Cell Stem Cell

MLL1 Inhibition Reprograms Epiblast Stem Cells to Naive Pluripotency

Graphical Abstract

Highlights

- MLL1 inhibition by MM-401 promotes reversion of EpiSCs to naive pluripotency

- MLL1 controls the rate-limiting step in EpiSC reprogramming

- An MLL1-dependent gene network is identified in pluripotent stem cells

- Epigenetic perturbation is sufficient to initiate EpiSC-to-ESC reversion

In Brief

Zhang et al. show that blocking the histone methyltransferase MLL1 with the small-molecule inhibitor MM-401 is sufficient to reprogram epiblast stem cells to naive pluripotency with high efficiency and synchronicity. They further find global redistribution of H3K4me1, causally linking MLL1-dependent H3K4 methylation to pluripotent cell fate.

SUMMARY

The interconversion between naive and primed pluripotent states is accompanied by drastic epigenetic rearrangements. However, it is unclear whether intrinsic epigenetic events can drive reprogramming to naive pluripotency or if distinct chromatin states are instead simply a reflection of discrete pluripotent states. Here, we show that blocking histone H3K4 methyltransferase MLL1 activity with the small-molecule inhibitor MM-401 reprograms mouse epiblast stem cells (EpiSCs) to naive pluripotency. This reversion is highly efficient and synchronized, with more than 50% of treated EpiSCs exhibiting features of naive embryonic stem cells (ESCs) within 3 days. Reverted ESCs reactivate the silenced X chromosome and contribute to embryos following blastocyst injection, generating germline-competent chimeras. Importantly, blocking MLL1 leads to global redistribution of H3K4me1 at enhancers and represses lineage determinant factors and EpiSC markers, which indirectly regulate ESC transcription circuitry. These findings show that discrete perturbation of H3K4 methylation is sufficient to drive reprogramming to naive pluripotency.

INTRODUCTION

Several metastable pluripotent states arise from either developing embryos in vivo or cell cultures in vitro (Cahan and Daley, 2013; Nichols and Smith, 2009). Mouse embryonic stem cells (ESCs) derived from the embryonic inner cell mass (ICM) represent the naive pluripotenct state. Naive ESCs harbor the requisite developmental potency and flexibility to produce all embryonic lineages when injected into the blastocyst embryo. Upon implantation, epiblast precursors differentiate to a "primed" pluripotent state in the post-implantation epiblast stem cells (EpiSCs). This primed state can be recapitulated by culturing ESCs in medium containing basic fibroblast growth factor (bFGF) (also called

FGF2) and Activin in vitro (Brons et al., 2007; Tesar et al., 2007). ESCs and EpiSCs represent two distinct pluripotent states and have different characteristics with regard to morphology, growth factor dependency, epigenetic states, and the ability to integrate into ICM and contribute to the germline (Nichols and Smith, 2009). EpiSCs and ESCs are interconvertible. Transition from ESCs to EpiSCs is relatively straightforward and can be achieved by adapting culture conditions (Buecker et al., 2014; Schulz et al., 2014). In comparison, EpiSC reversion to ESCs, either spontaneously or through 2i treatment, is extremely inefficient (Bao et al., 2009; Han et al., 2010). EpiSC reversion can be facilitated by overexpression of specific factors such as Klf4 (Guo et al., 2009), Klf2 and Nanog (Stuart et al., 2014), Esrrb (Festuccia et al., 2012), Tfcp2l1 (Ye et al., 2013), and Nr5a (Guo and Smith, 2010) or by deletion of Mbd3 (Rais et al., 2013). With the exception of Mbd3 deletion, whose role in reprogramming is still being debated (dos Santos et al., 2014), these manipulations shunt EpiSCs back to ESCs at a conversion rate of ~1%–5%, even in the presence of 2i and leukemia inhibitory factor (LIF) (Nichols and Smith, 2009). The low efficiency associated with EpiSC reprogramming suggests that there could be an unknown transcriptional or epigenetic barrier that prevents reversion of developmental commitments.

Mechanistic studies show that conversions between ESCs and EpiSCs are accompanied by dramatic reorganization of the epigenetic landscape (Buecker et al., 2014; Factor et al., 2014; Gafni et al., 2013). The transition of naive ESCs to EpiSCs is accompanied by global upregulation of H3K27me3 and DNA methylation (Theunissen et al., 2014), concomitant with the rise of heterochromatin in EpiSCs (Orkin and Hochedlinger, 2011). Consistently, X chromosome inactivation in female cells is a hallmark that differentiate the primed versus naive pluripotent state (De Los Angeles et al., 2015). In contrast to repressive chromatin marks, there is no global change in the level of H3K4me between ESCs and EpiSCs (Li et al., 2012; Marks et al., 2012). However, dynamic modulation of H3K4me at key regulatory loci has been described (Papp and Plath, 2013; Voigt et al., 2013). Emergence of "poised" enhancers that are critical for differentiation and decommissioning of "seed" enhancers that are important for naive pluripotent state have also been reported (Buecker et al., 2014; Factor et al., 2014). Notably, despite extensive studies depicting epigenetic changes, it is

CellPress

not clear whether they are merely the consequence of rewiring of the regulatory and transcription circuitry during cell fate alteration. Causative epigenetic modifications that are able to initiate EpiSC reversion and reset the naive pluripotent state remain largely unknown.

In metazoans, H3K4me is mainly deposited by the MLL family histone methyltransferases (HMTs) (Rao and Dou, 2015). The activities of the MLL family HMTs are tightly regulated by a core complex containing several conserved interacting proteins (i.e., WDR5, RbBP5, and ASH2L) (Dou et al., 2006). Given the highly accessible and hyperactive chromatin structures in ESCs, it is generally assumed that H3K4me plays an important "housekeeping" role in ESCs and is necessary for ESCs to maintain self-renewal and unlimited differentiation potential (De Los Angeles et al., 2015). However, genetic studies show that depletion of core components of the MLL complexes, WDR5 or ASH2L/DPY30, leads to distinct outcomes (Ang et al., 2011; Jiang et al., 2011). Furthermore, deletion of *Mll1*, *Mll2*, or *Set1a* gene in ESCs has no major effects on ESC self-renewal despite their essential functions during embryonic development in vivo (Bledau et al., 2014; Ernst et al., 2004; Glaser et al., 2009). These studies raise the question of whether H3K4me plays important roles in the pluripotent stem cells and, if so, what its function is. In this study, we use a small-molecule inhibitor MM-401 that specifically targets MLL1, but not other MLL family HMTs (Cao et al., 2014; Karatas et al., 2013), and demonstrate that MLL1-mediated H3K4me is an intrinsic epigenetic determinant that regulates acquisition of differentiated pluripotent identity. Blocking MLL1 function is sufficient to reprogram EpiSCs to naive pluripotency.

