been cut, the entire neuron including the cell body degenerates and does not regenerate. Hair cells deprived of their innervation usually degenerate ultimately—but not immediately, unless their blood supply is also impaired.

Another important cause of degeneration of hair cells is acoustic trauma from loud sounds (Davis et al., 1946; Lurie, Davis, and Hawkins, 1944; Rüedi and Furrer, 1946; Perlman, 1941). A blast or very intense continued sound may disrupt the conductive mechanism, or the organ of Corti, or both. Less intense sounds produce a temporary impairment of function. The external hair cells are more susceptible to permanent injury than the internal, and the cells responsible for the hearing of tones of about 4000 cps are particularly vulnerable. A 'dip' in the audiogram at 4000 cps is often seen in men who have been exposed to very loud sounds from machinery or gunfire, but a similar dip often occurs spontaneously from hereditary or other obscure causes (Wever, 1942).

There are two curious but consistent relations between nerve deafness and sound frequencies perceived. (1) The temporary nerve deafness produced by exposure to an intense pure tone causes hearing loss for tones *above* but not below the frequency of the exposure tone. The maximum loss is from half an octave to an octave above the exposure tone. Sensitivity for the exposure tone may be somewhat impaired, but always to a lesser degree. (2) Permanent nerve

deafness from whatever cause almost always impairs hearing for high tones more than the hearing for lower tones. A partial exception to this rule is the special vulnerability at about 4000 cps, but even in severe congenital or toxic nerve deafness there is likely to be some residual hearing for tones below 1000 cps. The transition from slight or moderate nerve loss for low tones to complete loss for high tones may be gradual, but sometimes it is very abrupt. The audiogram may fall off more than 40 db per octave. Corresponding abrupt low-tone hearing losses do not occur.

The foregoing description of nerve deafness, based on the threshold of hearing, is incomplete. Equal-loudness contours, determined by matching the loudness at various frequencies to the loudness of a standard 1000-cycle tone, become more and more nearly normal as louder and louder levels are explored. As a corollary of this proposition we find that, as the intensity of an exploring tone delivered to a partially nerve-deaf ear is increased, the perceived loudness of the tone increases more rapidly than it does for a normal ear. This effect is known as "recruitment" of loudness or as "regression" (Bruine-Altes, 1946), and, because of it, nerve deafness is sometimes called "variable" deafness. A practical result of this effect is that a partially nerve-deaf person may hear and discriminate speech sounds better at high intensities than his threshold audiogram would suggest.

The *threshold of discomfort* for loud sounds (about 120 db) is, on the average, about the same for hard-of-hearing as for normal ears (if the tones can be heard at all), even though the ear may show a high-tone hearing loss (Silverman, 1947). The thresholds of *tickle* and of *pain*, mediated by other sense modalities, are also about the same for hard-of-hearing ears as for normals, although there is a scatter of values over a range of about 20 db for both groups.

The mechanism of recruitment is not clear, but apparently recruitment appears when

the organ of Corti is abnormal, as in Ménière's disease, but not when the auditory nerve is injured, as by a tumor in the auditory canal (Dix, Hallpike, and Hood, 1948). We may suppose that auditory elements whose thresholds are high may be less susceptible to injury and degeneration than low-threshold elements, and that they may contribute proportionately a much greater share of subjective loudness; or there may be a nonlinear law of central summation of neural activity, analogous to recruitment of motor units in reflex motor responses, that obscures the loss of the low-threshold elements when the total activity becomes great.

Central Deafness

Central deafness may be physiological in origin, sometimes based on definite anatomical abnormalities, or it may be psychological or psychogenic. A psychological or functional hearing loss may be combined with a partial conductive or perceptive hearing loss as an 'overlay.' The functional character of the overlay is demonstrated when the hearing loss is relieved by appropriate psychiatric treatment. It is usually a form of hysteria or a conversion neurosis. This condition was clearly demonstrated in a considerable percentage of cases of hearing loss incurred in military service when they were treated by *narcosynthesis* (Martin, 1946).