RESULTS

MLL1 Is Upregulated during ESC Differentiation to EpiSCs

Upon examination of expression of the MLL family HMTs (through FUNGENE database) (Fish et al., 2013), we found that although most MLL family HMTs (i.e., *Mll1-4*, *Set1a*, and *Set1b*) as well as components of their residing complexes (e.g., *Wdr5*, *Rbbp5*) were expressed in ESCs, their respective expression pattern during spontaneous ESC differentiation was different (Figure S1A). Notably, *Mll1* was dynamically regulated at different time points during ESC differentiation, being upregulated at days 2–3, day 6, and day 10.5, respectively (Figure S1A). Consistently, upregulation of *Mll1* at both early and late stages of embryonic development (Kojima et al., 2014) was also found in vivo (Figure S1B). Interestingly, early upregulation of *Mll1* coincided with that of the epiblast marker *Fgf5* and was reversely correlated with naive pluripotent cell maker *Rex1* (Figure S1B). Examination of *Mll1* expression in multiple ESC and EpiSC lines confirmed that *Mll1* expression was correlated more with that of EpiSC markers (e.g., *Fgf5*, *Cer1*) than naive stem cell markers (e.g., *Nanog*, *Rex1*) (Figures S1C and S1D). As a control, expression of *Wdr5* and *Rbbp5*, two common components of the MLL family complexes, did not show correlation with EpiSC markers (Figure S1C). The RNA-sequencing (RNA-seq) results were validated by real-time RT-PCR for expression of *Mll1*, *Mll3*, and *Wdr5* as well as selected pluripotent stem cell markers in ESCs and EpiSCs (Figure S1D).

MLL1 Regulates ESC Differentiation to EpiSCs

To test whether MLL1 and its H3K4 methyltransferase activity play roles in ESC differentiation to EpiSCs, we used our recently developed inhibitor MM-401, which inhibits MLL1 activity by blocking the MLL1-WDR5 interaction (Cao et al., 2014). To determine MM-401 dose, we first treated *Mll1*^f/f and *Mll1*^−/− ESCs with increasing concentration of MM-401 for either 3 or 6 days. Enantiomer MM-NC-401 or DMSO was used as the controls. As shown in Figure S2A, both MM-NC-401 and MM-401 showed toxicity at concentrations above 100 μM after 6-day treatment, inhibiting growth of both *Mll1*^f/f and *Mll1*^−/− ESCs (Figure S2A and data not shown). Notably, MM-401 had no effects on *Mll1*^−/− ESCs at concentrations of 100 μM or lower despite modest growth inhibition on *Mll1*^f/f ESCs. On the basis of these results, we decided to use 50 or 100 μM MM-401 in our assays to avoid toxicity or off-target effects. At these concentrations, MM-401 had no effects on EpiSC growth (Figure S2B), cell attachments after passaging (Figure S2C), and embryoid body (EB) formation (data not shown).

Whereas both MM-401 treatment and *Mll1* deletion had no effects on ESC self-renewal as demonstrated by strong alkaline phosphatase (AKP) staining (Figure S2D), they led to reduced expression of epiblast markers (i.e., *Mixl1*, *Wnt3*, and *Evx1* and *Fgf5*), at early stage of EB differentiation (Figure S2E). To directly test whether MLL1 inhibition or deletion affects EpiSC differentiation, ESCs treated with either 4-hydroxytamoxifen (4-OHT) (for *Mll1* deletion) or MM-401 (for *Mll1* inhibition) were cultured in bFGF/Activin A/knockout serum replacement (KSR) media. It has been reported that bFGF/Activin A leads to efficient ESC to epiblast-like cell (EpiLC) differentiation in vitro, as demonstrated by weakened AKP staining and loss of *Rex1* expression (Schulz et al., 2014). Interestingly, this process was delayed by *Mll1* deletion or MM-401 treatment. After 72 hr culture in EpiLC-promoting conditions, a significant number of *Mll1*^−/− and MM-401-treated colonies retained strong AKP staining compared with untreated *Mll1*^f/f ESCs that had attenuated AKP staining (Figure S2F). Taken together, these data show that genetic deletion or pharmacologic MLL1 inhibition impairs ESC differentiation to EpiLCs.

Inhibition of MLL1 Promotes Reversion of EpiSCs to ESCs

We next considered the possibility that MLL1 inhibition might promote naive pluripotent state. To test this, we treated the EpiSC line (#9F) with MM-401 in LIF/KSR or bFGF/KSR media for 72 hr and continued to culture the cells in the presence of MM-401 and LIF/KSR beyond 6 passages (Figure 1A). To our surprise, EpiSC clones that had flat morphology, had weak AKP staining, and lacked expression of REX1 (Factor et al., 2013; Tesar et al., 2007), changed dramatically upon MM-401 treatment. The clones became dome shaped with compact cells in the center and exhibited intense AKP staining (Figure 1B). Continued culturing of the ESC-like clones in MM-401 and LIF/KSR medium for 6 passages led to establishment of stably reverted ESC (rESC) lines (MLL1i-rESC). The MLL1i-rESCs had high expression of naive ESC markers PECAM1 and REX1 (Figures 1C and 1D) as well as homogeneous expression of Nanog (Figure 1D). These naive ESC characteristics (dos Santos et al., 2014; Stuart et al., 2014; Takashima et al., 2014) were stably

(F) AKP staining of cells as indicated. bFGF/KSR or LIF/KSR media were used as indicated at left. One hundred to 210 clones were quantified for AKP^{2+} and morphology change under each condition. Experiments were repeated at least twice. The scale bar represents 200 μm.

See also Figures S1–S3.

larly, strong AKP staining was detected for 33.8% clones in media containing bFGF/KSR and MM-401 (Figure 1F). Notably, MM-401 mediated reversion was much more efficient than spontaneous or 2i-induced EpiSC conversion (Figures 1E and 1F) (Greber et al., 2010; Lanner and Rossant, 2010).

MLL1 Inhibition Reactivates Silenced X Chromosome in EpiSCs

One hallmark of the naive ESCs compared with the primed EpiSCs is the lack of inactive X chromosome (Xi) in female cells (De Los Angeles et al., 2015). Therefore, reactivation of Xi has been used as a bona fide marker for successful EpiSC reprogramming in vitro (Han et al., 2011). To examine whether MLL1 inhibition reactivates Xi in EpiSCs, we used a female EpiSC line (12F) derived from F1 hybrid embryos that carry polymorphic X chromosomes (*Mus musculus*-derived X^{Lab} and *Mus molossinus*-derived X^{JF1}) (see Experimental Procedures). As shown in Figure S3C, the X^{Lab} X chromosome harbors a *Gfp* transgene and a small deletion of the *Tsix* gene *(ΔTsix)*, while the X^{JF1} X chromosome is wild-type (Gayen et al., 2015). In this cell line, the X^{Lab} X chromosome exclusively expresses the *Xist* RNA and undergoes X-inactivation (Gayen et al., 2015). Reactivation of X^{Lab} allele in this cell line could be monitored via re-expression of *Gfp* transgene. Strikingly, MM-401 treatment led to GFP expression from the inactivated X^{Lab} allele after three days (Figure 2A, right). Half of the cells (~51.6%) in culture were GFP$^+$ at day 3, with concomitant morphological changes and PECAM1 expression (Figure 2A and data not shown). After two passages (~8 days), almost all clones in culture showed homogeneous GFP expression

maintained even after MM-401 was withdrawn for at least 30 passages (Figure S3A). To our knowledge, reversion of EpiSCs to ESCs by targeting a discrete histone modification has not yet been described and warranted further analyses.

To quantify EpiSC reversion efficiency en masse, we performed fluorescence-activated cell sorting (FACS) analysis on PECAM1 following treatment with MM-401. Interestingly, 49.1% and 32.0% EpiSCs that were cultured with LIF/KSR and with bFGF/KSR, respectively, showed increased PECAM1 expression as early as 72 hr after MM-401 (100 μM) treatment (Figure 1E). Despite initial expression of PECAM1, the naive pluripotency characteristics could not be stably maintained in cells cultured with bFGF/KSR and MM-401. The cells gradually lost PECAM1 expression after passaging (Figure S3B). Similar to EpiSC reversion en masse, MLL1 inhibition also led to rapid clonal reversion in a dose-dependent manner. About 25% and 48% EpiSC clones gained strong AKP staining after 72 hr of 50 and 100 μM MM-401 treatment, respectively (Figure 1F). Simi-

See also Figure S3.

(Figure 2B). To test clonal conversion efficiency by reactivation of the Xi chromosomes, we seeded 300 EpiSCs in 32 wells, which led to ~90 clones in each well with ~31% plating rate (Figure S3D). MM401 treatment did not affect EpiSCs seeding or attachment (Figure S3E). After 3 days of MM-401 treatment,

GFP⁺ clones emerged in all 32 wells in the presence of either LIF or bFGF (Figure S3F). About 45% (LIF) and 30% (bFGF) of clones in each well were GFP⁺ (Figure S3D, bottom). No GFP⁺ clones were observed in wells seeded with untreated EpiSCs (Figures S3D and S3F). These results suggest that initiation of

EpiSC reprogramming to ESC by MM-401 is efficient, synchronized, and independent of exogenous LIF or bFGF signaling.

To test whether Xi-reactivation was stably maintained in MLL1i-rESCs, we examined expression of the X-linked genes from X^{Lab} allele after multiple passages. Transcripts from genes on X^{Lab} can be distinguished from those on X^{JF1} by SNPs (Gayen et al., 2015; Maclary et al., 2014). We analyzed two transcripts associated with SNPs at *AtrX* (SNP 4393) and *Rnf12* (SNP 860) genes in the 12F EpiSC line and reverted MLL1i-rESCs. In EpiSCs, all *Atrx* and *Rnf12* transcripts were from the X^{JF1} chromosome that had adenosine at SNP 4693 and SNP 860, respectively (Figure 2C, left). In MLL1i-rESCs, however, *Atrx* and *Rnf12* transcripts were detected from both X chromosomes (Figure 2C, right). The comparable Sanger chromatogram peaks of the two alleles indicated that X^{Lab} in EpiSCs was stably reactivated, confirming stable EpiSC reversion.

MLL1 Inhibition Robustly Reprograms Multiple EpiSC Lines In Vitro

To rule out that the reactivation of the Xi-chromosome after MM-401 treatment was affected by the *Tsix* mutation in the 12F EpiSC line, we used fluorescence in situ hybridization (RNA-FISH) to examine X chromosome reactivation in another female EpiSC line (9F) that carried two wild-type X chromosomes. RNA-FISH experiments for the 12F EpiSC line and a male EpiSC line (22M) were included as the controls. RNA-FISH probes against Xist/Tsix (green) and Atrx (red) were used to differentiate inactive versus active X chromosomes as previously described (Gayen et al., 2015; Maclary et al., 2014). As shown in Figure 2D, both 9F and 12F EpiSCs showed Xist "cloud" on the Xi-chromosome and Atrx expression on the active X chromosome. However, the MM-401-treated 9F MLL1i-rESCs showed bi-allelic expression of *Atrx* and *Tsix* with simultaneous loss of Xist-coating (Figure 2D, middle right), which indicated activation of both X chromosomes. The control 12F MLL1i-rESCs showed bi-allelic expression of *Atrx* and single-allelic expression of *Tsix* due to *Tsix* mutation on the X^{Lab} allele (Figure 2D, bottom right). The percentages of 9F and 12F MLL1i-rESCs with bi-allelic expression of *Atrx* were 80% and 75%, respectively (Figure 2E). *Tsix* and *Atrx* expression was also detected from the only X chromosome in male 22M EpiSCs and its derived MLL1i-rESCs (Figure 2D, top).