Loss of understanding of the meaning of sounds, especially of speech, is another form of central deafness. This condition is termed *aphasia*. It may depend on definite injury to parts of the auditory cortex and/or its association areas. This condition, like psychogenic or hysterical deafness, has its counterparts in other sense modalities. Aphasia and psychogenic deafness are auditory only in their specific manifestations, not in their basic nature. Specific auditory impairments of thresholds, of discrimination, and of conditioned reflexes due to lesions of the auditory pathways (in animals) have been described in a previous section. It must be remembered, however, that in primates and

man, according to the principle of encephalization, the auditory impairment caused by cortical injury tends to be more severe than in dogs, cats, and other animals.

Diplacusis

Diplacusis, or false sense of pitch, may depend on a physical abnormality. Apparently edema or "hydrops of the labyrinth" may cause a slight shift of the pattern of vibration on the basilar membrane and a consequent change in the pitch of the sensation aroused by a tone of a given frequency (Shambaugh, 1940). Small differences in the 'tuning' of the two ears can also be found in many, perhaps most, normal individuals (Stevens and Egan, 1941; see also Chapter 25).

Tinnitus

Ringings in the ears and other head noises (except hallucinations, which are considered central in origin) heard in the absence of physical sound are physiological phenomena. They undoubtedly represent a spontaneous discharge of sensory elements in the auditory system. The usual source is an irritation or hypersensitivity of the hair cells or their nerves. A small amount of spontaneous activity is probably normal and presumably accounts for the faint 'white' noise or the faint ringing heard by almost everyone in a very quiet room. Tinnitus may become very loud (and annoying) after exposure to a loud sound. Here it is clearly an after-effect of mild mechanical injury to some of the hair cells. Tinnitus is often present in ears in which sensory degeneration seems to be in progress, as in progressive high-tone nerve deafness. The pitch of the tinnitus usually corresponds to a frequency for which hearing is impaired but not lost. It is a frequent symptom in otosclerosis, and may be caused (by some unknown mechanism) by irritation in the middle ear and even in the external canal. It is a constant feature and may be very severe in Ménière's disease. Here the symptom of vertigo (abol-

ished by destruction of the labyrinth or section of its nerve) indicates clearly a severe irritation of the labyrinthine sense organs. Mechanical irritation of the cochlear nerve, as by a tumor, may cause very severe, continuous, and distressing tinnitus.

Tinnitus causes a partial hearing loss for tones of the same or neighboring pitch. The hearing loss, measured by audiometer, is usually exaggerated because of the subject's uncertainty as to whether he hears the test tone or his tinnitus. There is usually some true loss of acuity, probably due to a physiological masking by a 'line-busy' effect, but it seldom amounts to more than 15 db, in spite of subjective impressions that head noises are much louder than this.

The pitch of a tinnitus may be very distinct, particularly when it is high pitched, and sometimes it may be accurately matched by an exploring tone. In other cases it resembles a vague low-pitched roar or even a wide band of noise. Attempts have been made to detect beats between a tinnitus and an exploring tone (Davis et al., 1946). All subjects but one have reported that beats are absent, and most investigators view with suspicion the classic positive report (Wegel, 1931).

PSYCHOPHYSIOLOGICAL INTERPRETATIONS

We are still far from a complete auditory theory, particularly in regard to the final psychophysiological steps. The early biophysical steps and some of the physiological correlates of the physical stimulus and of auditory sensation are fairly clear, however. There is good agreement as to the general structure of the physiological code of audition.

The two chief attributes of auditory sensation are pitch (correlated almost uniquely with the frequency of sound waves) and loudness (correlated strongly but not uniquely with their intensity). The out-

standing features of the neuroanatomical and physiological system are:

1. Multiple levels. There are primary, secondary, tertiary, etc., neurons that connect the sense organ with the lowest nerve center, the lowest with the next higher center, and so on. In these centers there are interconnections between neuron chains of the same side and also from one center to its opposite. Here integration can occur.