To assess whether pharmacologic MLL1 inhibition could revert EpiSC to naive ESCs across diverse genetic backgrounds and/or gender, we treated MM-401 on separately derived, additional EpiSC cell lines including inbred 129.1M (male) and 129.1F (female) from the 129/Sv mice and F1 hybrid 12M (male) and 22M (male) from a cross of *M. musculus* and *M. molossinus* mice, as previously described (Gayen et al., 2015). We similarly treated a previous female EpiSC line 129.T (Tesar et al., 2007). As shown in Figure 3A, 3-day MM-401 treatment of the EpiSC lines led to a substantial increase in reversion regardless of genetic background. Similar to 9F cells (Figure 1E), MM-401 treatment led to an increase of PECAM1$^+$ cells from initial 2.3% ± 1.1% to 45.4% ± 4.8% and 34.2% ± 1.3% in LIF/KSR or bFGF/KSR, respectively (Figure 3A, middle and right). Homogeneous expression of naive pluripotent markers REX1 and NANOG in these cells further confirmed that these cells had undergone reversion (Figure S3G). Taken together, our studies showed

that MLL1 inhibition robustly reprogrammed multiple EpiSC lines to naive ESCs in vitro.

MLL1 Deletion Induces Reversion from the Primed State In Vitro

To confirm that MM-401 acted through MLL1 inhibition during reversion, we tested whether genetic deletion of *Mll1* gene promoted reversion of the primed state to the naive pluripotent state. To this end, we derived the EpiLCs from the *Mll1*$^{fl/fl;ER-cre/+}$ ESCs as previously described (Schulz et al., 2014). *Mll1* deletion in the cells could be efficiently induced by 4-OHT treatments (Figure S3H). Mock-treated EpiLCs were stable under our assay conditions as demonstrated by lack of expression of PECAM1 and REX1 at all time points (Figures 3C and 3D). Similar to MM-401 treatment, *Mll1* deletion led to REX1 expression as early as 48 hr after 4-OHT treatments (Figure 3B). Marked and homogeneous NANOG expression was also observed upon *Mll1* deletion (Figure 3B). The reversion efficiency of *Mll1*$^{-/-}$ EpiLCs to ESCs was quantified by FACS analyses on PECAM1$^+$ (Figure 3D). About 50% of cells after *Mll1* deletion became PECAM1$^+$ (Figure 3D). To further demonstrate that loss of MLL1 indeed led to EpiSC reversion, we depleted MLL1 by small hairpin RNA (shRNA) in the EpiSC line 12F ($X^{lab;\Delta TsixGFP}$;X^{JF1}) (Figure 2). MLL1 shRNA was confirmed by real-time PCR and immunoblot (Figure S3I). After 72 hr of shRNA treatment, 55% of *Mll1 shRNA* transfected EpiSCs (RFP$^+$) showed Xi-reactivation, as indicated by GFP fluorescence (Figure S3J). No cells that were transfected with scrambled shRNA had GFP expression (Figure S3J). Taken together, these results strongly argue that blocking MLL1 is the causal epigenetic change that promotes EpiSC reprogramming. These results also confirm that MM-401 promotes EpiSC reversion via MLL1 inhibition.

MLLi-rESCs Are Developmentally Competent In Vivo

To determine whether rESCs derived by MLL1 inhibition are pluripotent in vivo, we tested the ability of MLL1i-rESCs in developing teratomas in vivo. To this end, we engrafted 12F MLL1i-rESCs to severe combined immunodeficiency (SCID) mice and monitored growth of teratomas. We also engrafted the *Mll1*$^{flox/flox}$ and *Mll1*$^{-/-}$ ESCs into SCID mice as the control. After 6 weeks, *Mll1*$^{-/-}$ rESC-derived teratomas were much smaller in size (Figure 4A) and showed defects in ectoderm and mesoderm differentiation (e.g., red blood cells and blood vessel formation) (Figure S4B), consistent with previous reports on *Mll1* null ESCs (Ernst et al., 2004; Katada and Sassone-Corsi, 2010; Yu et al., 1995). In contrast, the stably established MLL1i-rESCs showed no defects in teratoma development (Figure 4A). MLL1i-rESCs-derived teratomas contained well-differentiated endoderm, ectoderm, and mesoderm tissues indistinguishable from those of *Mll1*$^{flox/flox}$ ESCs (Figures 4B and S4A). The differences between MLL1i-rESCs and *Mll1*$^{-/-}$ rESCs are due to reversible effects of pharmacological inhibitor, because MM-401 was not present in vivo after engraftment. The histologic results were further confirmed by expression of lineage specific markers in *Mll1*$^{flox/flox}$ ESCs, *Mll1*$^{-/-}$ ESCs, and MLL1i-rESCs (Figure S4C). These results suggest that MLL1i-rESCs are able to fully differentiate into tissues from all three germ layers. They also highlight a dynamic requirement of MLL1 (or MLL1

contribute to the ICM (0 of 15 and 0 of 25; Figures 4D and 4E), confirming that R1-EpiLCs maintained a stable primed state in the absence of MM-401 treatment. The reprogrammed R1-rESCs contributed to live-born chimeras that developed into healthy adults (Figure 4F). MLL1i-R1-rESCs injected blastocysts resulted in 67% chimeric animals with 80% coat color chimerism (percentage agouti), similar to that of naive R1-ESCs (Nagy et al., 1993). Importantly, the reprog-

inhibition) in stem cell compartment that is different from its function at late gestational stages (see Discussion).

To determine whether MLL1i-rESCs could contribute to chimeras, we injected the 129.T-rESCs (Figures 3A and S3G) into C57BL/6 blastocysts. MM-401 was withdrawn from the cell culture prior to the injection. The injected blastocysts were then transferred into the C57BL/6 host mice. Chimeric animals were recovered at ~10% frequency (3 of 33) among live pups from the injected embryos (Figure 4C). The ability of MLL1i-rESCs to integrate into the blastocyst and give rise to chimeric mice unequivocally established MLL1i-rESCs as bona fide naive pluripotent cells.