2. Orderly spatial arrangement of the primary sensory surface and its projection at various levels in the central nervous system.

3. Multiple representation of the primary sensory surface at each level beyond the primary neuron.

4. The all-or-none law of transmission in neurons, and the limitations on frequency of discharge imposed by the refractory period.

5. Summation or integration of neural activity, both excitatory and inhibitory, not only in space (neuronal branching) but also in time (delay paths, after-discharge, and persistent subliminal changes of excitatory state).

6. The possibility of nonneuronal integration (electrical and/or chemical field effects) in nerve centers. This last principle is not yet clearly defined in neurophysiology and should not be invoked in present theory unless absolutely required.

It is generally accepted that movement of the basilar membrane somehow excites impulses in the nerve fibers that innervate the hair cells of the organ of Corti. The activity of single second-order neurons shows just the sort of selectivity in relation to frequency that would be expected from the anatomical distribution of the fibers of the auditory nerve and from direct observation of the regions of maximum amplitude of vibration of the basilar membrane. It is helpful to assume that the thresholds of different hair cells (or their nerve fibers), defined in terms of the amplitude of movement of the basilar membrane, vary in some consistent way. This makes it easier to explain intensity discrimination over a wide

range of intensities. The only plausible explanations of intensity discrimination seem to be on the basis of (1) number of fibers activated, or, better, (2) the total number of impulses per second in all fibers, or, still better, (3) a composite of number of impulses per second and a selective contribution to loudness from a class of fibers with relatively high threshold.

Auditory information on its way to the brain passes through its narrowest bottleneck in the auditory nerve. Here, in the first-order neurons, the limitations of the all-or-none law and the refractory period of nerve apply in full force. The pathways have not yet branched to provide the additional possibilities of temporal summation and spatial interaction. The latter may be part of the mechanism for decoding the condensed information transmitted up the nerve. In our present ignorance it is useless to speculate on the elaboration of patterns of neural activity in the nerve centers, or on the physiological basis of sensation. The crux of present auditory theory is the form in which information is conveyed in the auditory nerve, for (except for binaural effects) no information can be added beyond the internal auditory meatus.

For tones up to 1000 cps, or even a little higher, a frequency theory of pitch is possible. The impulses pass up the auditory nerve in well-defined volleys. The frequency of discharge in tactile fibers seems to be the basis of our ability to discriminate different rates of vibration. A frequency theory of pitch for these low tones is certainly possible, and it is favored by several students of auditory physiology as an adjunct to the place principle (Wever, 1939). This theory postulates a gradual transition from the place principle to the frequency principle *somewhere within the audio range* instead of at the transition from the sense of touch to the sense of hearing. In favor of this theory are (1) the very vague localization on the basilar membrane of any area of maximum excursion for low tones, (2) the

difficulty of selectively eliminating low-tone fibers by surgical section, and (3) the perception of periodicity (discussed in Chapter 25).

A few investigators still adhere to the generally discarded notion of a series of lightly damped resonators along the organ of Corti. Light damping allows the theoretical possibility of relatively sharp tuning, but the weight of evidence is heavily on the side of nearly critical damping of the basilar membrane. Pumphrey and Gold (1947) suggest that the damping of the organ of Corti is light and that it varies systematically from apex to base. Their observations on the recognition of the pitch of brief pulses of tone can be interpreted otherwise, however. Galambos' demonstration (1944) of inhibitory interaction between tones only slightly different in frequency provides a theoretical explanation for sharp frequency discrimination. Galambos also demonstrated some very sharp tuning of second-order neurons in cats. The gradient of activity among adjacent second-order nerve fibers can apparently be sharper than would seem likely from the small differences in the amplitude of vibration along the basilar membrane.