To assess the developmental potential of ESCs and MLL1i-rESCs of isogenic origin without genetic variability/diversity, we compared the abilities of well-established R1 ESCs and our reprogrammed R1 EpiLCs to contribute into the ICM integration and chimera generation. To this end, we treated R1-EpiLCs, confirmed by immunofluorescence for NANOG and REX1 (Figure S4C), with MM-401 for either 6 days or three passages (12 days) in LIF/KSR media (schematics in Figure S4D). Mock-treated R1-EpiLCs in bFGF/KSR or LIF/KSR media were included as the controls. About 10 hr prior to blastocyst injection, the cells were labeled by cell-permeable dye (Vybrant DyeCycle Ruby) for visualization. As shown in Figures 4D and 4E, the reprogrammed R1-EpiLCs were incorporated into ICM, and the incorporation efficiency correlated with duration of MM-401 treatment. At 20 hr post-injection, 100% of blastocysts (i.e., 24 of 24) injected with MM-401-treated passage 3 R1-EpiLCs had labeled cells in the ICM. Additionally, 33% of blastocysts (i.e., 10 of 30) injected with 6-day MM-401-treated R1-EpiLCs harbored labeled cells in the ICM. As a control, mock-treated R1-EpiLCs did not

rammed R1-rESCs could be transmitted to germline and gave rise to healthy F2 progenies (Figure 4H). Taken together, the results showed that MLL1 inhibition efficiently reprogrammed EpiSCs/EpiLCs to an authentic naive pluripotent state.

MLL1 Inhibition Rapidly Leads to Transcriptional Changes during EpiSC Reprogramming

To understand the underlying mechanisms, we examined transcriptome changes by RNA-seq at days 0, 3, and 6, as well as passage 6 (P6) and passage 30 (P30) during EpiSC reversion. We also analyzed the transcriptome of P30 MLL1i-rESC cells that were cultured without MM-401 since P6. The obtained transcriptomes were subjected to principal-component analysis (PCA). Interestingly, transcription profiles of EpiSCs after 3–6 days of MM-401 treatment were distinct from both untreated EpiSCs and final MLL1i-rESCs (Figure 5A). The rapid transcriptome changes after MM-401 treatment were consistent with the phenotypic changes in these cells. Furthermore, global reprogramming of the transcriptome was completed at P6 after MM-401 treatment. Transcriptome at this time point clustered together with that of P30 MLL1i-rESC cells. Interestingly, P30 MLL1i-rESCs that were cultured without MM-401 after P6 had similar transcription profiles as those P6 and P30 cells cultured with continuous presence of MM-401 (Figure 5A). These results suggested that MM-401-induced reversion resulted in a metastable pluripotent state at P6, which could be sustained independent of *Mll1*. An unsupervised Pearson correlation analysis showed that this metastable pluripotent state bore a more resemblance to naive ESCs than EpiSCs at the transcriptional level (Figure 5B). In support of these global analyses, P6 MLL1i-rESCs exhibited higher expression of naive specific

We categorized characteristic gene expression patterns after MM-401 treatment. Among ~8,000 genes commonly identified at all time points by RNA-seq (reads per kilobase per million [RPKM] > 1), ~2,800 genes were grouped into two clusters that shared similar expression kinetics during EpiSC reversion. Specifically, they were either abruptly upregulated (1,554 genes, cluster I) or downregulated (1,235 genes, cluster II) at day 3 of MM-401 treatment and maintained relative expression afterward (Figures 5D and S6A). Naive ESC markers *Rex1*, *Nanog*, and *Klf4* as well as EpiSC markers *Fgf5* and *Cer1* were found in clusters I and II, respectively. Their expression was confirmed by real-time PCR (Figure 5E). Complete lists of cluster I and II genes were included in Table S1. These results support a highly synchronized EpiSC reversion at the molecular level. Gene Ontology term analyses showed that cluster I genes were mostly involved RNA polymerase II transcription and amino acid metabolism (Figure 5F). In contrast, cluster II genes were enriched for several pathways important for epiblast development in vivo or ex vivo (Gadue et al., 2006; ten Berge et al., 2008). They include cell communication, ectoderm and mesoderm development, biological adhesion, and cadherin/Wnt signaling pathways (Figure 5F).
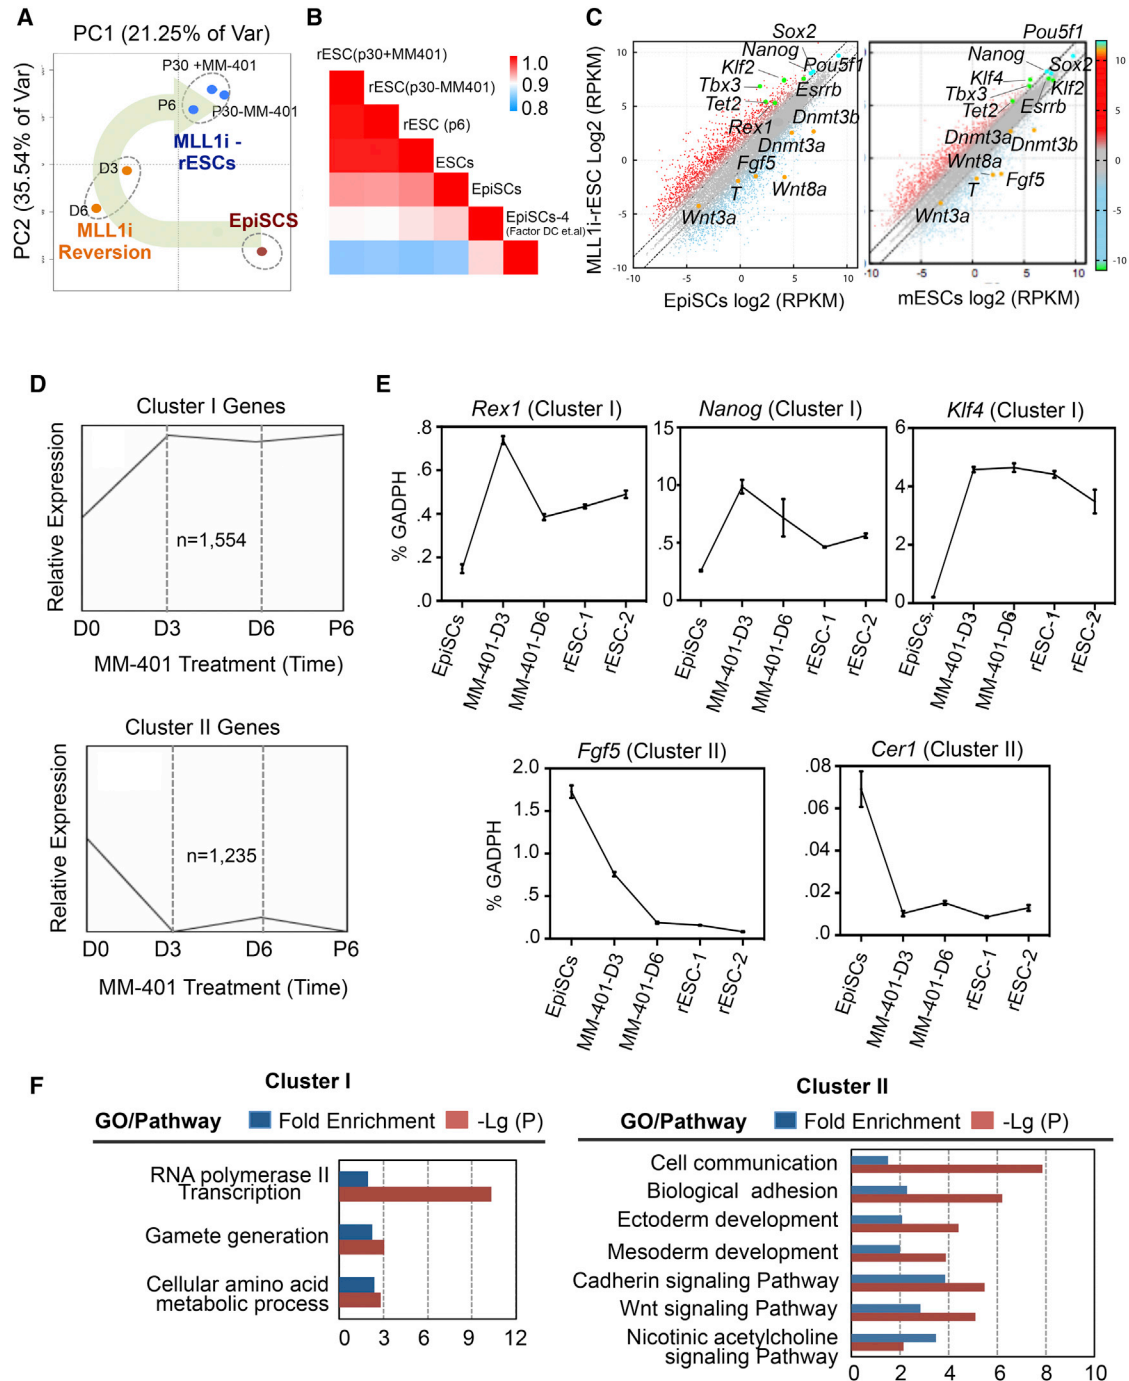

markers (e.g., *Klf4/2*, *Tbx3*, *Essrb*, *Tet2*, and *Rex1*) and lower expression of epiblast markers (e.g., *Fgf5*, *Wnt8a*, *Dnmt3a/b*, and *T*) compared with initial untreated EpiSCs (Figure 5C). Higher expression of *Sox2* and *Nanog* was also observed in these cells (Figure 5C, left). Furthermore, a comparison between MLL1i-rESC and authentic ESCs (LIF/serum) showed that MLL1i-rESCs had higher expression of naive markers (e.g., *Klf4* and *Tbx3*) and lower expression of primed cell markers (e.g., *Wnt3a*, *Fgf5*, and *Dnmt3b*) (Figure 5C, right), a feature reminiscent of the ground-state ESCs.

Figure 5. Characterization of the MLL1-Dependent Transcriptome

MM-401 Treatment Alters MLL1 Binding, H3K4me1 Distribution, and Gene Expression in EpiSCs

To identify MLL1 direct targets in EpiSCs and to characterize changes in H3K4me upon MM-401 treatment, we performed chromatin immunoprecipitation followed by Illumina-based, next-generation sequencing (ChIP-seq) for MLL1, H3K4me1, and H3K4me3 in EpiSCs with or without 4-day MM-401 treatment. ChIP-seq identified 1,303 MLL1 peaks in EpiSCs. As shown in Figure 6A, the majority of MLL1 binding sites in EpiSCs were at either intergenic regions (51.8%) or introns (42.7%) (for a complete list, see Table S2), suggesting that MLL1 probably functions at regulatory enhancers (defined by H3K4me1) in EpiSCs. About 8.3% of cluster II genes in Figure 5D were MLL1 direct targets. Importantly, MLL1 binding was reduced at ~62% of MLL1 direct targets after MM-401 treatment (Figure 6B; log$_2$ [tag ratio] < −1), consistent with disruption of the MLL1 complex by MM-401 (Cao et al., 2014). The gene rank highlighted lineage specific transcription factors (e.g., *Sox5*, *Sox17*, *Klf5*), epiblast markers (e.g., *Cer1* and *Gsc*), cadherins (e.g., *Cdh8*, *Cdh9*), and cell signaling genes (e.g., *Bmp5*, *Egr1*) as the MLL1 direct targets (Figure 6C). Notably, MLL1 did not bind to naive ESC markers (e.g., *Nanog* and *Pou5f1*), consistent with lack of self-renewal defects in *Mll1*$^{−/−}$ ESCs (Ernst et al., 2004). ChIP-seq results were confirmed by ChIP-qPCR at selected genes (Figure S5).

ChIP-seq for H3K4me1 and H3K4me3 in EpiSCs identified 99,356 and 26,543 peaks in EpiSCs, respectively (Tables S3 and S4). Consistent with previous studies (Factor et al., 2014), H3K4me1, but not H3K4me3, was dramatically different between ESCs and EpiSCs, with a Pearson correlation coefficient of 0.32 (Figures 6D and S6B). Interestingly, MM-401 treatment led to genome-wide change of H3K4me1 in EpiSCs (Figure 6D). The enhancer H3K4me1 profile in EpiSCs treated with MM-401 for 3 days bore a greater resemblance to that of ESCs than EpiSCs, with Pearson correlation coefficients of 0.61 and 0.32, respectively (Figure 6D). In comparison, H3K4me3 at gene promoters was little affected by MM-401 treatment (Figure S6B).

We next examined H3K4me1 changes at MLL1 direct targets. We found two typical H3K4me1 distribution patterns relative to MLL1 peaks in EpiSCs (Figure S6C, blue and purple lines). MM-401 treatment led to significant downregulation of H3K4me1 surrounding both classes of MLL1 targets (Figure S6C). We further examined H3K4me1 within 1 nucleosome (±200 bp) of the MLL1 peak centers in EpiSCs and ESCs. Strikingly, significant difference in H3K4me1 (Δlog$_2$ H3K4me1 tag count < −1 or > 1) was found at 740 of 1,303 MLL1 peaks between EpiSCs and ESCs (Figure 6E). Among them, 657 MLL1 targets (group I, 50.5% of total) had drastically lower H3K4me1 in ESCs than EpiSCs (Figure 6E). More important, H3K4me1 at these physiologically relevant sites was significantly downregulated by MM-401 during EpiSC reprogramming (Figure 6F). In fact, the vast majority of MLL1 targets that had lower H3K4me1 (Δ log$_2$ H3K4me1 tag count < −0.5, group II) after MM-401 treatment overlapped with group I genes above (Figure 6G; for complete list, see Table S5). As a result, we identified 293 genes (group III) that had significant H3K4me1 reduction in both ESCs and MM401-treated EpiSCs. Gene rank based on H3K4me1 tag count in EpiSCs is shown in Figure 7A. Representative genes with known functions at the stage of epiblast devel-

opment are highlighted (Figure 7A, gray line). ChIP-qPCR confirmation for H3K4me1 at selected genes is shown in Figure S5. Gene expression analyses showed that majority of the MLL1 direct targets were rapidly downregulated after MM-401 treatment (Figure 7B). Median reductions for group I and group II genes were ~2.8-fold (Δ log$_2$ RPKM = −1.5) (Figures 7B and S6D). Real-time qPCR confirmation of selected genes was shown in Figure S6E. These results suggest that MM-401 promotes EpiSC reversion by blocking developmentally upregulated H3K4me1 and consequent expression of MLL1 direct targets.

MLL1 Regulates a Gene Network in EpiSCs

Analysis of the MLL1 direct targets in EpiSCs showed that 222 of 421 group II genes (Figure 6G) belong to a gene network (Figure S7A). They distributed widely in cells (Figure S7A), suggesting that MLL1 is probably a master regulator and influences multifaceted functions in EpiSCs. Ninety-seven genes (44% of total) in this network had significant and rapid reduction in expression (log$_2$ fold change < −1) upon MM-401 treatment (Figure S7A, yellow). Interestingly, two pathways were especially enriched in this MLL1 network: (1) the biological adhesion pathway as exemplified by multiple membrane-bound proteins (e.g., *Cacna2d4*, *Stx18*, *Pappa*, and *Dpp4*) (Figure S7A, green circle) and (2) the developmental pathway as exemplified by prominent regulators of early cell lineage specification (e.g., *Nerrog1*, *Tub*, *Cdh9*, and *Efna5*) (Figures 7C and S7A, red circle) (Brennan et al., 2001; Puigserver et al., 2003). TGFβ/cadherin pathway genes were also identified in the MLL1 network. The prominence of lineage specification and cell adhesion pathways in the MLL1 network is stark contrast to the lack of naive ESC factors (e.g., *Pou5f1*, *Nanog*, and *Sox2*) (Figures 5F and 7C). These results suggest that MLL1 does not directly regulate the ESC core transcription circuitry. Instead, MLL1 inhibition seems to initiate reprogramming by repressing characteristic EpiSC features (see Discussion).

DISCUSSION

Here we show that MLL1 inhibition by small-molecule inhibitor MM-401 or *Mll1* deletion is sufficient to reprogram the primed EpiSCs to naive pluripotency. The EpiSC reprogramming occurs with high efficiency, with 50% cells exhibiting naive ESC features after 3 days. The rESCs have full development potential and give rise to live chimeras. Mechanistic studies identify an MLL1 network in EpiSCs and show that direct modulation of a discrete histone mark is sufficient to promote the naive pluripotent state. Rather than a passive epigenetic mark, MLL1-mediated H3K4me plays a causal role in the acquisition of naive pluripotency.

Our study shows that MM-401 is a powerful tool to study the role of *Mll1* in cell fate determination. MM-401 disrupts MLL1 chromatin binding at a significant subset of MLL1 targets in EpiSCs (Figure 6B) and induces EpiSC reprogramming in a fashion similar to *Mll1* gene deletion (Figure 3B). Previous genetic studies have established that *Mll1* deletion does not affect ESC self-renewal (Ernst et al., 2004; Glaser et al., 2009). Instead, it impairs ESC differentiation into neural or hematopoietic lineages, consistent with in vivo studies (Jude et al., 2007; Lim et al.,

2009; McMahon et al., 2007). Here we take advantage of the reversibility of the pharmacological inhibitor MM-401 to reveal a dynamic requirement of MLL1 in defining early pluripotent states. Unlike $Mll1^{-/-}$ ESCs, MLL1i-rESCs have full developmental potential upon MM-401 withdrawal in vivo. Our study indicates that MLL1 probably acts as a one-way directional valve

in preventing course reversal at key junctions of early epiblast differentiation, which is consistent with its dynamic expression during development (Figure S1). Notably, $Mll1^{-/-}$ embryos are

able to develop till mid- to late gestation (Yu et al., 1995), suggesting that loss of MLL1 function is not sufficient to entirely block developmental signals that drive early embryogenesis.

CellPress

This is consistent with our observation that MM-401 cannot stably sustain reverted naive ESCs in the presence of continuous bFGF signaling (Figure S3B). We also would like to point out that the effects of MM-401 or *Mll1* deletion in ESCs are distinct from those of *Wdr5* depletion (Ang et al., 2011), which probably disrupts ESC transcription circuitry independent of MLL1 (Li et al., 2012).

The EpiSC reprogramming by MLL1 inhibition or deletion is a surprise given the lack of apparent functions for MLL1 in ESC self-renewal and maintenance. This is a departure from previously reported reprogramming methods that involve either overexpression of ESC transcription factors and/or blockade of cell signaling (Cahan and Daley, 2013; Nichols and Smith, 2009). Instead, MLL1 inhibition directly affects lineage commitments toward ectoderm, mesoderm or both germ layers (Figures 7C and S7A). It also represses the EpiSC markers (Figure 7C). These results raise an interesting possibility that MM-401 restores naive pluripotency by blocking pathways that lead to the primed pluripotent state. It supports the notion that the naive pluripotent state represents a "passive" or "uninstructed" state (Silva and Smith, 2008) that can be captured by blocking alternative cell identity. In this context, we envision that blocking MLL1 serves to revert stem cells to the "uninstructed" naive pluripotent state by erasing developmental "scripts." Alternatively, because the naive pluripotent state is actively maintained by the network of core transcription factors and requires network reorganization for both entry and exit of the naive state (Factor et al., 2014; Gafni et al., 2013), it is also possible that MLL1 inhibition perturbs lineage determinant factors, which indirectly reorganize the naive transcription network through extensive feedback controls or cross-regulations (De Los Angeles et al., 2015). Indeed, transcriptome analyses show that MLL1 inhibition indirectly upregulates ESC markers during the reprogramming process (Figures 5F and 7). Interestingly, they include previously reported EpiSC reprogramming factors such as *Klf4* (Guo et al., 2009), *Klf2* and *Nanog* (Stuart et al., 2014), *Esrrb* (Festuccia et al., 2012), *Tfcp2l1* (Ye et al., 2013), and orphan nuclear receptor *Nr5a2* (Guo and Smith, 2010) (Figures 5E and S7B). We also see a modest reduction of *Mbd3* (Rais et al., 2013) (Figure S7B). Simultaneous regulations of parallel reprogramming pathways probably underlie the highly efficient and synchronized EpiSC reversion by MM-401. Specifically, MM-401-induced EpiSC reprogramming changes clone morphology within 24 hr (data not shown). About 50% cells have upregulation of PECAM1 and REX1 as well as Xi-reactivation occurring within 72 hr (Figures 1 and 2). We also would like to point out that MLL1i-rESCs, once reverted, stably maintain naive characteristics even in the absence of continuous MLL1 inhibition (Figures 4 and 5A).

Dynamic reorganization of H3K4me1-defined enhancer landscapes has been reported when ESCs differentiate into EpiSCs (Buecker et al., 2014; Factor et al., 2014). However, the causal link between epigenetic modifications and initiation of cell fate conversion has not been established. In fact, epigenetic changes are often depicted as consequences of changed transcription network or cell signaling (De Los Angeles et al., 2015). Here we show that epigenetic change itself may be sufficient to trigger EpiSC reprogramming and blocking MLL1 function constitutes a key rate-limiting step or barrier in EpiSC reversion. MLL1 inhibition in EpiSCs drastically shifts the enhancer landscape to that of naive ESCs (Figure 6D). Moreover, most of MLL1 binding sites undergo reversal of otherwise developmentally upregulated H3K4me1 upon MM-401 treatment (Figure 6F). Notably, MLL1 direct targets represent only a small fraction of H3K4me1 alteration during EpiSC reversion. It is likely that MLL1 inhibition leads to subsequent changes by other H3K4 methyltransferases that warrant future studies. One caveat is that although non-histone substrates of MLL1 have yet to be identified, we cannot completely rule out the possibility that other MLL1-dependent methylation event(s) drive the collapse of EpiSCs network.

Finally, our study supports that erasure, rather than deposition, of key epigenetic marks is associated with restoration of naive pluripotent state. Factors, such as MLL1, whose inhibition or deletion does not inhibit epiblast development in vivo or affect the ESC self-renewal in vitro, may still play a critical role to regulate acquisition of naive pluripotency. In this context, it would be interesting to examine whether blocking H3K27me3 and DNA methylation, which are dynamically upregulated, affects EpiSC reprogramming (Gafni et al., 2013; Nora et al., 2012). Future interrogation of the roles of epigenetic regulators at crucial developmental windows is key to furthering our understanding of epigenetic regulation in cell fate determination.

EXPERIMENTAL PROCEDURES

Establishment and Culture of Pluripotent Cell Lines
Mll1[f/f]; *Cre-ER*[TM] ESCs and *Mll1*[−/−] ESCs were derived from ICM of 3.5 days postcoitum blastocysts and cultured on top of mouse embryonic fibroblast (MEF) feeder cells in Glasgow minimum essential medium containing 15% fetal bovine serum and LIF. EpiSCs were derived from pre-implantation mouse embryos following previously described protocols (Gayen et al., 2015; Najm et al., 2011). EpiLC induction was performed in N2B27-based medium containing 15% KSR, 10 ng/ml bFGF, and 20 ng/ml Activin A.

EpiSC Reprogramming Experiment
EpiSCs were passaged in single cell or small clumps on MEF feeder cells. MM-401 (50–100 μM final concentration) was added to culture medium immediately or 2–3 days after EpiSCs forming clones. MM-401 is replenished to reach 50–100 μM concentration during each passage. rESC lines can be established by clone picking or en masse. rESCs for chimera test were derived clonally.

Immunofluoresence, AKP Staining, and RNA-FISH
Immunofluorescence was carried out for NANOG, OCT4, and REX1 at 1:200, 1:100, and 1:200 dilution, respectively. The Vector Alkaline Phosphatase Staining Kit was used for AKP staining. RNA-FISH was performed as described in Maclary et al. (2014). For details, see the Supplemental Information.

In Vivo Characterization of rESCs
The in vivo experiments were performed at the Transgenic Core Facility of University of Michigan. For ICM integration, rESCs were labeled with Vybrant DyeCycle Ruby dye 10 hr prior to blastocyst injection. The cells were visualized at 20 hr after injection.

ChIP-Seq and RNA-Seq Analyses
H3K4me1 and H3K4me3 ChIP-seq data for untreated cells were from GEO: GSE47949 (ESCs) and GEO: GSE57407 (EpiSCs). ChIP-seq reads were aligned to University of California, Santa Cruz, mm9 using Bowtie2 and analyzed by HOMER. RNA-seq was analyzed by Tophat (version 2.0.3). For details on pathway, PCA, and network analyses as well as antibody information see the Supplemental Information. Anti-MLL1 antibody is described in Dou et al., (2005).
